By the **experimental method** it has been shown that when a nerve-fibre is severed the part which is detached from the nerve-cell from which it is an offshoot degenerates, whilst the part which remains connected with the nerve-cell undergoes little or no change. This is called the law of "Wallerian" degeneration. Thus, if in a living animal one-half of the spinal medulla is cut across, and after a few weeks the animal is killed and the medulla examined, it will be seen that there are degenerated tracts of fibres in the white matter, both above and below the plane of division; but, still further, it will also be manifest that the tracts which are degenerated above the plane of division are not the same as those which are degenerated in the part of the medulla which lies below this level. The interpretation of this is obvious. The nerve-tracts which have degenerated above the plane of section are the offshoots of nerve-cells which lie in lower segments of the medulla or in spinal ganglia below the plane of section. Severed from these nerve-cells, they undergo what is called *ascending degeneration*. The nerve-tracts, on the other hand, which have degenerated in the portion of the medulla below the plane of division are the axons of cells which lie at a higher level than the plane of section, either in higher segments of the spinal medulla or in the brain itself. Cut off from the nerve-cells from which they proceed, they present an example of *descending degeneration*.

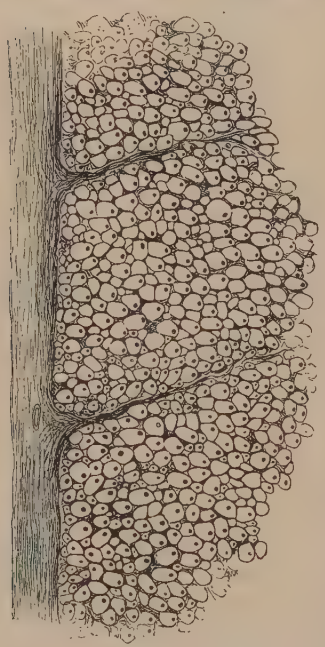

FIG. 447.—TRANSVERSE SECTION THROUGH THE WHITE MATTER OF THE MEDULLA SPINALIS, as seen through the microscope.

The **embryological method** was first employed by Flechsig, and it is often referred to as Flechsig's method. It is based upon the fact that nerve-fibres in the earliest stages of their development consist of naked axis-cylinders, and are not provided with medullary sheaths. Further, the nerve-fibres of different strands assume the medullary sheaths at different periods. If the fœtal central nervous system is examined at different stages of its development, it is a comparatively easy matter to locate the different tracts of fibres by evidence of this kind. Speaking broadly, the tracts which myelinate first are those which bring the central nervous system into relation with the peripheral parts (skin, muscles, etc.); then those fibres which bind the various segments of the central nervous system together; next, those which connect the spinal medulla with the cerebellum; and, lastly, the tracts which connect the spinal medulla with the cerebral hemispheres. The nervous apparatus for the performance of automatic movements is fully provided, therefore, before this is put under the control and direction of the higher centres. It by no means follows that in all the higher animals corresponding strands myelinate at relatively corresponding periods. Take the case of a young animal which from the time of its birth is able to move about and perform voluntary movements of various kinds in a more or less perfect manner, and compare it with the helpless new-born infant which is capable of exhibiting automatic movements only. In the former, the cerebro-spinal tracts, or motor tracts, which descend from the cerebrum into the spinal medulla, and which are the paths along which the mandates of the will travel, myelinate at an early period; whilst in the infant the corresponding fibres do not obtain their medullary sheaths until after birth. The study of the dates, therefore, at which the various strands of nerve-fibres myelinate not only gives the anatomist a means of locating their position in the white matter of the central nervous system, but it also affords the physiologist most important information regarding their functions, and also the periods at which these functions are called into play.

It is a matter of interest to note that influences which either accelerate or retard the periods at which nerve-fibres are brought into functional activity have also an effect in determining the dates at which these fibres assume their sheaths of myelin. Thus, when a child is prematurely born the whole process of myelinisation is, as it were, hurried up; and further, when in new-born animals light is freely admitted to one eye whilst it is carefully excluded from the other, the fibres of the optic nerve of the former myelinate more rapidly than those of the opposite nerve.

Study of the minute structure (Anatomical method) of the central nervous system, especially of material that has been stained by the methods of Golgi and Ramon y Cajal or by the use of methylene blue, completes the results attained by these other methods, by demonstrating the precise mode of origin and termination of the various fasciculi.

Posterior Funiculus and the Posterior Roots of the Spinal Nerves.—In the cervical and upper thoracic regions of the spinal medulla the posterior funiculus is divided by the posterior intermediate sulcus and septum into the **fasciculus cuneatus**, which lies laterally and next to the posterior column of gray matter, and the **fasciculus gracilis**, which lies medially and next to the posterior-median septum. The fasciculus cuneatus is composed of nerve-fibres which are for the most part larger than those entering into the formation of the fasciculus gracilis, and both tracts have a most intimate relation to the posterior nerve-roots; indeed, they are both composed almost entirely of fibres which enter the medulla by these roots, and then pursue a longitudinal course.

The nerve-fibres which form the posterior nerve-roots, on entering the medulla along the sulcus lateralis posterior, divide within the fasciculus cuneatus into ascending and descending branches which diverge abruptly as they pass respectively upwards and downwards. The **descending fibres** are, as a rule, short, and soon end in the gray matter of the spinal

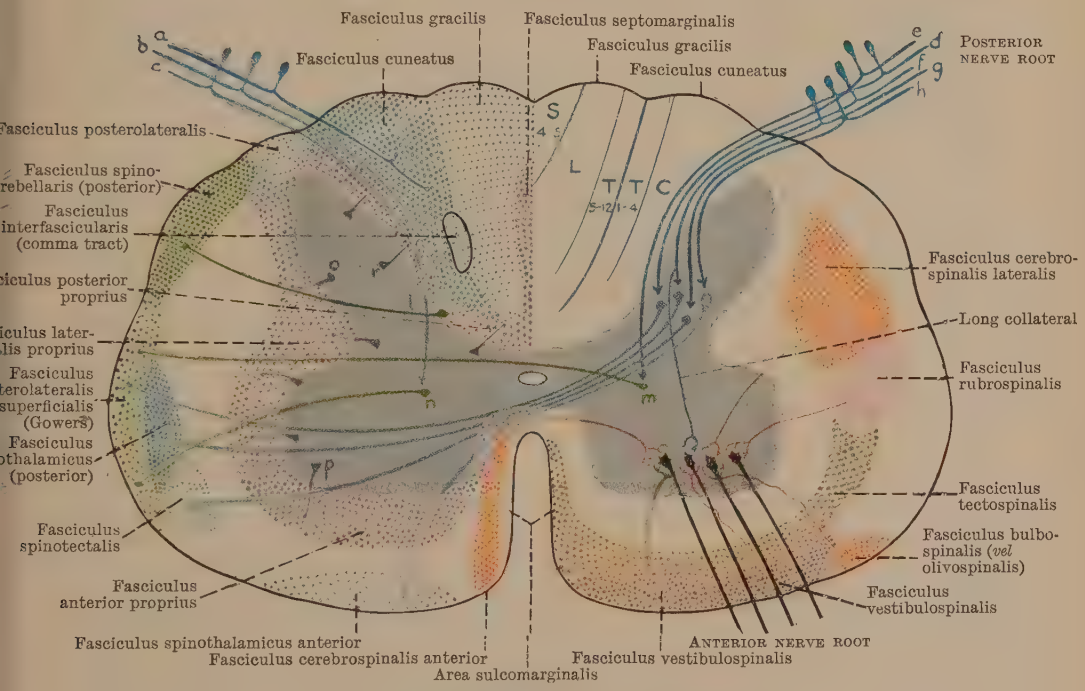

Fig. 448.—A Diagram to illustrate the Grouping of the various Fasciculi in the Spinal Medulla (in transverse section).

medulla. These descending fibres occupy an area in the posterior funiculus along the line of separation of the fasciculus gracilis and the fasciculus cuneatus, and, hence, may be called the **fasciculus interfascicularis (comma tract of Schultze)**. This area, when the spinal medulla is divided, undergoes descending degeneration and then presents a comma-shaped outline (Fig. 448).

The **ascending fibres** vary greatly in length, and at differing distances from the point where the parent fibres enter the medulla they end in the gray matter. A small contribution, however, of ascending fibres, from each posterior nerve-root, extends upwards to the upper end of the spinal medulla, to end in the medulla oblongata (Figs. 429 and 449).

As each posterior nerve-root enters, its fibres range themselves in the lateral part of the posterior funiculus close up against the posterior column of gray matter. The nerve-fibres of the nerve-root next above take the same position, and consequently those which entered from the nerve immediately below are displaced medially, and come to lie in the posterior funiculus nearer to the median plane. This process goes on as each nerve-root enters, and the result is that the fibres of the lower nerves are gradually pushed nearer and nearer to the posterior median septum in a successive series of lamellar tracts. Of course, the greater proportion of the fibres which are thus carried upwards from

the posterior nerve-roots sooner or later leave the posterior funiculus and enter the gray matter, to end there in relation to some of its cells; but, as we have said, every posterior nerve-root sends a few fibres up the whole length of that portion of the spinal medulla which lies above, and thus the posterior funiculus gradually increases in bulk as it is traced upwards, and in all except the lowest part of the spinal medulla, the posterior funiculus is separable into a fasciculus gracilis and a fasciculus cuneatus. The fasciculus gracilis is composed of the long ascending fibres of the posterior nerve-roots, which have entered the lower segments of the spinal medulla. To put the matter differently, the fibres of the sacral roots are displaced medially by the entering lumbar fibres, while the fibres of the lumbar roots are in their turn pushed medially by the entering thoracic fibres, and, lastly, the fibres of the cervical roots displace the thoracic fibres. The difference between the fasciculus gracilis and the fasciculus cuneatus consists simply in this, that the former is composed of the fibres of posterior nerve-roots which have entered the medulla at a lower level than those which enter into the formation of the fasciculus cuneatus. The fibres of the fasciculus gracilis, taking them as a whole, must therefore necessarily run a very much longer course.

Our knowledge of the constitution of the posterior columns of the spinal medulla is derived largely from the study of the course of degeneration in monkeys, after the medulla has been cut across—either partially or completely. But we have also a direct knowledge of the lamination of the posterior columns of the human spinal medulla (Fig. 448) that has been acquired from the examination of cases in which the medulla or its nerve-roots had been injured during life.

Numerous collateral fibrils stream into the gray matter of the posterior column both from the ascending and descending branches of the entering fibres of the posterior nerve-roots. These are classified into long and short collaterals. The **long collaterals** extend forwards into the anterior column of gray matter and end in relation to the ventral nerve-cells. The **short collaterals** end in relation to the nerve-cells in the substantia gelatinosa, and other nerve-cells of the posterior column of gray matter.

The majority of the fibres of the posterior nerve-root enter the spinal medulla on the medial side of the apex of the posterior column of gray matter. The manner in which these are related to the fasciculus cuneatus and the fasciculus gracilis has been noticed; but a certain number of those fibres which lie most laterally take a curved course forwards on the medial side of the posterior column of gray matter and then pass into it. In the thoracic region these curved fibres end in connexion with the cells of the nucleus dorsalis (Fig. 442, B, p. 527, and Fig. 429).

Fasciculus Posterolateralis (O.T. **Tract of Lissauer**).—The postero-lateral fasciculus is a small tract of nerve-fibres of minute calibre which assume their medullary sheaths at a comparatively late period. It is placed at the surface of the medulla close to the sulcus lateralis posterior. It is formed by some of the lateral fibres of the posterior nerve-roots which do not enter the fasciculus cuneatus, but pass upwards in the medulla close to the substantia gelatinosa, in which they ultimately end.

It must now be evident that the fibres which enter the medulla spinalis through each posterior nerve-root have three main modes of distribution: (1) the majority take part in the formation of the fasciculus cuneatus, and pass upwards or downwards to end in the gray matter at some other level in the central nervous system; (2) some fibres, and many collaterals of fibres in the fasciculus cuneatus, lie close to the posterior column and describe a series of graceful curves as they pass forwards, prior to turning laterally into all regions of the gray matter to end at the same level as they enter the medulla spinalis; (3) a third series form the postero-lateral fasciculus and end in connexion with the cells of the substantia gelatinosa and other cells in the posterior and anterior columns of gray matter (Fig. 429).

The fibres derived from the posterior nerve-roots which ascend in the posterior funiculi of the medulla spinalis to the medulla oblongata of the brain constitute a direct sensory tract; other fibres are described which give rise to a crossed sensory tract termed the **fasciculus spino-thalamicus**. These latter fibres arise as the axons of certain of the cells in the posterior column in connexion with which fibres from the posterior nerve-roots have ended, and crossing to the opposite side of the medulla spinalis through the anterior commissure they ascend in the antero-lateral funiculus to the brain, where they ultimately reach the thalamus. As the spino-thalamic tract ascends in the spinal medulla its fibres are not gathered into a compact strand, but are more or less loosely scattered in the lateral funiculus.

Association Fibres in the Posterior Funiculus.—But the whole of the fibres of the posterior funiculus are not derived from the posterior nerve-roots. A few fibres exist in this funiculus which have a different origin. They are derived from certain of the cells of the gray matter, and, entering the posterior funiculus, they divide into ascending and descending branches which pass upwards and downwards in the funiculus for a varying distance, before they finally turn in to end in the gray matter at higher and lower levels. These fibres, therefore, constitute links of connexion between different segments of the spinal medulla, and they constitute the **fasciculus posterior proprius**. Our information regarding these fibres at present is somewhat defective; but it is believed that the deepest part of the funiculus, *i.e.* the part next the posterior gray commissure, and the **fasciculus septo-marginalis** of Bruce, placed in apposition with the posterior-median septum and in the adjoining part of the surface, belong mainly to this category.

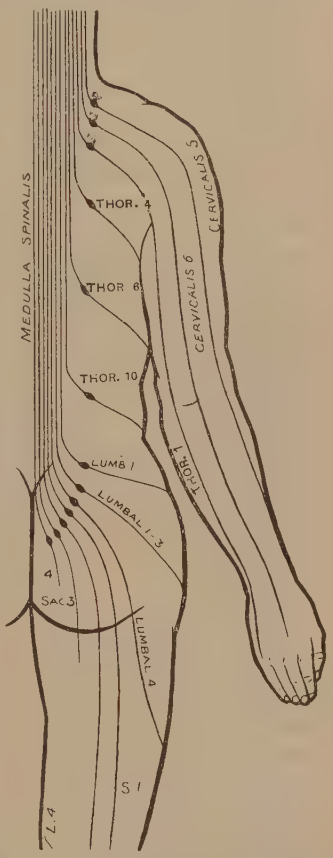

FIG. 449.—DIAGRAM TO SHOW THE MANNER IN WHICH THE FIBRES OF THE POSTERIOR NERVE-ROOTS ENTER AND ASCEND IN THE POSTERIOR FUNICULUS OF THE SPINAL MEDULLA. (From Edinger.)

Funiculus Lateralis and Funiculus Anterior.—It is convenient to consider the anterior along with the lateral funiculus and to call the whole mass of white substance that is left, after eliminating the posterior funiculus, the **antero-lateral funiculus**. In contact with the surface of the gray columns there is a broad band of white matter the parts of which are known respectively as the **fasciculus proprius anterior** and **lateralis** (O.T. the ground bundles of the antero-lateral funiculus). It is composed wholly of fibres which spring from nerve-cells in the gray columns, and, after passing for varying distances upwards or downwards, end in the gray matter of the spinal medulla. Thus they constitute an intrinsic system of fibres linking together different levels of the spinal medulla. They become medullated before any other fibres, except the root-fibres and their continuations in the posterior funiculus. When cut across some of the fibres degenerate above, others below, the injury, and the degeneration extends for varying distances upwards and downwards respectively.

The best-known long or extrinsic systems of fibres in the antero-lateral funiculus are those known as the **fasciculus cerebrospinalis lateralis** (O.T. **crossed pyramidal tract**), the **fasciculus cerebrospinalis anterior** (O.T. **direct pyramidal tract**), the **fasciculus cerebellospinalis** (O.T. **direct cerebellar tract**) (*which goes from the spinal medulla to the cerebellum, and ought therefore to be called spinocerebellaris, as it will be subsequently named in this account*), and the **fasciculus anterolateralis superficialis** (O.T. **Gowers' tract**).

There are, however, many other fasciculi at least as important as these, but there is as yet no close agreement as to their precise limits or connexions. One reason for this is that some of the elements of one tract may become intermingled with those of another; moreover, the position and relations of certain of them vary considerably at different levels of the spinal medulla. In Fig. 429 an attempt has been made to present the present state of our knowledge of these great strands of white fibres. This diagram is not intended to represent any definite level of the spinal medulla, though certain features are shown which occur only in the cervical region; and in respect of other features, the arrangement found in lower regions of the spinal medulla has been introduced to render the diagram more serviceable.

Much of the apparent complexity of this chart will disappear if the reader recalls some general statements (p. 513) made with regard to the outstanding

features of the brain. It was then explained that when afferent nerves, coming from the skin and muscles, enter the spinal medulla, they not only establish relations with the motor nuclei and other spinal structures in the neighbourhood of their insertion, but also give rise, directly or indirectly (see Fig. 429), to many fasciculi which pass upwards in the spinal medulla to reach the medulla oblongata, the pons and cerebellum, the mesencephalon (corpora quadrigemina), the thalamus, and the cerebral hemisphere. In the neighbourhood of each level where these ascending sensory tracts end, such as for example the region of the vestibular nucleus and cerebellum, the tectum mesencephali, the corpus striatum, and the cerebral hemisphere, great descending tracts originate and pass downwards in the spinal medulla (Fig. 429—*the red lines*). Thus we have cerebro-spinal, rubro-spinal, tecto-spinal, vestibulo-spinal, and bulbo-spinal fasciculi passing down the spinal medulla; and each system eventually ends around the series of motor nuclei (Fig. 429), many of them in the spinal medulla.

In the antero-lateral funiculus the various fasciculi will be found to be grouped roughly into three bands:—Next to the gray columns is the fasciculus proprius; then comes a band of descending (motor) fasciculi; and then, upon the surface, a series of ascending (sensory) fasciculi. This arrangement, however, is not maintained with any degree of exactitude in the anterior funiculus, where the sharp demarcation between ascending and descending fasciculi is in great part destroyed by the intermingling of fibres passing in opposite directions.

The fibres of the posterior nerve-root have already been studied so far as their relation to the posterior funiculus is concerned. No clear conception of the nature and significance of the ascending fasciculi in the antero-lateral funiculus can be obtained unless they also are studied in relationship with the fibres of the posterior root.

It has already been explained that of the fibres which enter the spinal medulla in the posterior root the great majority enter the posterior funiculus, where they bifurcate (Fig. 448, *a*); one branch of each fibre passes upwards either in the funiculus gracilis or in the funiculus cuneatus, or it may pass from the latter into the former; the other descends in the fasciculus interfascicularis (O.T. comma tract). Other fibres perhaps enter the postero-lateral fasciculus (O.T. Lissauer's bundle). But all the other fibres of the posterior root, together with the majority of the fibres of the fasciculus cuneatus, sooner or later enter the gray matter (Fig. 448, *b* to *h*) of the spinal medulla.

Some of them (*b*) pass directly to end in the nucleus dorsalis of their own side, and from its cells fresh fibres arise, which pass laterally through the posterior column and lateral funiculus to reach the surface, where they bend upwards as constituent fibres of the spino-cerebellar fasciculus. These pass upwards throughout the whole length of the spinal medulla (above their place of origin), into the medulla oblongata, thence into the cerebellum through the restiform body.

Other fibres on the same side (*c*), and perhaps also on the other side (*d*), end amidst cells of the gray matter, the axis-cylinder processes of which pass into the antero-lateral superficial fasciculus (O.T. Gowers' tract). In this tract they ascend throughout the spinal medulla, medulla oblongata, and pons, to enter the cerebellum alongside the brachium conjunctivum (superior peduncle). This element in the antero-lateral fasciculus is sometimes designated the **fasciculus spinocerebellaris anterior**, to distinguish it both from the non-cerebellar fibres of the parent fasciculus and from the **fasciculus spinocerebellaris [posterior]** (O.T. **the direct cerebellar tract**). These two spino-cerebellar tracts convey to the cerebellum information from the muscles and overlying skin which assists it to co-ordinate the muscles for carrying on precisely adjusted movements.

Other fibres of the posterior nerve-root (*e*, *f*, *g*, and *h*) terminate in relationship with cells in the gray columns of their own side of the spinal medulla, the axons of which cross the median plane in the anterior commissure to pass respectively (*e*) into the antero-lateral superficial fasciculus [not to be confused with the cerebellar constituents of this bundle]; (*f*) into the real **fasciculus spinothalamicus [posterior]**, of which the last-mentioned fibres are merely outlying members; (*g*) into the **fasciculus spinotectalis**, to ascend to the mesencephalon; and (*h*) into

the marginal area of the anterior funiculus to form a group which may be called the **fasciculus spinothalamicus anterior.**

The careful investigations of the late Dr. Page May led him to attach a definite physiological significance to this grouping of the ascending paths. The **fasciculus spinothalamicus** [**posterior**] is supposed to convey upwards to the thalamus (for transmission to the cerebral cortex, which is concerned with the conscious appreciation of sensations) all impulses of *pain, heat, and cold* coming from the skin upon the opposite side of the body. The **fasciculus spinothalamicus anterior** conveys impulses of *touch* and *pressure* from the opposite side.

The **spino-cerebellar fasciculi** [**anterior** and **posterior**] convey to the cerebellum respectively homolateral and bilateral unconscious afferent impulses underlying muscular co-ordination and reflex tone.

Among the descending tracts that establish connexions between various parts of the brain (see Fig. 429) and the motor nerve-cells in the anterior column may be mentioned the **cerebro-spinal**, the **rubro-spinal** (from the red nucleus), the **tecto-spinal** (from the corpora quadrigemina), the **vestibulo-spinal** (from the terminal nucleus of the vestibular nerve), and the **bulbo-spinal tracts.** The last-mentioned forms a peculiar triangular area upon the surface immediately to the lateral side of the anterior nerve-roots (Fig. 448), but there is great uncertainty as to its mode of origin: it is often called the **fasciculus olivospinalis**, from the fact that its discoverer, Helweg, believed it to originate from the olivary nucleus in the bulb or medulla oblongata. It may be regarded as an outlying part of the vestibular (or cerebellar) tract to the motor nuclei of the spinal medulla.

The **fasciculus cerebrospinalis lateralis** (O.T. **crossed pyramidal tract**) is a large well-defined descending tract which lies immediately in front of the posterior column of gray matter, and subjacent to the posterior spino-cerebellar fasciculus, which shuts it out from the surface. Below the point where the posterior spino-cerebellar fasciculus begins the cerebro-spinal fasciculus becomes superficial, and in this position it can be traced as low as the fourth sacral nerve, at which level it ceases to exist as a distinct strand. The cerebro-spinal fasciculus is composed of an admixture of both large and small fibres. These arise in the brain from the large pyramidal cells of the motor or precentral area of the cerebral cortex, and pass downwards through various subdivisions of the brain to gain the spinal medulla. As they enter the spinal medulla they cross the median plane from one side to the other, and it thus happens that the cerebro-spinal tract in the right lateral funiculus of the spinal medulla has its origin in the cortex of the left cerebral hemisphere, and *vice versa.* As the tract descends in the spinal medulla it gradually diminishes in size; and this is due to the fact that, as it traverses each spinal segment, numerous fibres leave it to enter the anterior column of gray matter, and end in connexion with the anterior motor cells from which the fibres of the anterior nerve-roots arise. The entire strand is ultimately exhausted in this way. Numerous collateral fibrils spring from the cerebro-spinal fibres, and, entering the gray matter, end in a similar manner. In this way a single cerebro-spinal fibre may be connected with several spinal segments before it finally ends. The lateral cerebro-spinal fasciculus must be regarded as a great motor strand which brings the spinal motor apparatus under the control of the will.

Sharpey Schafer believes that many of the fibres of the cerebro-spinal fasciculus end in connexion with the cells of the nucleus dorsalis.

In many marsupials, rodents, and ungulates the lateral cerebro-spinal fasciculus lies in the posterior funiculus of the spinal medulla.

The **fasciculus lateralis proprius** represents the remainder of the lateral funiculus. Its fibres are largely derived from the cells situated in all parts of the gray matter, and also from the nerve-cells of the opposite side of the spinal medulla. After a course of very varying length in the fasciculus lateralis, these fibres turn medially and re-enter the gray matter. Such fibres may thus be regarded as **inter-segmental association fibres** binding two or more segments of the spinal medulla together. It may be mentioned that the association fibres which link together segments of the spinal medulla which are near to each other lie close to

the gray matter, whilst those which connect the more distant segments are situated further out in the lateral funiculus.

Funiculus Anterior.—One well-defined tract is situated in the funiculus anterior. This is termed the **fasciculus cerebrospinalis anterior.** The remainder of the funiculus receives the name of the **fasciculus anterior proprius.**

The **fasciculus cerebrospinalis anterior** (O.T. **direct pyramidal tract**) is usually a nerve-strand of small size which lies near the anterior median fissure. As a rule it cannot be traced lower than the middle of the thoracic region of the spinal medulla. It is a descending tract and must be associated with the lateral cerebro-spinal fasciculus of the opposite side, seeing that both of these strands arise from the motor area of the cortex of the same cerebral hemisphere. From this it must be clear that the anterior cerebro-spinal fasciculus does not cross the median plane as it enters the spinal medulla, but descends on the side of the spinal medulla corresponding to the cerebral hemisphere in which it arises. Nevertheless, its fibres do not end in the same side of the spinal medulla, but at every step along the path of the strand they make use of the anterior commissure, and cross to the opposite side of the spinal medulla, to terminate in relation to the opposite ventral motor cells in the same manner as the lateral cerebro-spinal fibres.

From this crossing of the cerebro-spinal fasciculi, it follows that the destruction of the fibres which compose them as they descend in one side of the brain must result in paralysis of the muscles supplied by the efferent nerves of the opposite side of the spinal medulla.

In cases of old brain lesion it is sometimes possible to detect some degenerated fibres in the lateral cerebro-spinal fasciculus of the sound side of the spinal medulla, and from this it is supposed that this tract contains a few uncrossed fibres. If this is the case, each side of the spinal medulla stands in connexion with the motor area of both cerebral hemispheres.

It is well to note that the fibres of both lateral cerebro-spinal fasciculi are not medullated until the time of birth. They are the latest of all the fasciculi of the spinal medulla to myelinate.

Commissura Anterior Alba.—The anterior white commissure is composed of medullated nerve-fibres passing from one side of the spinal medulla to the other and entering the anterior column of gray matter, and also the anterior funiculus of white matter. It is to be regarded more as a decussation than as a commissure, and its width, which varies somewhat in different regions, fluctuates in correspondence with the diameter of the spinal medulla.

Amongst the fibres which cross in the anterior commissure may be mentioned: (1) The fibres of the fasciculus cerebrospinalis anterior; (2) collaterals from both the anterior and lateral funiculi; (3) axons of many of the cells of the gray matter; (4) the dendritic processes of some of the medial anterior cells.

Commissura Grisea.—Although this is composed of gray matter with a large admixture of neuroglia, numerous nerve-fibres pass transversely through it, so as to establish relations between the cells in the gray matter on the two sides of the spinal medulla.

THE ENCEPHALON OR BRAIN.

The **brain** is the enlarged and greatly modified upper part of the cerebro-spinal nervous axis. It is surrounded by the same membranes that envelop the medulla spinalis (viz., the dura mater, the arachnoid, and the pia mater), and it almost completely fills up the cavity of the cranium. So closely, indeed, is the skull capsule moulded upon the brain that the impress of the latter is almost everywhere evident upon the inner surface of the cranial wall. The relations, therefore, of cranium to brain are totally different from those presented by the vertebral canal to the spinal medulla. As we have noted, the medulla spinalis occupies only a part of its bony case; and there is not only a wide and roomy space between the arachnoid and the pia mater, but also an interval of some width between the dura mater and the walls of the vertebral canal.

General Appearance of the Brain.—When viewed from above the brain presents an ovoid figure, the broad end of which is directed backwards. Its greatest transverse diameter is usually found in the neighbourhood of that part which lies between the two parietal tuberosities of the cranium. The only parts

which are visible when the brain is inspected from this point of view are the two convoluted **cerebral hemispheres.** These present an extensive convex surface, which is closely applied to the internal aspect of the cranial vault, and are separated from each other by a deep median cleft, termed the **fissura longitudinalis cerebri**, which extends from the front to the back of the brain.

The inferior aspect of the brain is usually termed the **basis cerebri.** It presents an uneven and irregular surface, which is more or less accurately adapted to the inequalities on the floor of the cranial cavity. Upon this aspect of the brain some of its main subdivisions may be recognised. Thus, posteriorly, is seen the short cylindrical portion, called the **medulla oblongata,** through which, at the foramen magnum, the brain becomes continuous with the medulla spinalis. The medulla oblongata lies on the ventral aspect of the cerebellum, and occupies the vallecula

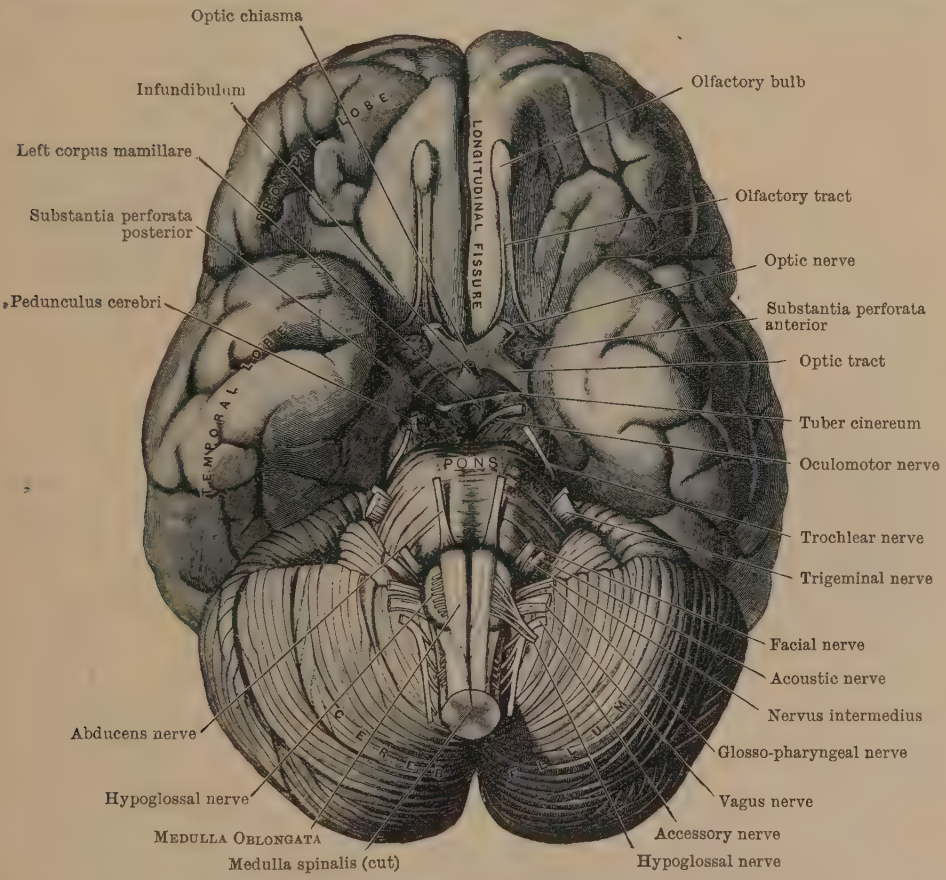

Fig. 450.—The Base of the Brain with the Cerebral Nerves attached.

or hollow which intervenes between the two cerebellar hemispheres. The **cerebellum** is a mass of considerable size which is placed below the posterior portions of the two cerebral hemispheres. It is easily recognised on account of the closely set, curved, and parallel fissures which traverse its surface and give it a foliated appearance. Above the medulla oblongata, and in close connexion with it, is a prominent white elevation called the **pons.** Immediately in front of the pons there is a deep hollow or recess. This is bounded behind by the pons, on each side by the projecting temporal lobe of the cerebral hemisphere, and in front by the orbital portions of the frontal lobes of the cerebral hemispheres. Passing out from each side of the anterior part of this recess is the deep **lateral fissure** of the brain which intervenes between the pointed and projecting extremity of the temporal lobe and the frontal lobe of the cerebrum, whilst, in the median plane in front, the longitudinal fissure, which separates the frontal portions of the cerebral hemispheres, opens into it.

Within the limits of this deep hollow, on the base of the brain, two large rope-like strands, the **pedunculi cerebri**, may be seen issuing from the inferior surface of the cerebral hemispheres. As they pass downwards these peduncles are inclined obliquely towards the median plane, so that when they plunge into the pons they are situated in close apposition the one to the other (Fig. 452). Turning round the lateral side of each peduncle, where it emerges from the cerebrum, a flattened band termed the **optic tract** may be observed. These bands come from the anterior part of the hollow, where they are joined together by a short connecting piece termed the **optic chiasma**. The **optic nerve** is inserted, on each side, into the antero-lateral angle of the chiasma.

The pedunculi cerebri, the optic tracts, and the optic chiasma enclose a deep rhomboidal or lozenge-shaped interval on the base of the brain, which is termed the **fossa interpeduncularis**. Within the limits of this area the following parts may be seen as we pass from behind forwards: (1) the substantia perforata posterior; (2) the corpora mamillaria; (3) the tuber cinereum and the stalk of the hypophysis cerebri (O.T. pituitary body).

At its posterior angle, immediately in front of the pons, the interpeduncular fossa is very deep and is floored by a layer of gray matter, in which are numerous small apertures. This is the **substantia perforata posterior**. Through the apertures which are dotted over its surface the small postero-medial basal branches of the posterior cerebral artery enter the brain.

The **corpora mamillaria** are two small white pea-like eminences placed side by side in front of the substantia perforata posterior.

The **tuber cinereum** is a slightly-raised field of gray matter, which occupies the interval between the anterior portions of the optic tracts in front of the corpora mamillaria. Springing from the anterior part of the tuber cinereum, immediately behind the optic chiasma, is the **infundibulum**, or the stalk which connects the hypophysis cerebri with the base of the brain (Fig. 452).

Lateral to the limits of the anterior part of the interpeduncular space there is, on each side, a small depressed triangular field of gray matter, which leads laterally into the lateral cerebral fissure. It is perforated by the antero-medial and the antero-lateral groups of basal arteries, and receives the name of the **substantia perforata anterior**.

General Connexions of the Several Parts of the Brain.—The medulla oblongata, the pons, and the cerebellum occupy the posterior cranial fossa, and they are separated from the cerebral hemispheres, which lie above them, by a partition of dura mater, termed the tentorium cerebelli. Further, they surround a cavity, a portion of the primitive cavity of the early neural tube, which is termed the **fourth ventricle** of the brain, and they all stand in intimate connexion, one with the other. The medulla oblongata is for the most part carried upwards into the pons; but at the same time two large strands from its dorsal aspect, termed the **restiform bodies**, are prolonged into the cerebellum, and constitute its **inferior peduncles**, or the chief bonds of union between the medulla (oblongata and spinalis) and the cerebellum. The pons has large numbers of transverse fibres entering into its composition, and the great majority of these are gathered together on each side in the form of a large rope-like strand. This plunges into the corresponding hemisphere of the cerebellum, and constitutes its **middle peduncle**, which is known as the **brachium pontis**.

The cerebrum, which forms the great mass of the brain, occupies the anterior and middle cranial fossæ, and extends backwards into the occipital region above the tentorium and the cerebellum. The greater part of the cerebrum is formed by the cerebral hemispheres, which are separated from each other in the median plane by the longitudinal fissure. At the bottom of this fissure is the **corpus callosum**, a broad commissural band which connects the two hemispheres with each other. Each hemisphere is hollow, the cavity in its interior being termed the **lateral ventricle** of the brain. Between and below the cerebral hemispheres, and almost completely concealed by them, is the **inter-brain** or **diencephalon**. The principal parts forming this portion of the brain are two large masses of gray matter, termed the **thalami**. Between these is the **third ventricle** of the brain—a

deep narrow cavity occupying the median plane. The third ventricle communicates with the lateral ventricles by two small apertures, called the **foramina interventricularia.**

The cerebrum is connected with the parts in the posterior cranial fossa (pons, cerebellum, and medulla oblongata) by a narrow stalk called the **mesencephalon** or **mid-brain.** The mid-brain is built up of—(1) the **pedunculi cerebri**, passing from the pons to the cerebrum; (2) the **corpora quadrigemina**, forming its dorsal part; and (3) the **brachia conjunctiva** (O.T. **superior cerebellar peduncles**), proceeding from the cerebellum to the cerebrum. It is tunnelled by a narrow passage, the **aquæductus cerebri**, which extends between the fourth and third ventricles.

In a view of the intact brain the greater part of the mesencephalon and diencephalon is hidden by the cerebral hemispheres; but a precise idea will be

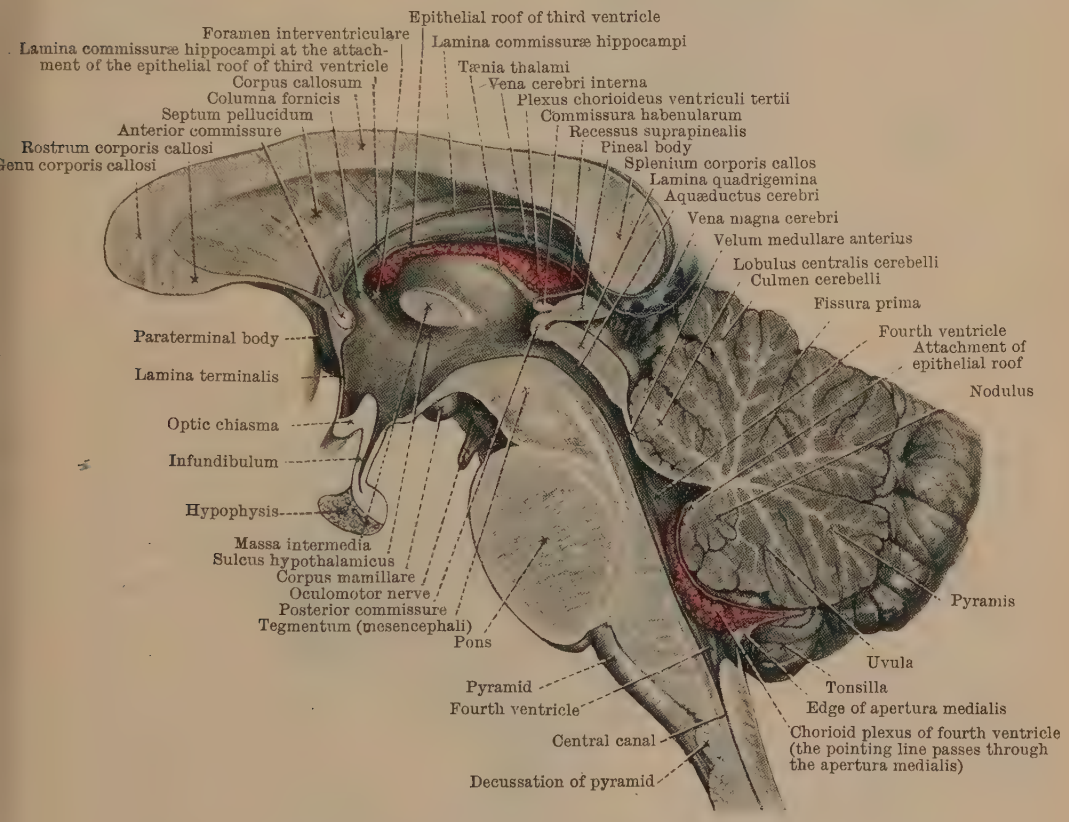

FIG. 451.—THE PARTS OF THE BRAIN CUT THROUGH IN A MEDIAN SAGITTAL SECTION. The side walls of the ventricular cavities are also shown.

obtained of the inter-relationships of the various parts of the brain, if we study the relationship of these structures to the series of cavities in the interior of the brain as they are displayed in a median sagittal section (Fig. 451).

The central canal which tunnels the spinal medulla is seen to extend into the medulla oblongata for a short distance; then it expands into the irregular cavity of the fourth ventricle, the floor (anterior wall) of which is formed partly by the medulla oblongata and partly by its continuation upwards, the **pars dorsalis pontis.** Behind the fourth ventricle lies the cerebellum, but it forms only a small part of the roof **(tegmen).** The roof consists mainly of the **velum medullare anterius** above and the thin epithelial lamina **(lamina chorioidea epithelialis)** below.

The fourth ventricle is continued upwards into the **aquæductus cerebri**, which tunnels the mesencephalon, of which the thick mass of the **tegmentum** is placed in front of it and the **lamina quadrigemina** behind.

The aqueduct opens in front into the third **ventricle**, the major portion of

each side wall of which is formed by the **thalamus**. Near the antero-superior corner of each side wall of the third ventricle the small **foramen interventriculare** (O.T. **foramen of Monro**) leads into the cavity of the corresponding cerebral hemisphere, which is known as the **lateral ventricle.**

MEDULLA OBLONGATA.

The **medulla oblongata** is the continuation upwards of the medulla spinalis. It is a little more than 25 mm. (one inch) in length, and it may be regarded as beginning immediately above the uppermost root of the first cervical nerve, or,

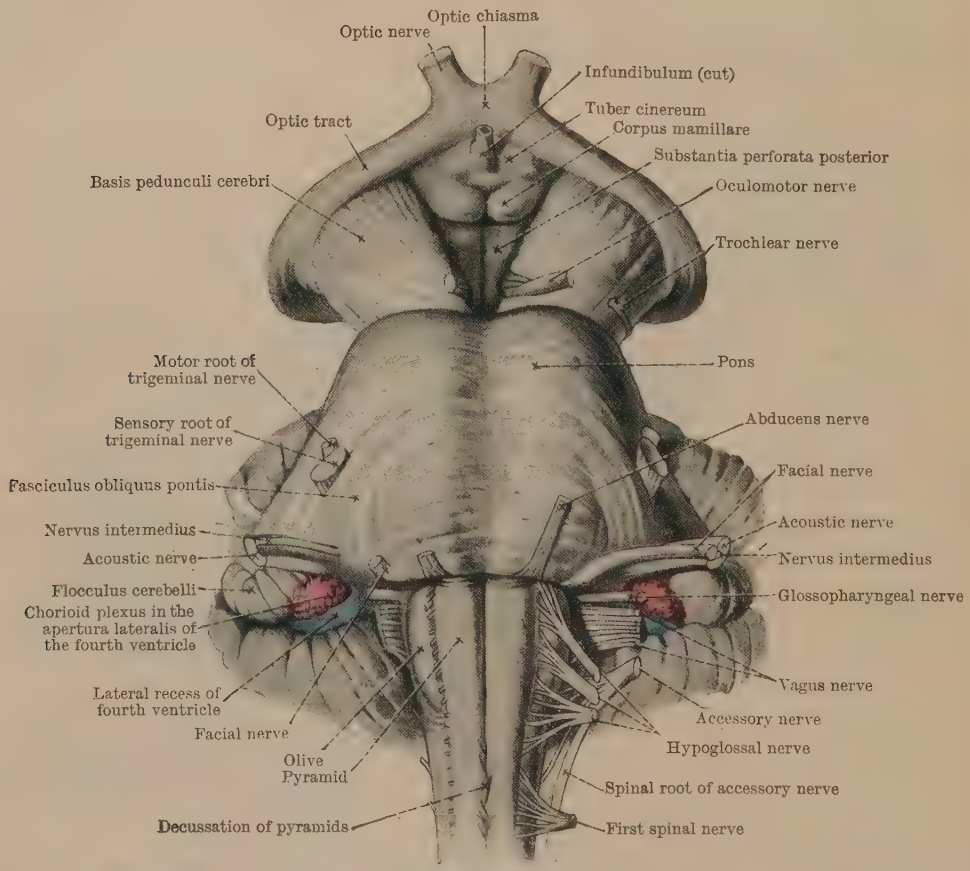

FIG. 452.—FRONT VIEW OF THE MEDULLA OBLONGATA, PONS, AND MESENCEPHALON.

roughly, about the level of the foramen magnum. From this it proceeds upwards in a very nearly vertical direction, and ends at the lower border of the pons. At first its girth is similar to that of the spinal medulla, but it rapidly expands as it approaches the pons, and consequently it presents a more or less conical form. Its anterior surface lies behind the grooved surface of the basilar portion of the occipital bone, whilst its posterior surface is sunk into the vallecula of the cerebellum. The medulla oblongata is a bilateral structure, and this is indicated on the surface by the presence of **anterior and posterior median fissures**, on the ventral and dorsal surfaces respectively.

The **fissura mediana anterior**, as it passes from the spinal medulla on to the medulla oblongata, is interrupted at the level of the foramen magnum by several strands of fibres which cross the median plane from one side to the other. This intercrossing is termed the *decussation of the pyramids.* Above this level the fissure

is carried upwards to the lower border of the pons, but is often rendered very shallow by numerous external arcuate fibres which emerge upon the surface between its lips and then curve laterally to reach the posterior part of the medulla oblongata. At the lower margin of the pons it expands slightly and ends in a blind pit, which receives the name of the **foramen cæcum** of Vicq d'Azyr.

The **fissura mediana posterior** is present only on the lower half of the medulla oblongata. As it ascends it rapidly becomes shallower. Half-way up, where the central canal opens into the fourth ventricle, the lips of the posterior median fissure are thrust apart from each other and constitute the boundaries of a triangular field, which is seen when the epithelial roof of the lower part of the fourth ventricle is removed. This triangular field is the lower part of the **fossa rhomboidea**, or the floor of the fourth ventricle of the brain. The lower half of the medulla oblongata, containing as it does the continuation of the central canal of the spinal medulla, is frequently termed the **closed part of the medulla oblongata**; the upper half, above the opening of the canal, which contains the lower part of the fourth ventricle, is called the **open part** of the medulla oblongata.

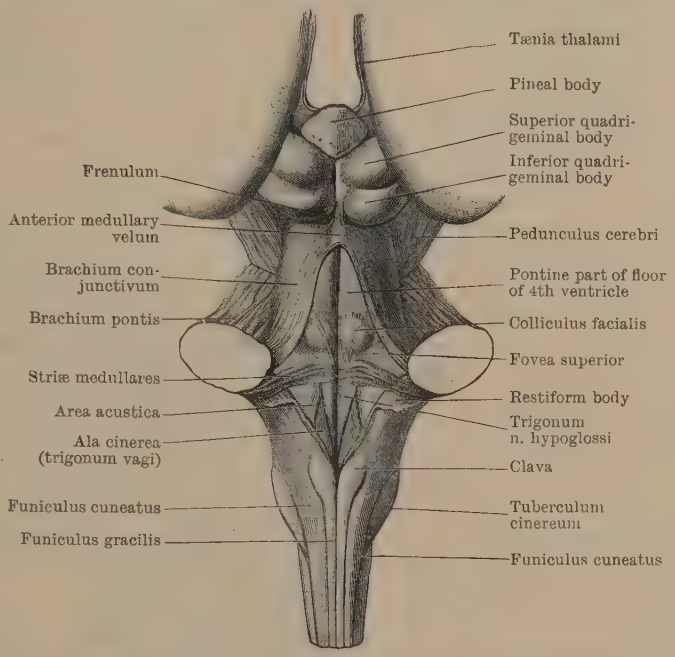

FIG. 453.—POSTERIOR VIEW OF THE MEDULLA, PONS, AND MESENCEPHALON OF A FULL-TIME HUMAN FŒTUS.

The examination of the floor of the fourth ventricle will be deferred for the present, and the appearance presented by the surface of the medulla oblongata may now engage our attention. In the spinal medulla the corresponding surface area is divided into three districts or funiculi by the emerging motor roots and the entering sensory roots of the spinal nerves. Of these the sensory enter along the bottom of the sulcus lateralis posterior, whilst the motor fila are spread over a relatively broad surface area and have no groove in connexion with their emergence from the spinal medulla. In the case of the medulla oblongata corresponding rows of fila enter and emerge from the surface of each side. The fila of the hypoglossal nerve carry up the line of the anterior nerve-roots of the spinal medulla. In one respect, however, they differ: they emerge in linear order and along the bottom of a distinct furrow, termed the **sulcus lateralis anterior**, which proceeds upwards on the surface of the medulla oblongata. The fila which carry up the line of the posterior nerve-roots on the surface of the medulla oblongata are the root-bundles of the accessory, the glosso-pharyngeal, and the vagus nerves. These are attached along the bottom of a furrow which is the direct continuation upwards of the sulcus lateralis posterior of the spinal medulla, and therefore receives the name of the **sulcus lateralis posterior** of the medulla oblongata. The root-bundles of these nerves differ, however, in so far that they are not all composed of afferent fibres which spring from ganglionic cells placed without and enter the medulla. Certain of them are purely efferent (roots of accessory), whilst others contain a considerable number of efferent as well as afferent fibres, and are therefore to be regarded as mixed roots.

By the sulci laterales, and also by the two rows of fila attached along the

bottom of these furrows, the surface of the medulla oblongata on each side is divided into three districts, viz., an anterior, a lateral, and a posterior, similar to the surface areas of the three funiculi on the side of the spinal medulla. Indeed, at first sight, they appear to be direct continuations upwards of these three portions of the spinal medulla; this, however, is not the case, because the fibres of the three funiculi of the spinal medulla undergo a rearrangement as they proceed upwards into the medulla oblongata.

Anterior Area of the Medulla Oblongata—Pyramis.—The district between the anterior median fissure, and the sulcus lateralis anterior, along the bottom of which the root fila of the hypoglossal nerve issue from the medulla oblongata, receives the name of the **pyramid.** An inspection of the surface is sufficient to show that the pyramid is composed of a compact strand of longitudinally directed nerve-fibres. It represents, in fact, the portion of the great cerebro-spinal fasciculus which is destined to carry fibres from the cerebral hemisphere to all the motor nuclei on the other side of the medulla oblongata and medulla spinalis. Somewhat constricted at the place where it emerges from the pons (Fig. 452) it swells immediately to form a prominent rounded column, which passes vertically downward, separated from the pyramid of the other side by the fissura mediana anterior. Towards the lower part of the medulla oblongata it gradually tapers.

Although the pyramid at first sight appears to be continuous with the anterior funiculus of the medulla spinalis, only a very small proportion of the fibres contained in the latter are derived from the pyramid. This at once becomes manifest when the lips of the anterior median fissure are thrust apart at the place of junction between the medulla oblongata and spinal medulla. The pyramid is then seen to divide at this level into two parts, viz., a small portion composed of a variable number of the most lateral fibres of the pyramid, termed the **fasciculus cerebrospinalis anterior** (O.T. **direct pyramidal tract**), and a much larger portion, situated next the median fissure, called the **fasciculus cerebrospinalis lateralis** (O.T. **crossed pyramidal tract**). The anterior cerebro-spinal fasciculus is continued down into the anterior funiculus of the medulla spinalis, and in this it takes up a medial position next the median fissure. The lateral cerebro-spinal fasciculus is broken up into three or more coarse bundles, which sink backwards and at the same time cross the median plane, to take up a position in the posterior part of the opposite lateral funiculus of the spinal medulla. The term **decussatio pyramidum (decussation of the pyramids)** is applied to the intercrossing of the corresponding bundles of the lateral cerebro-spinal fasciculi of opposite sides.

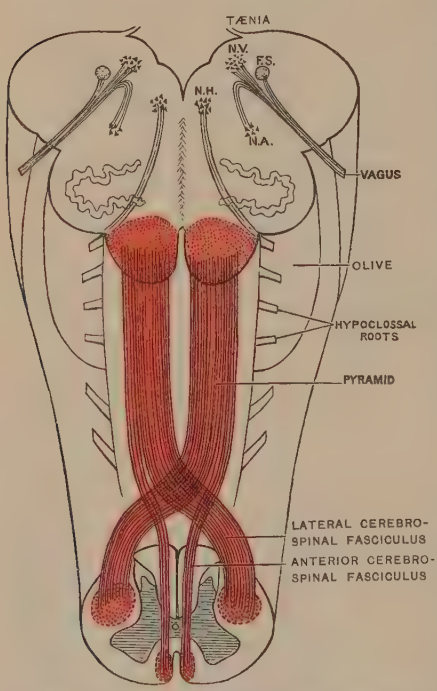

FIG. 454.—DIAGRAM OF THE DECUSSATION OF THE PYRAMIDS (modified from van Gehuchten).

NH, Nucleus hypoglossi; NV, Vago-glosso-pharyngeal nucleus; FS, Tractus solitarius; NA, Nucleus ambiguus.

The anterior cerebro-spinal fasciculus is, therefore, the only part of the pyramid which has a place in the anterior funiculus of the spinal medulla. The much larger part of this funiculus, termed the fasciculus anterior proprius, as it is traced up into the medulla oblongata, is seen to be thrust aside by the decussating bundles of the lateral cerebro-spinal fasciculus. It thus comes to occupy a deep position in the substance of the medulla oblongata, behind and to the lateral side of the pyramid.

Lateral Area of the Medulla Oblongata.—This is the district on the surface of the medulla oblongata which is included between the two rows of nerve-roots, viz., the hypoglossal roots in front, and the root-bundles of the accessory, the vagus, and the

glossopharyngeal nerves behind. It presents a very different appearance in its upper and lower parts. In its lower portion it simply appears to be a continuation upwards of the lateral area of the spinal medulla; in its upper part a striking oval prominence bulges out on the surface of the medulla, and receives the name of **oliva** (O.T. **olivary eminence**).

The lower part of this district, however, is very far from being an exact counterpart of the lateral funiculus of the spinal medulla. The large lateral cerebro-spinal tract is no longer present, seeing that it forms, in the medulla oblongata,

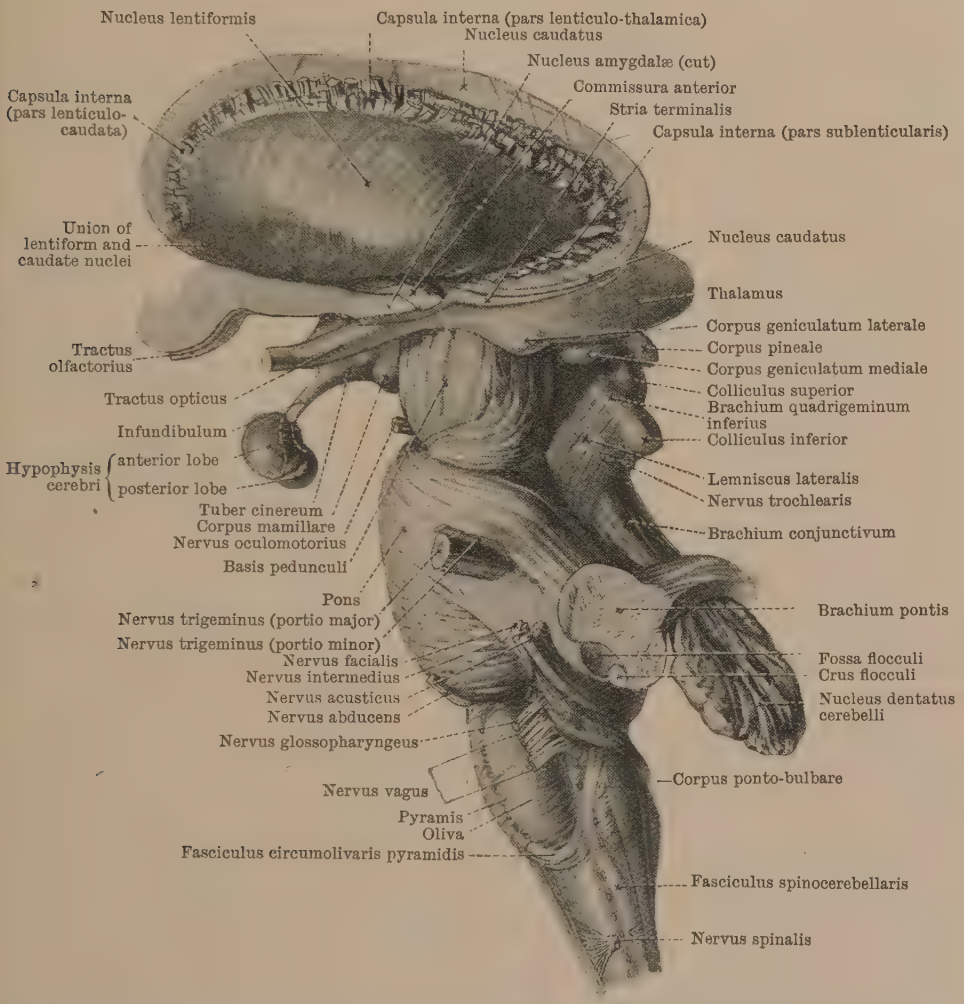

FIG. 455.—LEFT LATERAL ASPECT OF A BRAIN FROM WHICH THE CEREBRAL HEMISPHERE (WITH THE EXCEPTION OF THE CORPUS STRIATUM) AND THE CEREBELLUM (EXCEPTING ITS NUCLEUS DENTATUS) HAVE BEEN REMOVED.

the greater part of the pyramid of the opposite side. Another strand of fibres, viz., the fasciculus spinocerebellaris (posterior), prolonged upwards in the lateral funiculus of the medulla spinalis, gradually leaves this portion of the medulla oblongata. This tract lies on the surface, and is frequently visible to the naked eye as a white band (Fig. 455), which inclines obliquely backwards into the posterior district of the medulla oblongata to join its upper part, or, in other words, to join the restiform body. The remainder of the fibres of the lateral funiculus, comprising the fasciculus lateralis proprius and the fasciculus anterolateralis superficialis, is continued upwards in the lateral area of the medulla oblongata, and at the inferior border of the olive the majority of these fibres disappear from the surface by dipping into

the substance of the medulla oblongata under cover of that projection. A small proportion of the fibres, however, are retained on the surface and travel upwards towards the pons, in the interval which exists between the posterior border of the olive and the roots of the vagus and glossopharyngeal nerves.

The **olive** is a smooth oval projection which bulges out from the upper part of the lateral area of the medulla oblongata. Its long axis is vertical and is about half an inch long. It marks the position of the subjacent **nucleus olivaris inferior**, a crumpled thin-walled sac of gray matter, which is separated from the surface only by a very thin layer of superficial white matter.

Posterior Area of the Medulla Oblongata.—In its inferior half, this district is bounded behind by the posterior median fissure, and in its superior half by the lateral margin of the medullary part of the floor of the fourth ventricle of the brain. In front it is separated from the lateral area by the row of root-fila belonging to the accessory, glossopharyngeal, and vagus nerves. As in the lateral area, we recognise an inferior portion and a superior portion, which appear continuous but in reality are almost quite distinct the one from the other.

The inferior part of the posterior area corresponds more or less closely with the posterior funiculus of the spinal medulla. In the cervical region the posterior funiculus is divided by a septum of pia mater into a medial fasciculus gracilis and a lateral fasciculus cuneatus. These are prolonged upwards into the medulla oblongata, and in the lower part of the posterior area they stand out distinctly, and are separated one from the other by a continuation upwards from the spinal medulla of the sulcus intermedius posterior. In the medulla oblongata the medial of these strands is called the **funiculus gracilis**, whilst the lateral one is designated the **funiculus cuneatus.** When they reach the level of the inferior part of the floor of the fourth ventricle, each ends in a slightly expanded bulbous prominence. The swollen extremity of the funiculus gracilis is called the **clava.** This is thrust aside from its fellow of the opposite side by the opening up of the medulla oblongata to form the floor of the fourth ventricle, and the central canal opens on the surface in the angle between the two clavæ.

The elongated prominences formed on the surface of the medulla oblongata by these two strands and their enlarged extremities are due to the presence of two elongated nuclei or collections of gray matter which make their appearance subjacent to the strands, and represent the termini of these uppermost extensions of the spinal posterior root-fibres. These are termed respectively the **nucleus gracilis** and **nucleus cuneatus.** [*As it is the* slenderness *of the one nucleus and the* wedge-shape *of the other in transverse section which gave rise to the terms* gracilis *and* cuneatus *respectively, it is clearly wrong to introduce the word* **funiculi** *into the* B.N.A. *terminology. The funiculi were named from the nuclei and not the nuclei from the funiculi.*]

But a third longitudinal elevation is also apparent on the surface of the inferior part of the posterior area of the medulla oblongata. This is placed on the lateral side of the funiculus cuneatus—between it and the posterior row of nerve-roots—and it has no counterpart in the posterior funiculus of the medulla spinalis. It is called the **tuberculum cinereum.** It is produced by a mass of substantia gelatinosa coming close to the surface and forming a bulging in this situation. Extremely narrow below, it widens as it is traced upwards, and finally ends in an expanded extremity. A thin layer of white matter, composed of longitudinally arranged fibres, is spread over this district, and separates the substantia gelatinosa from the surface. These fibres constitute the **tractus spinalis** of the **trigeminal nerve**, which here assumes a superficial position as it descends in the medulla oblongata.

Corpus Restiforme.—The **restiform body** forms the upper part of the posterior area of the medulla oblongata. It lies between the floor of the fourth ventricle and the roots of the vagus and glossopharyngeal nerves. It is a large and prominent rope-like strand, which inclines upwards and laterally, and then finally takes a turn backwards and enters the cerebellum. It forms the great link of connexion between the cerebellum on the one hand and the medulla oblongata and spinal medulla on the other, and consequently it is also called the **inferior cerebellar peduncle**. A study of the surface of the medulla oblongata yields some important

information regarding the constitution of the restiform body. Thus, the posterior spino-cerebellar tract (Fig. 455), from the lateral column of the spinal medulla, can be traced into it; and large numbers of fibres which take a curved course on the surface of the medulla oblongata may likewise be followed into it; these are the external arcuate fibres. Numerous other fibres enter the restiform body on its deep aspect, but these will be studied at a later stage.

Fibræ Arcuatæ Externæ.—The **external arcuate fibres** enter into the constitution of the restiform body, after pursuing a longer or shorter course on the surface of the medulla (Fig. 455).

They are more particularly seen in the neighbourhood of the olive, over the surface of which they may be observed coursing in the form of a number of fine curved bundles or as a continuous sheet of fibres. They vary greatly in number and in distinctness, and they are sometimes so numerous that they cover the olive almost entirely. An attentive examination will show that the majority of them come to the surface in the median fissure between the pyramids, and also, not infrequently, in the groove between the pyramid and olive, or through the substance of the pyramid itself. The anterior median fissure in its upper part is often almost completely blocked up by these emerging fibres. The external arcuate fibres, reaching the surface of the medulla in this manner, turn backwards, and the great majority enter the restiform body and form a considerable part of its outer portion.

Other arcuate fibres arise in the cuneate and gracile nuclei, and enter the restiform body of the same side. Van Gehuchten, however, denies this.

There is frequently present, especially upon the left side, a bundle of fibres that is usually mistaken for a group of arcuate fibres. It is the **fasciculus circum-olivaris pyramidis** (Fig. 455). It consists of a bundle of varying size which emerges from the pyramid, bends backwards, curving round the inferior border of the olive, and then passes obliquely upward and backwards to end in a fusiform ridge of gray matter, the **corpus ponto-bulbare** (Essick), which crosses the restiform body very obliquely (Fig. 455, the ridge immediately posterior to the fila of the vagus nerve).

These structures are of great morphological interest, and will be referred to again in the succeeding pages (see Fig. 469, p. 566).

PONS.

The **pons** (**Varolius**) is a marked white prominence on the basal aspect of the brain which is interposed between the medulla oblongata and the pedunculi cerebri, and lies in front of the cerebellum. It is convex from side to side, and from above downwards, and transverse streaks on its surface show that, superficially at least, it is composed of bundles of nerve-fibres, most of which course transversely. On each side these transverse fibres are collected together in the form of a large compact strand, which sinks in a backward and lateral direction into the white matter of the corresponding hemisphere of the cerebellum. This strand is termed the **brachium pontis**, and the term "pons," applied to the entire structure, expresses in an admirable way the arch-like manner in which this portion of the brain bridges across the interval between the two cerebellar hemispheres.

The *ventral surface* of the pons is in relation to the basilar part of the occipital bone and the dorsum sellæ of the sphenoid bone. It presents a median groove (**sulcus basilaris**), which gradually widens as it is traced upwards: it lodges the basilar artery. This median depression is produced by the prominence which is caused on each side by the passage of the cerebro-spinal fasciculus downwards through the pons. The **trigeminal nerve**, with its large entering sensory root and its small emerging motor root, is attached to the side of the anterior aspect of the pons, nearer its superior than its inferior border (Fig. 455). It is usual to restrict the term "pons" to that portion of the structure which lies between the two trigeminal nerves, and to apply the designation of brachium pontis to the part which extends beyond the nerve into the hemisphere of the cerebellum. The **abducens nerve**, the **facial nerve**, and the **acoustic nerve** are attached to the brain at the inferior border of the pons. The abducens nerve emerges at the inferior border of the pons

opposite the lateral border of the pyramid; the facial and acoustic are also attached to the inferior edge of the pons, but far away from the median plane. The acoustic nerve is in contact with the cerebellum and the facial is on its medial side, with its sensory root (the nervus intermedius) between them (Figs. 452, 455). A large bundle of fibres upon the front of the pons departs from the transverse course pursued by most of the pontine fibres, and starting at the medial side of the trigeminal nerve, passes almost vertically downwards between the facial and acoustic nerves (Fig. 496, p. 591) and reaches the lateral aspect of the medulla oblongata, where it passes into the corpus ponto-bulbare (Fig. 455). This bundle is known as the **fasciculus obliquus [pontis]**. It is interesting to observe that while the facial nerve lies upon the medial side of this oblique bundle, its sensory root (the nervus intermedius) is placed on its lateral aspect, alongside the acoustic nerve (Fig. 497, p. 592).

Immediately below the insertion of the acoustic nerve at the inferior margin of the pons a little calyx-like appendage of the epithelial roof of the fourth ventricle **(recessus lateralis)** projects laterally, partly behind the glossopharyngeal nerve. Through an elliptical aperture in this epithelial process **(apertura lateralis ventriculi quarti)** a little cauliflower-like mass of chorioid plexus becomes extruded between the acoustic and the glossopharyngeal nerves (Fig. 497, p. 592).

The *posterior surface* of the pons looks backwards towards the cerebellum, and presents a triangular area covered with gray matter, which forms the superior part of the anterior wall or floor of the fourth ventricle. This area is directly continuous inferiorly with the medullary part of the floor of the fourth ventricle, and is bounded on each side by a band of white matter termed the **brachium conjunctivum** (Fig. 456).

Brachia Conjunctiva (O.T. **Superior Peduncles of the Cerebellum**).—The brachia conjunctiva are hidden from view by the superior part of the cerebellum, under cover of which they lie. They emerge from the hemispheres of the cerebellum, and, as they proceed upwards on the dorsal aspect of the pons, they converge towards each other until, at the inferior level of the corpora quadrigemina, the medial margins of the two brachia become almost contiguous (Fig. 456, p. 551). At first they form the lateral boundaries of the superior part of the fourth ventricle; but, as they ascend and approach closer to each other, they gradually come to overhang that cavity, and thus enter into the formation of its roof. They disappear from the surface of the brain by dipping under cover of the quadrigeminal bodies and entering the substance of the mesencephalon.

Velum Medullare Anterius.—Filling up the triangular interval between the two brachia conjunctiva, and stretching across from the medial and free margin of the one to the corresponding margin of the other, is a thin layer of white matter which completes the roof or dorsal wall of the upper part of the fourth ventricle, and receives the name of the **anterior medullary velum.** When traced downwards, the velum is seen to be carried, with the brachia conjunctiva, into the white matter of the cerebellum. Spread out on its posterior or superior surface is a small, thin, tongue-shaped prolongation of gray matter from the cortex of the cerebellum, which is termed the **lingula**, whilst issuing from its substance close to the inferior quadrigeminal bodies are the two **trochlear nerves.**

VENTRICULUS QUARTUS.

Fourth Ventricle.—The **fourth ventricle of the brain** is somewhat rhomboidal in form. Below, it tapers to a point and becomes continuous with the central canal of the lower half of the medulla oblongata; above, it narrows in a similar manner and is continued into the **aquæductus cerebri**, which tunnels the mesencephalon. The posterior wall is termed the **tegmen** or **roof** and is concealed by the cerebellum. The anterior wall is called the **floor** and is formed by the dorsal surface of the pons and the corresponding surface of the medulla oblongata. On each side a long, curved, and narrow prolongation of the ventricular cavity is carried laterally from its widest part and curves round the upper part of the corresponding restiform body. This is termed the **recessus lateralis.** The roof of the cavity is very thin and is intimately connected with the cerebellum. It is better, therefore, to defer its description until that part of the brain has been studied.

Fossa Rhomboidea (floor of the fourth ventricle).—In its inferior part the floor of the fourth ventricle is formed by the dorsal surface of the ventral part of the medulla oblongata, whilst in its superior part it is formed by the dorsal surface of the pons (Fig. 456). The area thus constituted is lozenge-shaped, its widest part being opposite the superior ends of the restiform bodies or inferior peduncles of the cerebellum. A thick layer of gray matter, continuous with that which surrounds the central canal, is spread out like a carpet over the ventricular floor, and covering this there is the usual ependymal layer which lines all the ventricles of the brain. The area is circumscribed by definite lateral boundaries. Thus, *below*, it is bounded on each side by (1) the clava, (2) the expanded upper end of the funiculus cuneatus, and (3) the restiform body; whilst *above*, the lateral limits are formed by the brachia conjunctiva.

The floor of the fourth ventricle is divided into two symmetrical portions by a median groove. Its lower narrow pointed portion between the two clavæ receives the name of the **pars inferior**, or, from its resemblance to the point of a pen,

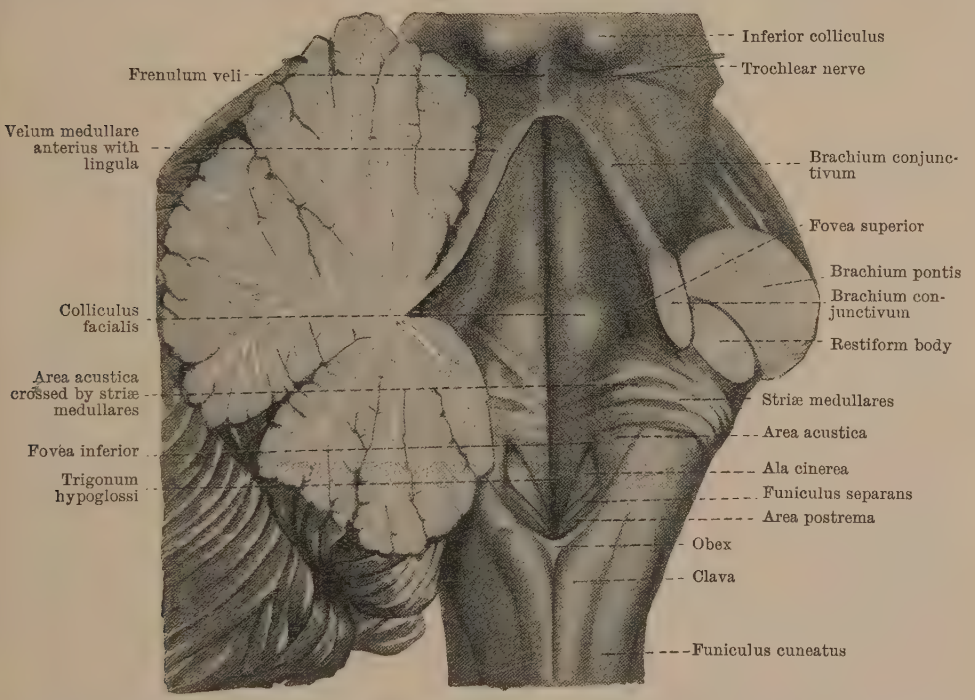

FIG. 456.—FLOOR OF THE FOURTH VENTRICLE. On the right side the right half of the cerebellum has been removed by cutting through its three peduncles and dividing it in the median plane. On the left side the left half of the cerebellum is drawn over to the left so as to expose the floor of the ventricle fully.

the **calamus scriptorius**. Crossing each half of the floor, at its widest part, are several more or less conspicuous bundles of fibres termed the **striæ medullares**. They begin upon the lateral and posterior aspects of the restiform body, where they spring from the cochlear nuclei, pass transversely medially, and disappear from view in the median furrow. The striæ medullares exhibit a large amount of variation in different specimens, both in their degree of prominence and also in the direction which they pursue. It is not uncommon to find that no trace of them is visible upon the surface.

On the inferior (bulbar) district of the ventricular floor a small triangular depression, placed immediately below the striæ medullares, catches the eye. This is termed the **fovea inferior**. It is shaped somewhat like an arrow-head. The apex or point looks towards the striæ, whilst the lateral angles of the base are prolonged downwards in the form of diverging grooves (Fig. 456). Of these, the medial groove runs towards the opening of the central canal at the calamus scriptorius, whilst the lateral groove runs towards the lateral boundary of the floor. In this

manner the portion of the floor which lies below the striæ medullares is mapped out into three triangular areas. The medial subdivision is slightly elevated and is termed the **trigonum nervi hypoglossi,** because subjacent to the medial part of this area is the nucleus of origin of the hypoglossal nerve. The intermediate area, between the two diverging grooves which proceed from the base of the fovea inferior, is the **ala cinerea.** It is sometimes called the **trigonum n. vagi** because the nucleus of the vagus and the glossopharyngeal nerves lies subjacent to it. Near the lateral angle is the **area acustica.** The base of this area is directed upwards and runs directly into an eminence over which the striæ medullares pass. Subjacent to this district of the floor of the ventricle lies the large terminal chief nucleus of the vestibular division of the acoustic nerve. A more accurate name for the area acustica would be **area vestibularis.**

A close inspection of the pars inferior fossæ rhomboideæ will show that the base of the trigonum vagi is separated from the medial margin of the clava by a narrow lanceolate strip of the ventricular floor, to which Retzius has given the name of **area postrema.** Beneath this area, which is very vascular, lies the nucleus postremus (J. T. Wilson), and marking it off on its superior and medial aspect from the base of the trigonum vagi there is a translucent cord-like ridge called the **funiculus separans.**

When the floor of the ventricle is examined under water with a magnifying glass, the trigonum hypoglossi is seen to consist of a narrow medial strip which corresponds to the hypoglossal nucleus, and a wider lateral part which has been shown to be the surface representation of another nucleus termed the **nucleus intercalatus.**

On the part of the floor of the ventricle which lies above the striæ medullares, and corresponds to the dorsal surface of the pons, there is also a slight depression, termed the **fovea superior.** Between it and the median groove is a marked prominence called the **eminentia medialis.** Inferiorly this elevation passes downwards and becomes continuous with the trigonum hypoglossi, whilst superiorly it is carried upwards towards the opening of the aquæductus cerebri. In both directions it gradually becomes less prominent, but still it forms a distinct elongated elevation, which stretches alongside the whole length of the median groove. As already stated, the **area acustica** extends upwards into the pontine part of the ventricular floor and forms an elevated region in the most lateral part of its widest portion, below and to the lateral side of the fovea superior. Proceeding upwards from the fovea superior to the opening of the aquæductus cerebri there is a shallow depression termed the **locus cœruleus,** seeing that it usually presents a faint slate-blue colour. When the ependyma is scraped away from the surface of this part of the floor, the colour is seen to be due to the **substantia ferruginea,**—a name applied to a linear group of strongly pigmented cells, which lies in the lateral part of the gray matter covering this portion of the ventricular floor. When transverse sections are made through the superior part of the pons, the substantia ferruginea appears on the cut surface as a small black spot or dot.

INTERNAL STRUCTURE OF MEDULLA OBLONGATA AND PONS.

The structure of the medulla oblongata and pons differs in a marked degree from that of the spinal medulla: indeed, in its superior part, it presents very little in common with the latter. Some of the largest fasciculi which come up from the spinal medulla (such as the funiculus posterior) end in the lower part of the medulla oblongata; others leave the medulla oblongata and pass into the cerebellum; and of the bundles of fibres which pass upwards or downwards, from or to the spinal medulla respectively, most of them come to occupy very different positions in the medulla oblongata and pons.

The gray matter instead of being moulded into one compact column, as is the case in the spinal medulla, becomes broken up into a series of discrete nuclei. Thus, there are developed from the basal lamina of the rhombencephalon not one compact mass like the spinal anterior column, but three distinct broken columns of efferent nuclei (Fig. 452, p. 544):—(1) a **medial somatic column**, which in turn is broken up into two parts, a bulbar nucleus (*the hypoglossal*) which supplies the motor fibres to the tongue muscles, and a pontine nucleus (*the abducens*) which supplies the lateral rectus muscle of the eye; (2) a **lateral somatic column**, broken up into separate nuclei, viz., *accessorius, ambiguus, facial,* and *trigeminal,* supplying

the sterno-mastoid and trapezius muscles and the striated muscles of the larynx, pharynx, and face and those concerned with mastication; and (3) a **splanchnic column** of nuclei, giving efferent fibres which pass out in the vagus, glossopharyngeal, and facial nerves, to be widely distributed to unstriped muscle, glands, and other tissues in the head, neck, thorax, and abdomen.

Further, the terminal nuclei of the sensory nerves which are developed in the alar lamina of the rhombencephalon do not unite to form a definite posterior column, as happens in the spinal medulla, but form discrete masses; and as these act as receptive organs for a much greater variety of sensory nerves than are represented in the spinal nerves there is a much greater number of nuclei than would be formed if the various components of the posterior column in the spinal medulla were dissociated. Thus, there are terminal nuclei in the medulla oblongata not only for the ordinary cutaneous nerves, but also for nerves coming from the mucous membranes of the alimentary and respiratory organs, as well as from other visceral structures; and there are also special nerves of taste (nervus intermedius and glossopharyngeal), of hearing (cochlear part of the acoustic), and of equilibration (vestibular part of the acoustic). But this does not exhaust the peculiar features of the terminal sensory nuclei of the rhombencephalon. In the description of the spinal medulla attention was called to the fact that certain of the fibres of the posterior nerve-root did not end in the gray matter of the spinal medulla, but passed upwards throughout the whole length (above their points of entry) of the funiculus posterior to reach the medulla oblongata. Special terminal nuclei are developed from the alar lamina to receive these fibres. They are the nucleus gracilis and nucleus cuneatus.

In addition, part of the terminal vestibular nucleus receives accessions of fibres from these (gracile and cuneate) nuclei as well as from other sensory terminal nuclei in the spinal medulla and develops into that great mass of tissue, the cerebellum, to which vast numbers of other fibres come and go, adding considerably to the complexity of the region of the pons and medulla oblongata. Moreover, there is developed from the alar lamina a whole series of other masses of gray matter—the **nucleus olivaris inferior**, **nuclei arcuati**, **nucleus pontobulbaris**, and **nuclei pontis**—as links in the complex chains that bind all parts of the central nervous system to the great co-ordinating mechanism of the cerebellum.

Thus it comes about that, instead of having, as in the spinal medulla, a definite column of gray matter ensheathed in a thick mass of white substance, the rhombencephalon is composed of many scattered masses of gray matter; and its white substance is represented partly by great longitudinal strands, but also by many great systems of fibres passing transversely through its substance, or upon its surface, *e.g.*, the superficial fibres of the pons and many of the arcuate fibres.

From what has already been said concerning the external form of the medulla oblongata and pons it will be apparent that the distortion of the neural tube which occurred as the result of the pontine flexure has also been largely responsible for the distinctive features of this region of the brain.

As the pontine flexure develops, a strain is thrown upon the thin roof-plate, which yields and becomes stretched so as to permit the thick lateral walls of the neural tube to fall laterally (Figs. 457 and 458). One result of this process is the great lateral expansion of the cavity of the hind-brain, which assumes the characteristic rhomboid form. If the thin and greatly attenuated epithelial roof is torn away from the rhombencephalon of an embryo of the third month the fourth ventricle will present the appearance (viewed from behind) shown in Fig. 457. The ventricle is seen to be prolonged laterally, on each side, to form a little recess upon the lateral aspect of the rhombencephalon. This is called the **recessus lateralis.**

This thin epithelial roof becomes invaginated towards the cavity of the fourth ventricle, on each side of the median plane, in the whole length of the epithelial roof, *i.e.* from the cerebellar attachment, above, almost as far as the closed part of the medulla oblongata below (Fig. 451). The upper end of this invaginated fold becomes prolonged laterally as far as the extremity of the recessus lateralis (Fig. 497). Pia mater and blood-vessels extend into these folds, which are then known as the **chorioid plexuses** of the fourth ventricle. At the extremities of these two

plexuses, which are situated at the three corners of the epithelial roof of the ventricle, oval or elliptical perforations develop in the roof at about the fifth month of fœtal life. These are known as the **apertura medialis ventriculi quarti** (O.T. **foramen of Magendie**), which opens between the clavæ on the posterior surface and the **aperturæ laterales** upon the anterior faces of the lateral recesses (Fig. 478), behind the insertion of the glossopharyngeal nerve on each side. Through each of these lateral openings the great swollen cauliflower-like extremity of the chorioid plexus becomes extruded from the ventricle. The inferior extremities of the two plexuses lying side by side present an analogous relationship to the apertura medialis, but they are exceedingly attenuated and the epithelial lamella from which they spring becomes dragged backwards into contact with the cerebellum (Fig. 451), so that, when seen from below, the apertura medialis is a great funnel-shaped tube leading into the fourth ventricle and the chorioid plexuses look like two delicate vascular fringes on the cerebellum.

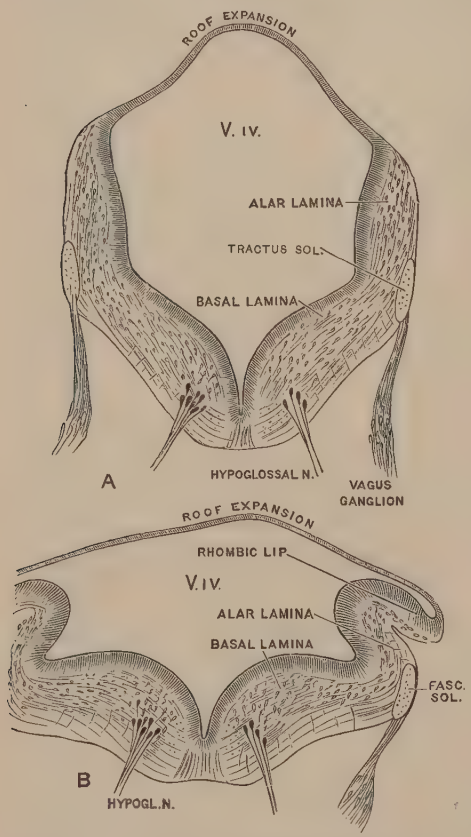

FIG. 457. — TRANSVERSE SECTIONS ACROSS THE MEDULLA OBLONGATA IN TWO HUMAN EMBRYOS, REPRESENTING DIFFERENT STAGES IN THE EXPANSION OF THE ROOF AND THE FALLING LATERALLY OF THE SIDE WALLS. (From His, slightly modified.)

These three apertures are the only means provided for the escape of the fluid contained in the ventricles of the central nervous system. The fluid is poured into a space, enclosed by the arachnoid, which is called the subarachnoid space.

As a result of the pontine flexure the side walls of the neural tube in the neighbourhood of the bend fall away the one from the other and eventually come to be placed in the same transverse plane, one with the other and also with the floor-plate. At the time this process is in operation (see Fig. 457) the alar and basal laminæ are particularly well defined, and the limiting sulci are accentuated by the bending of the side wall; but this sharp distinction is soon lost as the result of the great expansion of the basal lamina (Fig. 459). This is due not only to growth of its intrinsic elements, but even more to its invasion by large numbers of neuroblasts which migrate from the alar into the basal lamina.

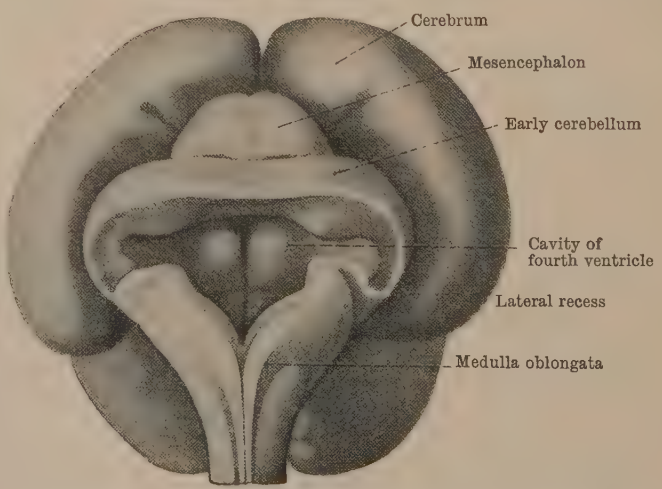

FIG. 458.—THE BRAIN OF AN EMBRYO OF ELEVEN WEEKS, viewed from behind. The epithelial roof of the fourth ventricle has been removed. At this stage the cerebellum is in the form of a simple band or plate which arches over the posterior aspect of the anterior part of the cavity of the hind-brain. (From His.)

Later still, the development of the great sensory and motor tracts contributes largely to the dimensions of the basal lamina.

As the two basal laminæ (one on each side of the median plane) increase in thickness the epithelial cells in the intervening floor-plate become stretched and lengthened (Fig. 457), so that a definite septum or **raphe** is formed between the two halves of the rhombencephalon.

The fate of the extreme posterior edge of the alar lamina is very interesting. The nervus acusticus is inserted into this edge in the region of the recessus lateralis, and from it masses of neuroblasts develop to form receptive nuclei for the two parts of this nerve, these being the cochlear and vestibular. These are the **nucleus cochlearis** and **nucleus vestibularis** respectively. Sensory fasciculi, bringing impulses from muscles, skin and related structures in all parts of the body, make their way into the superior part of the vestibular nucleus, and it grows and forms a large thickening of the posterior edge above the recessus lateralis. Eventually, as it extends medially (Fig. 458), it reaches and invades the roof-plate and fuses with the corresponding rudiment of the other side. Thus a semilunar band, the primitive cerebellum, is formed, arching across the posterior aspect of the metencephalon. The part of the dorsal edge which lies below the vestibular nucleus becomes bent over (forwards) to form what is known as the **rhombic lip** (Fig. 457). It is destined to be transformed into a series of masses of gray matter, the chief function of which is to emit fibres to carry impulses into the cerebellum. But most of these fibres pass not so much to the part of the cerebellum derived from their own side as to that of the opposite side. Thus, from above downwards, the thickened margin of the fossa rhomboidea on each side develops into the following structures:—cerebellum, the rest of the vestibular nucleus, the cochlear nucleus, the nuclei pontis (and arcuate nuclei), the olivary nucleus, the nucleus gracilis and the nucleus cuneatus. At an early stage of development most of the neuroblasts that form the rudiments of the nuclei pontis, nuclei arcuati, and nucleus olivaris inferior begin a process of migration, the course of which is determined by the source and direction of the afferent tracts passing into each nucleus. Such migrations are of common occurrence throughout the brain, and attempts to explain them have given rise to much discussion. The factor that appears to lead certain nerve-cells away from the place where they originally developed has been called *neurobiotaxis* by Arïens-Kappers. But the solution of the problems of these apparent migrations is quite a simple one. Take the case of a nerve-cell (*A*), at an early stage of development, which collects afferent impulses through its dendrites from the cell *B*, and emits an efferent impulse through its axon to the cell *C*: as the whole nervous system is very small at the stage under consideration, the three cells will necessarily be close the one to the other—a fact which may be represented by the positions of the letters thus:—

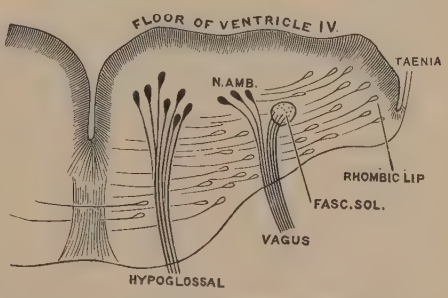

Fig. 459.—Transverse Section of the Human Embryo at a Later Stage than those shown in Fig. 457. (After His.)

B—*A*—*C*.

In the course of subsequent growth it must inevitably happen that the points *B* and *C* will become removed further and further apart. If we suppose that the cell *B* remains constant, the cell *A* will be faced with two alternatives if it is to continue to link together the elements *B* and *C*: either its dendrites or its axon must elongate. Now the axon is specially modified in structure for conducting impulses for long distances, and the dendrites are not so specialised. Therefore it invariably happens that it is the axon that becomes lengthened. In other words the cell-body *A*, considered in its relations to *C*, appears to migrate towards the direction *B* from which its chief supply of afferent impulses comes. This may be represented thus:—

B—*A*————————————*C*.

In the specific case we are considering the vestibular nucleus and the cerebellum receive their chief supply of afferent fibres from the incoming vestibular nerve: hence there is no reason for migration. Similarly the nucleus gracilis and nucleus cuneatus receive the fibres which come up through the funiculus posterior and remain where they are. But the nuclei pontis, the olivary nucleus, and the arcuate nuclei are "fed" with impulses passing downwards (and some perhaps upwards) in the basal lamina, close to the median plane, and they "migrate" towards the direction from which their afferent paths are approaching; the nuclei pontis towards the peduncles of the cerebrum bringing cerebro-pontine fibres from the cerebral cortex, and the olivary nucleus to the neighbourhood of certain descending tegmental tracts and ascending spinal sensory tracts that seem to supply the attractive force which leads them to forsake the rhombic lip of the alar lamina and migrate into the basal lamina.

The majority of the cells destined to form the nuclei pontis wander obliquely upwards and forwards between the facial and acoustic nerves to reach the basal lamina of the metencephalon. But strewn along this pathway from the edge of the fossa rhomboidea to the front of the pons are scattered nerve-cells which have, so to speak, fallen by the way, and remain to indicate in the adult brain the path taken by the majority of their sister cells. This remnant forms the **corpus ponto-bulbare**: the pontine fibres that spring from its cells and are making their way upwards to fall in line (Fig. 469, p. 566) with the other transverse fibres of the pons form the **fasciculus obliquus** [pontis], and the cerebro-pontine fibres that pass below the pons in order to reach this outlying part (corpus ponto-bulbare) of the nuclei pontis constitute the **fasciculus circumolivaris pyramidis** (Fig. 488, p. 582).

But not all of the elements of the nuclei pontis that migrate pass into the metencephalon; a certain proportion of them invariably pass into the myelencephalon. These collect upon the anterior surface of the pyramids to form small irregular patches of gray matter which have received the name **nuclei arcuati**. Their afferent fibres (probably cerebro-pontine) come from the pyramids; and their efferent fibres (which proceed to the cerebellum) form some of the **fibræ arcuatæ externæ**, which are visible upon the surface of the medulla oblongata (Fig. 463).

Olivary Nuclei.—The most conspicuous of the isolated clumps of gray matter in the medulla are the inferior olivary nucleus and the two accessory olivary nuclei. The **nucleus olivaris inferior** is the mass of gray substance which produces the swelling known as the olive, and constitutes a very striking object in transverse sections through this region. It presents the appearance of a thick wavy or undulating line of gray matter, folded on itself, so as to enclose a space filled with white matter. It is in reality a crumpled lamina arranged in a purse-like manner, with an open mouth or slit, which is called the **hilum** (hilus nuclei olivaris), directed towards the median plane. The hilum does not reach either extremity, so that in transverse sections through either end of the nucleus the gray lamina is seen in the form of a completely closed capsule. Into and out of the open mouth of the olivary capsule streams a dense crowd of fibres. These constitute what is called the **olivary peduncle.**

The **accessory olivary nuclei** are two band-like laminæ of gray matter, which are respectively placed on the dorsal and medial aspects of the main nucleus. In transverse section each of these nuclei presents a rod-like appearance (Fig. 461).

The **medial accessory olivary nucleus** extends lower down in the medulla oblongata than the main nucleus, and it is much larger in its lower than in its upper part. It begins immediately above the decussation of the pyramids, where it is seen lying on the lateral side of the cerebro-spinal fasciculus and the lemniscus medialis (Fig. 466). Higher up it lies across the mouth of the main nucleus and on the lateral side of the medial lemniscus. The **dorsal accessory olivary nucleus** is placed close to the dorsal aspect of the main nucleus. The two accessory nuclei fuse together before they finally disappear.

The nerve-cells of the inferior olivary nucleus are small and round, and emit a large series of short radiating, complexly branched dendrites, so that the cell-body seems to lie in the centre of a spherical mass formed by its own dendrites and an almost equally complex mass of intertwined end branches of the axons which bring impulses into these cells. There is no definite information as to the place of origin of these afferent fibres. Flechsig and Bechterew, using different methods of investigation, have demonstrated the

presence of a large descending tract in the mesencephalon and rhombencephalon, which ends amidst the cells of the lateral pole of the olivary nucleus. This has been called the *fasciculus thalamo-olivaris*, but it is not quite certain that it arises in the thalamus, although its origin must be somewhere in the neighbourhood of it. Flechsig denies that any fibres reach the olivary nucleus from the spinal medulla, but the proximity of the spino-thalamic and bulbo-thalamic (lemniscus medialis) fibres and the demonstration of Ramon y Cajal that fibres enter the nucleus olivaris from adjoining fasciculi in these regions suggest that there may be a spinal afferent path.

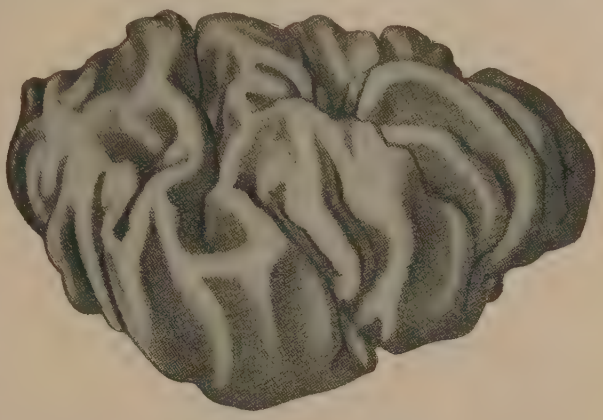

Fig. 460.—The Inferior Olivary Nucleus, as reconstructed and figured by Florence R. Sabin.

View of the dorso-lateral and lateral surfaces.

There seems to be a direct relationship between the size of the inferior olivary nucleus and the extent of the cortical area that presides over highly skilled movements.

The axons emitted by the cells of the olivary nucleus cross the median raphe and pass through the opposite side of the medulla oblongata as internal arcuate fibres, which enter the restiform body and pass into the cerebellum.[1]

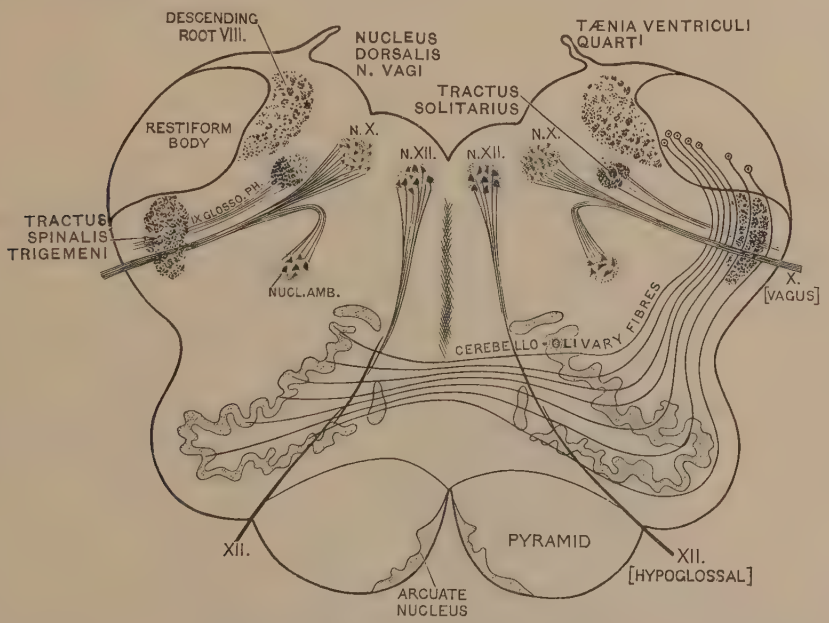

Fig. 461.—Diagram of the Fasciculus Olivocerebellaris (Cerebello-Olivary Fibres).

N.X., Vago-glossopharyngeal nucleus. N.XII., Hypoglossal nucleus.

These fibres are seen only in the superior part of the medulla oblongata. They form the deep part of the restiform body and constitute its chief bulk. Streaming out from the hilum of the inferior olivary nucleus, they cross the median plane, and in the opposite side of the medulla oblongata they either pass through the inferior

[1] These fibres should be called the *fasciculus olivocerebellaris*, by which designation they will be referred to in this account, but in the recognised nomenclature (which most writers do not follow in this instance) the tract is called "*cerebello-olivaris*."

olivary nucleus of that side or sweep round it. Ultimately, on the dorsal aspect of the olivary nucleus, they are gathered together in the form of a conspicuous group of arcuate fibres, which curve backwards to take up a position in the deep part of the restiform body. In passing back, they traverse the tractus spinalis of the trigeminal nerve and break it up into several separate bundles. The olivo-cerebellar fibres thus connect the inferior olivary nucleus of one side with the opposite side of the cerebellum. Each part of the inferior olivary nucleus is connected with a definite part of the cerebellum.

Decussation of the Pyramids and the Changes produced thereby.—As we examine, under the microscope, a series of successive transverse sections through the inferior end of the medulla oblongata and the upper end of the spinal medulla, the most striking change which meets the eye is the decussation of the lateral cerebro-spinal tracts. From their position alongside the anterior median fissure of the medulla oblongata most of the fibres of the pyramid cross the median plane and, after passing through the anterior column of gray matter, bend downwards in the lateral funiculus of the opposite side of the spinal medulla. Strands from the right lateral cerebro-spinal tract alternate with corresponding strands from the left side, and the interval between the bottom of the anterior median furrow and the gray matter surrounding the central canal becomes filled up with a great mass of inter-crossing bundles of fibres.

As a rule the medial three-fourths of the pyramid are composed of fibres which, lower down in the opposite lateral funiculus of the spinal medulla, form the fasciculus cerebro-spinalis, whilst the lateral fourth of the pyramid proceeds downwards in the anterior funiculus of the spinal medulla of the same side, as the fasciculus cerebrospinalis anterior. A considerable amount of variation, however, occurs in the proportion of fibres which is allotted to the formation of these two tracts. Sometimes the lateral cerebro-spinal tract is much larger than usual, and then the anterior cerebro-spinal tract suffers a corresponding diminution in size. Cases, indeed, occur in which the entire pyramid enters into the decussation, and in these there is no anterior cerebro-spinal tract. Further, it is not uncommon to meet with variations of an opposite kind which lead to an increase of the anterior cerebro-spinal tract at the expense of the lateral cerebro-spinal tract. Sometimes the decussation is asymmetrical, and the corresponding cerebro-spinal tracts on opposite sides of the spinal medulla are then unequal in size. One factor that often comes into play and causes asymmetry is the prolongation downwards into the pyramid on one side (usually the left) of some of the cerebro-pontine fibres. In such cases these fibres soon leave the pyramid and form the **fasciculus circumolivaris**.

The variations indicated above receive an additional interest when viewed in the light of comparative anatomy. It would appear that only in man and the anthropoid apes is the decussation of the pyramids in the inferior part of the medulla oblongata incomplete. According to Sherrington, an anterior cerebro-spinal tract in the spinal medulla of the anthropoid apes stands in connexion with the arm-centre in the cerebral cortex. If this is the case in man it must have other connexions as well, seeing that it is carried down the spinal medulla for a considerable distance beyond the level of the spinal segments which give motor fibres to the upper limb. In the lower apes an anterior cerebro-spinal tract does not seem to exist: the whole pyramid crosses over to the opposite side of the spinal medulla in the shape of the lateral cerebro-spinal tract.

As we have noted, the decussating pyramidal bundles pass through the anterior column of gray matter, and cut it into two portions (Fig. 462). The basal part remains in position on the anterior and lateral aspect of the central canal, and forms part of the thick layer of gray matter which surrounds it. The detached head of the anterior column is set free; and from the large multipolar cells which lie in its midst some of the fibres of the anterior root of the first cervical nerve, and also some of the root fibres of the accessory nerve, take origin.

As we proceed into the medulla oblongata another effect of the decussation of the pyramids is seen in the submergence from the surface of the strand of fibres which, in the anterior funiculus of the spinal medulla, lies to the lateral side of the anterior cerebro-spinal tract, and which receives the name of the fasciculus anterior proprius. While the decussation is going on the fasciculus proprius is thrust aside, and in the medulla oblongata it takes up its position as a flattened

band-like strand on the lateral side of the pyramid (Fig. 462). When the decussation is completed, this strand is seen to lie close to the median plane on the dorsal aspect of the pyramid, where it is separated from its fellow of the opposite side by the median raphe alone (Fig. 463). In the upper part of the medulla oblongata it approaches still nearer to the dorsal surface and appears to form the greater part of a strand, which is termed the **medial longitudinal bundle** (Figs. 465 and 466). The detached head of the anterior column of gray matter of the spinal medulla, as it is traced upwards, is observed to cling closely to its original relationship with the fasciculus anterior proprius. It is applied to the lateral side of this strand, and, gradually becoming smaller, finally disappears at the level of the inferior part of the inferior olivary nucleus.

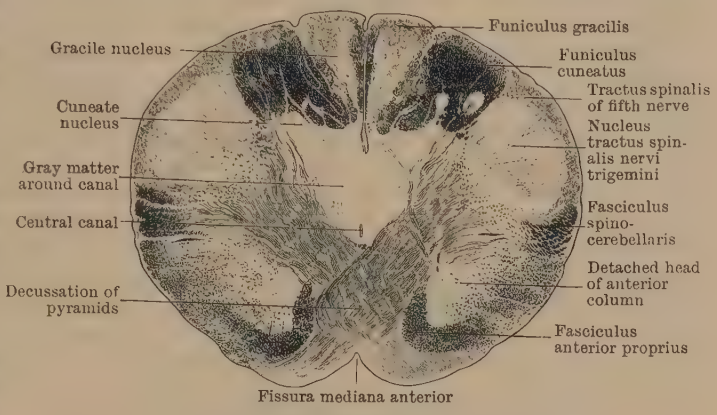

FIG. 462.—TRANSVERSE SECTION THROUGH THE INFERIOR END OF THE MEDULLA OBLONGATA OF A FULL-TIME FŒTUS.

Treated by the Weigert-Pal method. The gray matter is bleached white, and the medullated tracts of fibres are black.

Cuneate and Gracile Fasciculi, with their Nuclei.—As the fasciculus gracilis

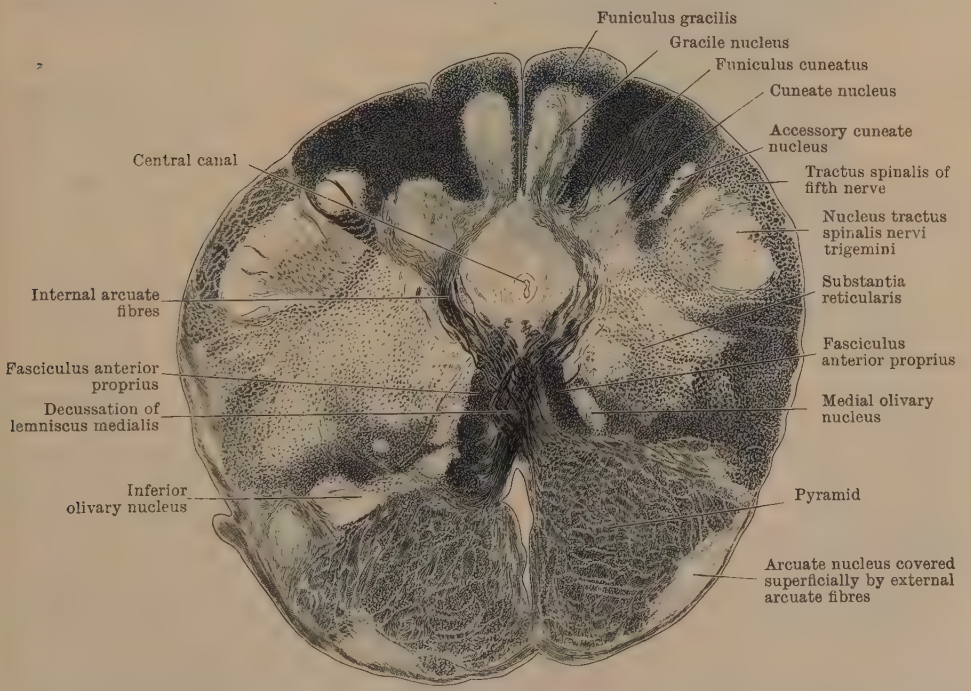

FIG. 463.—SECTION THROUGH THE CLOSED PART OF THE ADULT MEDULLA OBLONGATA IMMEDIATELY ABOVE THE DECUSSATION OF THE PYRAMIDS (Weigert-Pal specimen).

and the fasciculus cuneatus of the posterior funiculus of the spinal medulla are traced up into the medulla oblongata they seem to increase in bulk, and in transverse sections they assume the form of massive wedge-shaped strands, quite distinct from each other. They increase in width and lose considerably in depth,

and consequently the transverse diameter of the area which they occupy becomes greater. As a result of this, and also owing to the removal of the lateral cerebro-spinal tract from the lateral funiculus of the spinal medulla immediately in front, the posterior column of gray matter is gradually rotated forwards and comes to lie transversely and in the same straight line with its fellow of the opposite side (Figs. 462 and 463). The substantia gelatinosa, at the same time, becomes increased in quantity and presents a horseshoe-shaped outline in transverse section. It clasps within its concavity the somewhat reduced head of the posterior column, and forms with it a conspicuous circular mass of gray matter which lies close to the surface, and produces upon it the bulging termed the tuberculum cinereum. The basal portion of the posterior column of gray matter remains upon the dorsal and lateral aspect of the central canal, and forms a portion of the central gray mass of the closed part of the medulla oblongata; but very soon the neck of the column, which at this level is greatly reduced owing to the absence of entering posterior nerve-roots, is invaded by bundles of fibres which traverse it in different directions and convert it into a formatio reticularis. By this means the rounded head of the posterior column becomes cut off from the central gray matter, and from this point upwards it remains as an isolated gray column intimately associated with the spinal root of the trigeminal nerve. It has, in fact, become the **nucleus tractus spinalis nervi trigemini.**

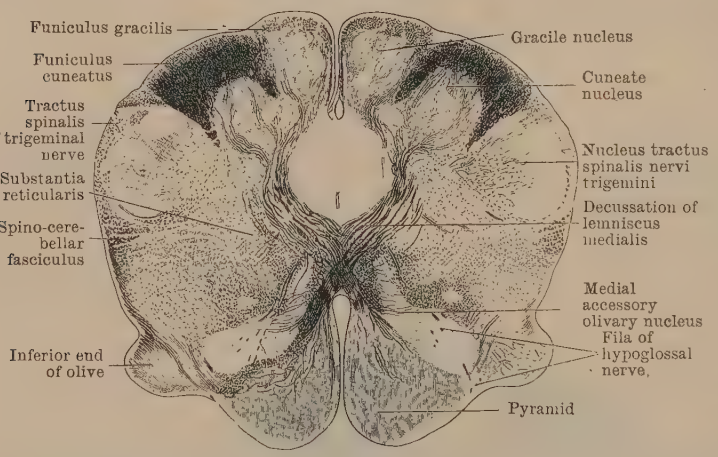

FIG. 464.—TRANSVERSE SECTION THROUGH THE CLOSED PART OF A FŒTAL MEDULLA OBLONGATA, IMMEDIATELY ABOVE THE DECUSSATION OF THE PYRAMIDS. Treated by Weigert-Pal method.

The **gracile** and **cuneate nuclei** are seen in their most typical form in sections at the level of the decussation of the pyramids (Figs. 463 and 464). The **gracile nucleus** appears in the form of a relatively slender mass of gray matter in the interior of the funiculus gracilis.

The **cuneate nucleus** is a direct offshoot from that part of the base of the posterior column of gray matter which is preserved as a portion of the central gray mass. In transverse section it is seen to invade the funiculus cuneatus upon its deep aspect, and it gradually grows backwards into its substance. It presents a very different appearance from the gracile nucleus, because throughout its whole length the gray nucleus and the fibres of the strand are separated from each other by a sharp line of demarcation. A little higher up, a second and much smaller mass of gray matter appears in the funiculus cuneatus, superficial to the main nucleus. This is termed the **accessory** or the **lateral cuneate nucleus** (Fig. 463).

As a series of sections is studied from below upwards, it will be noticed that the number of fibres in the gracile and cuneate funiculi rapidly decreases, until, at the level of the clava and cuneate tubercles, it is seen that these eminences are composed almost entirely of the gray nuclei, covered by a thin layer of the few remaining fibres of the two fasciculi involved. It would appear that no fibres belonging to the funiculus gracilis and funiculus cuneatus get beyond these nuclei. They all end in fine terminal ramifications around the cells of the nuclei. In the case of the funiculus cuneatus the bundles of fibres, as they pass from the surface into the subjacent gray nucleus, are very distinctly seen in transverse sections through the bulb.

When the medulla oblongata opens up into the fourth ventricle the gracile

and cuneate nuclei are pushed laterally by the expanding ventricular floor, and the gracile nucleus soon comes to an end; but the cuneate nucleus extends upwards for a short distance farther, and terminates only when the restiform body begins to take definite shape on its lateral aspect.

Decussatio Lemniscorum.—Immediately above the level of the decussation of the pyramids another decussation of fibres takes place in the substance of the medulla oblongata in the median plane, and upon the dorsal aspect of the pyramids. This is the **decussation of the lemniscus medialis**, or the **sensory decussation**, so called in contradistinction to the term "motor decussation," which is sometimes applied to the decussation of the pyramids. The fibres which take part in this decussation are called **internal arcuate fibres**, and they are derived from the cells of the gracile and cuneate nuclei. From the deep aspects of these nuclei these fibres stream forwards and medially towards the median raphe, forming a series of concentric curves in the substance of the medulla oblongata. They cross the median plane and decussate with the corresponding fibres of the opposite side, upon the dorsal aspect of the pyramids. Having thus gained the opposite side of the medulla oblongata, they immediately turn upwards and form a conspicuous strand of longitudinal fibres, which ascends close to the median plane and is separated from its fellow of the opposite side by the median raphe alone. This strand is termed the **lemniscus medialis.**

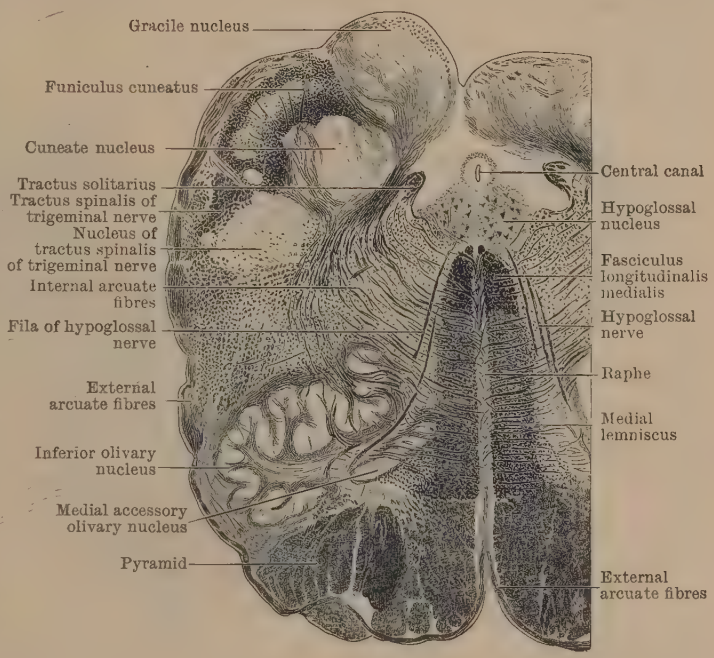

FIG. 465.—TRANSVERSE SECTION THROUGH THE MEDULLA OBLONGATA IN THE INFERIOR OLIVARY REGION.

As we proceed up the medulla oblongata internal arcuate fibres which first come into sight appear as coarse bundles which curve forwards in a narrow group round the central gray matter (Figs. 465 and 466). Soon, other finer bundles appear, which describe wider curves on the lateral side of the coarser group, until a very large part of each half of the medulla is seen to be traversed by these arcuate fasciculi (Fig. 466). The internal arcuate fibres decussate in the median plane with the internal arcuate fibres of the opposite side. They then change their direction and turn upwards, and the lemniscus, as already stated, takes form and gradually increases in volume as it ascends. This great and important tract is thus laid down between the pyramid and the **fasciculus longitudinalis medialis**; and the consequence of this is that the latter tract is pushed still farther backwards, and, when the lemniscus is fully established, it comes to lie immediately beneath the gray matter of the floor of the fourth ventricle (Fig. 466). But the lemniscus is not in direct contact with the fasciculus longitudinalis, for a bundle of fibres, the continuation of which has been seen in the anterior funiculus of the medulla spinalis, the **fasciculus tectospinalis**, separates them, as well as fibres coming from sensory nuclei of the cerebral nerves which are crossing the raphe to join the medial lemniscus (Fig. 466).

It is important that we should realise at this stage the full significance of the decussation of the lemniscus and have a clear conception of the connexions of the

fibres which take part in it. The funiculus posterior, which ends in the cuneate and gracile nuclei, is derived from the posterior roots of the spinal nerves. The lemniscus fibres therefore carry on the continuity of part of the posterior funiculus, the gracile and cuneate nuclei, which are thrown across its path in the lower part of the medulla oblongata, constituting merely a nodal interruption. At this point the lemniscus is transferred to the opposite side of the medulla oblongata. But it will be remembered that a large proportion of the fibres of the entering posterior nerve-roots of the spinal nerves end in connexion with the cells of the posterior column of gray matter of the spinal medulla. It must not be supposed that the path represented by these latter fibres comes to a termination thereby; from these posterior column cells other fibres arise which cross, in the anterior white commissure, to the opposite side of the spinal medulla and proceed up the spinal medulla to the lateral part of the medulla oblongata. These fibres constitute the **spino-thalamic tract** already referred to. *The practical bearing of this is that, owing to the crossing of the lemniscus medialis and lower down of the spino-thalamic tract, unilateral*

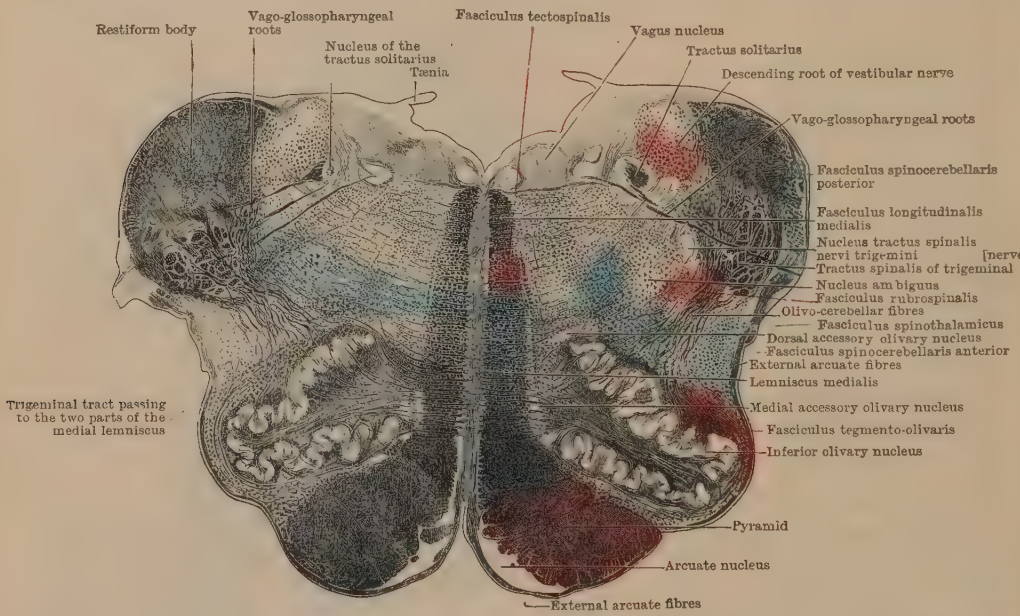

FIG. 466.—TRANSVERSE SECTION THROUGH THE MIDDLE OF THE OLIVARY REGION OF THE MEDULLA OBLONGATA.

The floor of the fourth ventricle is seen, and it will be noticed that the restiform body on each side has now taken definite shape. Some of the descending tracts in red; ascending tracts in blue.

lesions of the medulla oblongata are apt to produce complete hemi-anæsthesia; whilst unilateral lesions of the spinal medulla produce only partial hemi-anæsthesia.

The pyramid forms a massive tract in front of and quite distinct from the lemniscus medialis. The lemniscus medialis, the tecto-spinal bundle, and the medial longitudinal bundle are, in the first instance, not marked off from each other. They appear as a broad flattened band applied to the raphe. One edge of this band is directed backwards and reaches the gray matter on the floor of the fourth ventricle, while the other edge looks forwards and is in contact with the pyramid. In the upper part of the medulla oblongata the lemniscus and the medial longitudinal fasciculus begin to draw asunder from each other. The intermediate longitudinal fibres become reduced in number and the two strands grow denser—the one on the dorsal aspect of the pyramid, and the other immediately beneath the gray matter of the floor of the fourth ventricle (Fig. 466).

The **fasciculus longitudinalis medialis** is largely formed of fibres homologous with those which in the spinal medulla constitute the fasciculus anterior proprius. As they are followed upwards these fibres are thrust back by the two decussations: the lower decussation pushing them behind the pyramids, and the upper decussation

displacing them still farther backwards to a position behind the lemniscus medialis.

Corpus Restiforme.—The gracile and cuneate nuclei gradually give place to the **restiform body** in the superior part of the posterior district of the medulla oblongata. Fibres from various quarters converge to form this great strand. It first takes shape as a thin superficial layer of longitudinal fibres, which are gathered together on the lateral aspect of the cuneate nucleus; but after that nucleus has come to an end, and as the superior part of the medulla oblongata is reached, the restiform body is seen to have grown into a massive strand, which presents a kidney-shaped or oval outline on transverse section (Fig. 466); and it ultimately enters the white central core of the cerebellum as its inferior peduncle. The fibres which build up the restiform body are the following: (1) the fasciculus spinocerebellaris [posterior], (2) arcuate fibres coming from the nucleus gracilis and nucleus cuneatus of both sides of the medulla oblongata; (3) external arcuate fibres coming from the arcuate nuclei; and (4) olivo-cerebellar fibres.

The **fasciculus spinocerebellaris [posterior]** extends upwards from the lateral funiculus of the medulla spinalis. In the lateral district of the medulla oblongata it occupies a similar position; but before the olive is reached it inclines backwards, crosses the posterior lateral furrow and passes obliquely upwards into the restiform body. As its fibres diverge backwards, they pass over and cover up the tractus spinalis of the trigeminal nerve and its nucleus, thus shutting them out from the surface. The fibres of the fasciculus spinocerebellaris, in the first instance, enter into the lateral or superficial part of the restiform body.

Bruce has shown that the fibres of the spino-cerebellar tract ultimately lie in the centre of the restiform body, forming as it were its central core, and that, in the cerebellum, they can be traced to the superior vermis.

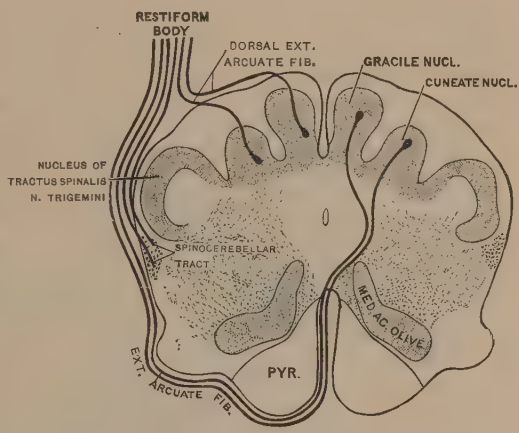

FIG. 467.—DIAGRAM, which shows in part the fibres which enter into the constitution of the restiform body.

The **posterior external arcuate fibres** take origin from the gracile and cuneate nuclei, and enter the superficial part of the restiform body of the same side.

The **anterior external arcuate fibres** proceed from the inferior portions of the gracile and cuneate nuclei of the opposite side. It can easily be determined that, after decussating in the median plane, all the internal arcuate fibres which arise from these nuclei do not enter the lemniscus medialis. A large proportion of them gain the surface by sweeping round the medial aspect of the pyramid in the anterior median fissure. Many of them gain the surface by piercing the pyramid or by passing out between it and the olive. These fibres constitute the anterior external arcuate group, and on the surface of the medulla oblongata they sweep backwards around it, forming a thin layer over the olive and ultimately reaching the restiform body. The anterior external arcuate fibres, as well as the spino-cerebellar tract-fibres, cover over the tractus spinalis of the trigeminal nerve, which thus comes to take up a deeper position in the substance of the medulla oblongata (Figs. 466 and 467).

The other elements in the restiform body, viz., those derived from the nucleus olivaris inferior and the nuclei arcuati, have already been described.

Thus, the restiform body conveys to the cerebellum (1) fibres conveying impulses from the posterior spinal roots of the same and also from the opposite side of the medulla spinalis, the former after being interrupted in the nucleus dorsalis and the nucleus gracilis and nucleus cuneatus of the same side, the latter in the nucleus gracilis and nucleus cuneatus of the other side; and (2) fibres from the olivary and

arcuate nuclei, which convey impulses from the higher regions of the brain, directly or indirectly (probably the latter) from the motor area of the cerebral cortex.

Formatio Reticularis.—Behind the olive and the pyramid is the **formatio reticularis.** In the medulla oblongata it occupies a position which, to a large extent, corresponds with that of the lateral funiculus in the spinal medulla. In transverse section it appears as an extensive area, which is divided into a lateral and a medial field by the fila of the hypoglossal nerve as they traverse the substance of the medulla oblongata to reach the surface. In the lateral portion, which lies behind the olive, a considerable quantity of gray matter, continuous with that in the spinal medulla, is present in the reticular formation; it is therefore called the **formatio reticularis grisea.** In the medial part, which lies behind the pyramid, the gray matter is extremely scanty, and the reticular matter here is termed the **formatio reticularis alba.**

The nerve-fibres which traverse the formatio reticularis run both in a transverse and in a longitudinal direction. The **transverse fibres** are the internal arcuate fibres. The **longitudinal fibres** are derived from different sources in the two fields. In the formatio grisea they represent to a large extent the fibres of the lateral funiculus of the spinal medulla, after the removal of the posterior spino-cerebellar and the lateral cerebro-spinal tracts. They consist, therefore, of the fibres of the fasciculi rubro-spinalis, thalamo-olivaris, spinothalamicus, and spinocerebellaris anterior (antero-lateralis superficialis) of the spinal medulla. In the formatio alba the longitudinal fibres are the tract of the lemniscus medialis, the fasciculus tectospinalis, and the medial longitudinal bundle, all of which have already been described.

Central Canal and the Gray Matter which surrounds it.—The central canal, as it proceeds upwards through the closed part of the medulla, is gradually forced to assume a more dorsal position, owing to the accumulation of fibres on its ventral aspect. (Moreover, the posterior cleft-like part of the cavity of the fœtal neural tube, which becomes obliterated in the spinal medulla by the fusion of its walls, remains patent in the medulla oblongata. Hence the central canal in the closed part of the medulla oblongata extends backwards to the roof-plate.) First the decussation of the pyramids, and then the decussation of the medial lemniscus, both of which take place in front of the canal, tend to push it backwards; and the formation of the longitudinal strands in which these intercrossings result (viz., the pyramid and the medial lemniscus), together with the continuation upwards of the funiculus anterior proprius, leads to a great increase in the amount of tissue which separates it from the anterior surface of the medulla oblongata. In the closed part of the medulla oblongata the canal is surrounded by a thick layer of gray matter, which is continuous with the basal portions of the anterior and posterior columns of gray matter of the spinal medulla. This central gray matter is sharply defined on each side by the internal arcuate fibres, which curve forwards and medially around it. Finally, the central canal opens on the dorsal aspect of the medulla oblongata into the cavity of the fourth ventricle. The central mass of gray matter which surrounds the canal in the closed part of the medulla oblongata is now spread out in a thick layer on the floor of the fourth ventricle, and in such a manner that the portion which corresponds to the basal part of the anterior column of the spinal medulla is situated close to the median plane, whilst the part which represents the base of the posterior column occupies a more lateral position. This is important, because the nucleus of origin of the hypoglossal nerve is placed in the medial part of the floor, whilst the nuclei of termination of the afferent fibres of the vagus, glossopharyngeal, and acoustic nerves lie in the lateral part of the floor. The gray matter of the ventricular floor is covered with ependyma.

Three Areas of Flechsig.—In transverse sections, through the upper, open part of the medulla oblongata, the fila of the hypoglossal and vagus nerves are seen traversing the substance of the medulla oblongata. The nucleus of origin of the hypoglossal is placed in the gray matter of the floor of the fourth ventricle close to the median plane; the nucleus of the vagus is situated in the gray matter of the ventricular floor immediately to the lateral side of the hypoglossal nucleus. From these nuclei the root-bundles of the two nerves diverge from each other as they are traced to the surface and subdivide the substance of the medulla, as seen in transverse section, into the three areas of Flechsig, viz., an anterior, a lateral, and a posterior.

The **anterior area,** which is bounded medially by the median raphe and laterally by the

hypoglossal roots, presents within its limits: (*a*) the pyramid; (*b*) the lemniscus medialis; (*c*) the fasciculus tectospinalis; (*d*) the medial longitudinal fasciculus; (*e*) the medial accessory olivary nucleus; (*f*) the arcuate nucleus.

The **lateral area** lies between the root fibres of the hypoglossal and those of the vagus. It contains: (*a*) the inferior olivary nucleus; (*b*) the dorsal accessory olivary nucleus; (*c*) the nucleus lateralis; (*d*) the nucleus ambiguus; (*e*) the splanchnic efferent nucleus of the vagus and glossopharyngeal nerves; (*f*) the formatio reticularis grisea.

The **posterior area** is situated behind the vagus roots, and within its limits are seen: (1) the restiform body; (2) the superior part of the cuneate nucleus; (3) to the medial side of this a crowd of transversely cut bundles of fibres, loosely arranged and forming the descending root of the vestibular part of the acoustic nerve; (4) close to these, but placed more deeply, a round, compact, and very conspicuous bundle of transversely cut fibres, viz., the tractus solitarius, or descending root of the vagus and glossopharyngeal nerves; (5) the large tractus spinalis of the trigeminal nerve close to the lateral side of its nucleus composed of substantia gelatinosa.

INTERNAL STRUCTURE OF THE PONS.

When transverse sections are made through the pons, it is seen to be composed of a basilar part and a dorsal or tegmental part. The latter may be regarded as

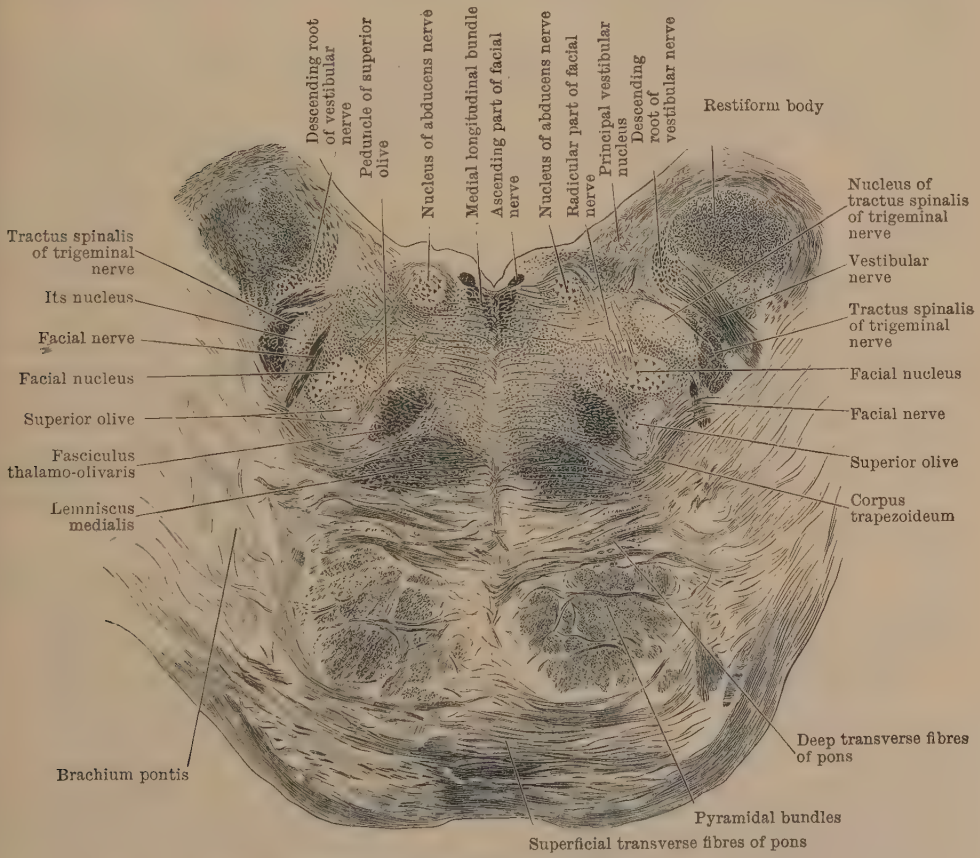

FIG. 468.—SECTION THROUGH THE LOWER PART OF THE PONS IMMEDIATELY ABOVE THE MEDULLA OBLONGATA.

the upward prolongation of the medulla oblongata, exclusive of the pyramids which are drawn forward into the basilar part.

Pars Basilaris Pontis.—This constitutes the chief bulk of the pons. It is composed of: (1) transverse fibres arranged in coarse bundles, called the **fibræ pontis**; (2) longitudinal fibres, gathered together in massive bundles; and (3) a large amount of gray matter, termed the **nuclei pontis**, which fills up the interstices between the intersecting bundles of fibres.

The **fasciculi longitudinales**, to a large extent, consist of the same fibres which, lower down, are gathered together in the two solid pyramidal tracts of the medulla

oblongata. When the pyramids are traced upwards into the pons they are seen to present the form of two compact bundles. Superiorly, however, they are broken up into smaller bundles by the transverse fibres of the pons, and are spread out over a wider area. At the upper border of the pons they again come together and form two solid strands, each of which is continuous with the central part of the corresponding basis of the cerebral peduncle. Added to these there are twice as many other fibres entering the pons from the basis pedunculi to terminate in the nuclei pontis.

The **fibræ pontis** at the inferior border of the pons are placed on the superficial or ventral aspect of the pyramidal bundles. As we proceed upwards they increase in number, and many are seen breaking through the pyramids and even passing across upon their dorsal aspect. Laterally, these transverse fibres are collected together into one compact mass, which enters the white central core of the cerebellum and constitutes the **brachium pontis** (O.T. **middle cerebellar peduncle**). At the median plane the transverse fibres of the two sides of the basilar portion of the pons intercross and form a coarse decussation.

The **nuclei pontis** form a considerable part of the bulk of the basilar portion of the pons. The gray matter is packed into the intervals between the intersecting transverse and longitudinal bundles.

There is some analogy between the pyramidal portions of the medulla oblongata and the ventral part of the pons. In the medulla oblongata fine arcuate fibres, on their way to the surface, pass through the pyramids. Other external arcuate fibres sweep over the surface of the pyramids. These present a strong resemblance to the transverse fibres of the pons. They likewise reach the cerebellum, although by a different route, viz., the restiform body. The nuclei pontis are represented also in the pyramidal part of the medulla oblongata by the arcuate nuclei, which are covered over by the external arcuate fibres, and even tend to penetrate, to a slight extent, into the pyramidal tracts. These arcuate nuclei, as already pointed out, are continuous with the nuclei pontis.

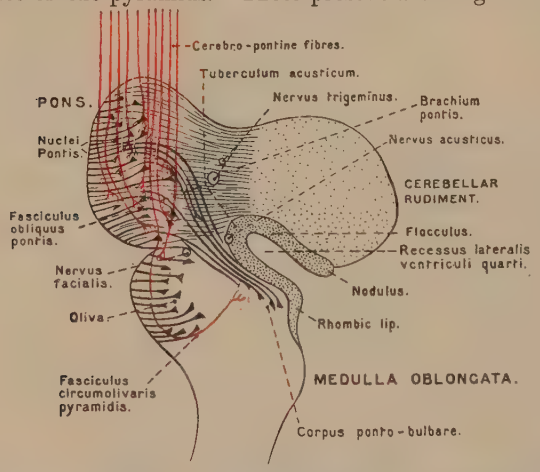

FIG. 469.—DIAGRAM OF THE LEFT LATERAL ASPECT OF THE FŒTAL RHOMBENCEPHALON REPRESENTING SOME OF THE CELL GROUPS AND FIBRE TRACTS.

Connexions of the Longitudinal and Transverse Fibres. — When a transverse section through the superior part of the pons is compared with one close to its inferior border, it becomes at once apparent that the numerous scattered bundles of longitudinal fibres which enter the ventral part of the pons from above, if brought together into one tract, would form a strand very much larger than the two pyramids which leave its lower aspect and enter the medulla oblongata. It is clear, therefore, that many of the longitudinal fibres which pass into the pons from above do not pass out from it below into the medulla oblongata. What becomes of these fibres that are thus absorbed in the pons? It is known that the pyramidal bundles suffer a small loss by the fibres which they send to the nuclei of origin of the efferent nerves which arise within the pons (viz., the motor root of the trigeminal, abducens, and facial nerve nuclei); but this loss is, comparatively speaking, trifling. It is clear, therefore, that other longitudinal bundles enter the pons from above apart from those which form the pyramidal tracts. These bundles occupy a lateral and dorsal position in the ventral part of the pons, and may be termed the **cerebro-pontine fibres**, seeing that they come from the cerebral cortex and end in fine ramifications around the cells of the nuclei pontis (Fig. 468).

The transverse fibres take origin as axons of the cells of the nuclei pontis. Crossing the median plane, they enter the brachium pontis of the opposite side, and thus reach the cerebellar cortex, where they end in ramifications round certain of the cortical cells.

Some authorities believe that there are also fibres passing in the opposite direction, *i.e.* from the cerebellum to the nuclei pontis; but there is some doubt concerning the existence of any such fibres. The brachium pontis thus may contain both efferent and afferent cerebellar fibres; but no fibres pass continuously through the pons from one brachium pontis into the other.

Certain of the transverse fibres of the pons turn backwards and enter the dorsal or tegmental part of the pons, but the precise connexions of these are doubtful.

Corpus Trapezoideum.—This name is applied to a group of transverse fibres which traverse the lower part of the pons (Fig. 468). They are quite distinct from those which have been just described as entering the brachium pontis, and they lie in the boundary between the dorsal and basilar parts of the pons, but encroaching considerably into the ground of the former. They arise from the cells of the terminal nucleus of the cochlear division of the acoustic nerve, and constitute a tract which establishes certain central connexions for that nerve. They will be more fully described when we treat of the cerebral connexions of the acoustic nerve.

Pars Dorsalis Pontis (Dorsal or Tegmental Part of the Pons).—On the dorsal surface of the tegmental part of the pons there is spread a thick layer of gray matter, covered with ependyma, which forms the floor of the upper or pontine part of the fourth ventricle. Beneath this the median raphe of the medulla oblongata is continued up into the pons, so as to divide its tegmental part into two symmetrical halves.

In the *inferior part of the pons*, immediately beyond the medulla oblongata, the restiform body is placed on the lateral side of the dorsal part (Fig. 468). In transverse sections through the pons it appears as a large, massive oval strand of fibres which inclines backwards into the cerebellum, and thus leaves the pons. Between the restiform body and the median raphe the tegmental part of the pons is composed of substantia reticularis, continuous with the same material in the medulla oblongata. Thus, arcuate or transverse fibres, curving in towards the raphe, and also longitudinal fibres, are seen breaking through a mass of gray matter which occupies the interstices of the intersecting fibres. To the naked eye the formatio reticularis presents a uniform gray appearance, but its constituent parts are revealed by low powers of the microscope in properly stained and prepared specimens. Embedded in this substantia reticularis are various clumps of compact gray matter and certain definite strands of fibres. These we shall describe as we pass from the restiform body medially towards the median raphe.

(1) **Spinal Root of the Trigeminal Nerve and its Nucleus.**—Close to the medial side of the restiform body, but separated from it by the vestibular root of the acoustic nerve as it proceeds backwards through the pons, is seen a large crescentic group of coarse transversely divided bundles of fibres. This is the tractus spinalis (O.T. spinal root) of the trigeminal nerve; and applied to its medial concave side is a small mass of gray matter, which is the direct continuation upwards of the substantia gelatinosa.

(2) The **nucleus of the facial nerve** comes next. It is sunk deeply in the dorsal part of the pons and lies close to the transverse fibres of the corpus trapezoideum. It is a conspicuous, obliquely placed, ovoid clump of gray matter. From its lateral and dorsal aspect the root-fibres of the facial nerve stream backwards and medially towards the gray matter on the floor of the fourth ventricle. Passing forwards between this nucleus and the trigeminal sensory nucleus a solid nerve-bundle may be observed. This is the facial nerve, traversing the pons towards its place of emergence from the brain.

(3) Immediately medial to the facial nucleus, but placed more deeply in the tegmental part of the pons, is the **superior olivary nucleus.** It lies in a bay formed for it by the transverse fibres of the corpus trapezoideum. These fibres curve round its ventral aspect, and many of them may be observed penetrating into its substance. In man, it is a very small mass of gray matter, and presents little resemblance to the inferior olivary nucleus, except in the size and shape of its constituent cells. In sections through the part of the pons where it attains its greatest size, it appears in the form of two, or it may be three, small isolated

masses of gray matter. It is intimately connected with the acoustic fibres, and establishes manifold connexions between them and the nuclei of other nerves.

Upon the medial and dorsal aspect of the superior olive there is a dense group of longitudinal fibres. These constitute the **fasciculus thalamo-olivaris** or **central tegmental tract**, to which we have already referred in discussing the inferior olivary nucleus (Fig. 468). It is uncertain whether this tract arises in the thalamus.

(4) The **medial longitudinal bundle** and the **lemniscus medialis** come next. As they proceed upwards through the tegmental part of the pons, these longitudinal tracts occupy the same relative position as in the medulla oblongata. They are placed close to the median raphe; but they have drawn further apart from each other, and their fibres are more distinctly concentrated into separate strands, with an interval of some little width between them, which is occupied by the **tecto-spinal**

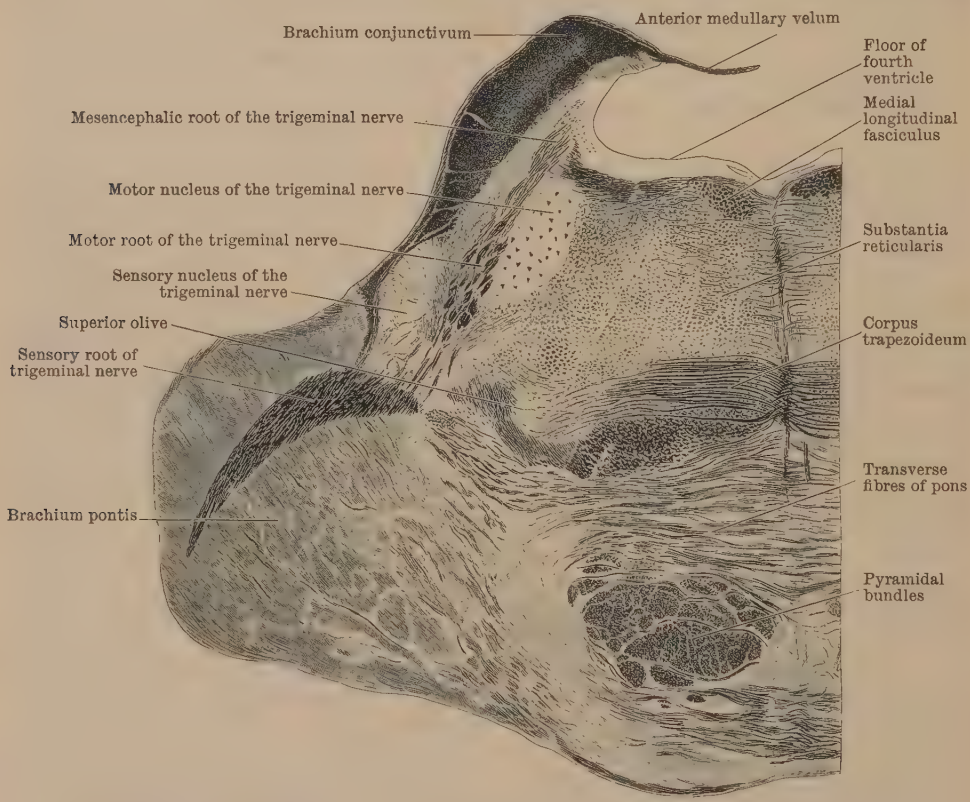

FIG. 470.—TRANSVERSE SECTION THROUGH THE PONS AT THE LEVEL OF THE NUCLEI OF THE TRIGEMINAL NERVE.

tract. The **medial longitudinal bundle** lies immediately under cover of the gray matter of the floor of the fourth ventricle. The **lemniscus medialis** is placed close to the trapezial fibres, many of which traverse it as they pass towards the median plane.

(5) The **nucleus of the abducens nerve** also forms a conspicuous object in sections through the lower part of the pons. It is a round mass of gray matter, which is situated close to the lateral side of the medial longitudinal bundle, and immediately under cover of the gray matter of the floor of the fourth ventricle. From its medial side numerous root-bundles of the abducens nerve pass out and proceed forwards between the lemniscus medialis and the superior olivary nucleus. They occupy in the pons, therefore, a position similar to that occupied by the hypoglossal root-fibres in the medulla oblongata.

Up to the present only the inferior part of the dorsal portion of the pons has been described, *i.e.* the portion immediately adjoining the medulla oblongata. As we proceed upwards and gain a point *above the level of the trapezial fibres*, many of the structures which have attracted attention lower down gradually

disappear from the formatio reticularis. The lemniscus medialis becomes markedly increased in size by the addition of the fibres of the spino-thalamic tract. Further, the floor of the fourth ventricle becomes narrower, and other objects appear in the tegmental substance.

The **brachium conjunctivum** (O.T. **superior cerebellar peduncle**) is a very conspicuous object in sections through the middle and upper parts of the pons. In transverse section it presents a semilunar outline, and as it emerges from the cerebellum it lies immediately on the lateral side of the fourth ventricle, towards which its concave aspect is turned (Fig. 470). Its dorsal border is joined with the corresponding brachium of the opposite side by the thin lamina of white matter, termed the *anterior medullary velum*, whilst its ventral border is sunk to a small extent in the dorsal part of the pons. As it is traced upwards it sinks deeper and deeper into the pons until it becomes completely submerged, with the exception of the dorsal border to which the anterior medullary velum is attached. It now lies on the lateral side of the tegmental or reticular substance of the pons, and this position it maintains until the mesencephalon is reached (Fig. 471).

About *half-way up the pons* the nuclei of the trigeminal nerve mark a very

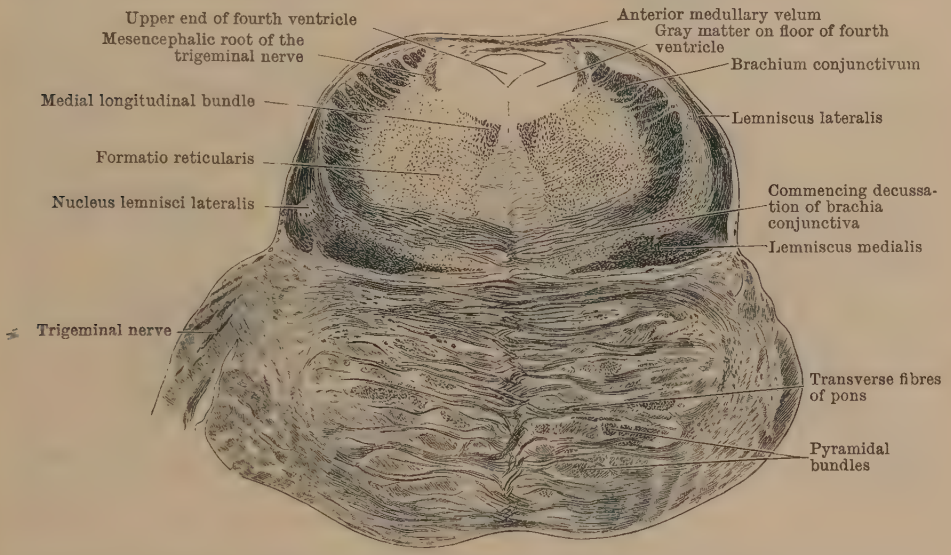

Fig. 471.—Section through the Superior Part of the Pons, above the Level of the Trigeminal Nuclei.

important stage in its tegmental portion. These nuclei are two in number on each side, viz., a large oval terminal nucleus for certain of the sensory fibres of the nerve and a nucleus of origin, equally conspicuous, for certain of the motor fibres (Fig. 470). The **sensory nucleus** lies close to the lateral surface of the pons, deeply sunk in its tegmental part, and in the interval between the submerged anterior border of the brachium conjunctivum and the ventral part of the pons. The **motor nucleus** is placed on the medial side of the sensory nucleus, but somewhat nearer the dorsal surface of the pons. At this level the tractus spinalis of the trigeminal nerve begins by the bending downwards of the fibres of the sensory portion. The sensory and motor roots of the fifth nerve traverse the ventral part of the pons on their way to and from the region of the nuclei.

Above the level of the nuclei of the trigeminal nerve a new tract of fibres comes into view. This is the **mesencephalic root** of the trigeminal nerve, as it descends towards the rest of the nerve. It is a small bundle of nerve-fibres, semilunar in cross section, which lies close to the medial side of the brachium conjunctivum and on the lateral and deep aspect of the gray matter on the floor of the fourth ventricle (Figs. 470 and 471).

On a slightly deeper plane than the mesencephalic root of the fifth nerve, between it and the medial longitudinal bundle, and in close relation to the gray

matter of the floor of the ventricle, is the collection of pigmented cells which constitutes the **substantia ferruginea.**

The **medial longitudinal bundle,** as it is traced upwards through the tegmental part of the pons, maintains the same position throughout, and as it ascends it becomes more clearly mapped out as a definite and distinct tract. It lies close to the median raphe, and immediately subjacent to the gray matter of the floor of the fourth ventricle.

The **lemniscus medialis,** as it ascends through the tegmental part of the pons, undergoes striking changes in shape. In the lower portion of the pons its fibres, which in the medulla oblongata are spread out along the side of the median raphe, are collected together in the form of a loose bundle, which occupies a wide field, somewhat triangular in shape, on either side of the median raphe and immediately behind the basilar portion of the pons. As it proceeds up, the fibres spread out laterally until a compact ribbon-like layer is formed in the interval between the tegmental and basilar portions of the pons (Figs. 471 and 472).

Above the level of the trigeminal nuclei another flattened layer of fibres comes

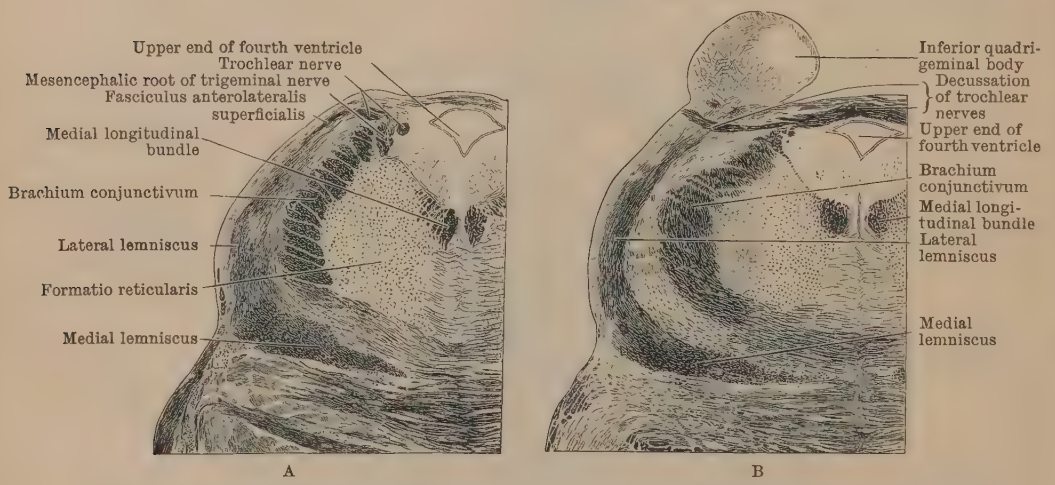

Fig. 472.—Two Sections through the Dorsal Portion of the Pons at its Superior Part, close to the Mesencephalon.

A is at a slightly lower level than B.

into view to the lateral side of the lemniscus medialis. To this the name of **lemniscus lateralis** is given. These fibres spread laterally and backwards, and finally take up a position on the lateral surface of the brachium conjunctivum. In the angle between the medial and lateral lemnisci a little knot of compact gray matter, termed the **nucleus lemnisci lateralis,** comes into view (Fig. 471). This appears to be in more or less direct continuity with the superior olivary nucleus. Many of the fibres of the lemniscus lateralis take origin in this nucleus. Bruce called attention to the continuity between the superior olive and the nucleus of the lateral lemniscus in man, and Cunningham confirmed the observation in so far as the orang brain is concerned. In many other mammals the nuclei are quite distinct.

THE CEREBELLUM.

In the foregoing account it has been seen that the cerebellum is formed from two distinct rudiments, each derived from the posterior edge of the alar lamina immediately above the pontine flexure and the insertion of the vestibular nerve. As development proceeds during the second month there is a rapid proliferation of cells in the mantle layer of the cerebellar rudiments, and they become considerably thickened. But at first this thickening manifests itself not so much as a swelling of the superficial aspect of the cerebellum but as a bulging inwards into the cavity of the fourth ventricle (Fig. 473).

The accentuation of the pontine flexure at this stage brings the two cerebellar rudiments into the transverse direction and in line one with the other and with the roof-plate, which is now being thickened by immigrant neuroblasts from the medial extremities of the two cerebellar rudiments. When one organ is thus formed by the union in the roof-plate of the originally separate rudiments, it presents the form of a dumb-bell shaped mass (Fig. 473). Upon the inferior aspect of this mass there is a slight ridge, to which the **tela chorioidea ventriculi quarti** is attached. Opposite the lateral cerebellar rudiments (but not in the median plane) the attachment of the tela becomes thickened to form the posterior medullary velum.

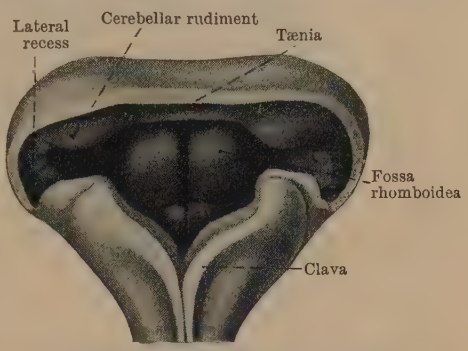

FIG. 473.—DORSAL ASPECT OF THE RHOMBENCEPHALON IN A HUMAN EMBRYO.

Early in the third month the growth of the cerebellar rudiment begins to manifest itself by lateral bulgings of its surface.

The rhombic lip, the inferior part of which has been seen to play an important part in the development of the nuclei pontis and nucleus olivaris inferior, is also continued upwards beyond the pontine flexure on to the cerebellar rudiment, where it forms a marginal fringe. Thus, even in the second month, a groove can be detected upon the cerebellum separating off a band which is continuous with the tuberculum acusticum. The part nearest to the tuberculum represents the rudiment of the **flocculus** and the medial extremity the **nodulus** (Fig. 473). During the third month the cerebellum appears as a bar transversely placed across the upper part of the roof of the fourth ventricle, and as the lateral extremities of this bar expand (Fig. 474), it assumes a dumb-bell shape not unlike that presented a few weeks earlier (Fig. 473) on its ventricular aspect. As these lateral bosses (**hemispheres**) develop, a mass of transverse fibres in connexion with them also becomes apparent. It represents the fibræ transversæ of the pons. They arise from the cells (nuclei pontis) which have wandered into the basal lamina of the metencephalon from the rhombic lip of the myelencephalon (Fig. 469); and the fibres which enter each cerebellar hemisphere come mainly from the nuclei pontis of the other side. Towards the end of the fourth month, or even a month earlier in some cases, a little bud grows out from the cerebellum on each side immediately above the flocculus. It is the **parafloccculus** or **flocculus secundarius**. In man it never attains a large size, but in most mammals it develops into a large lobe, even as big as one-third the size of a cerebellar hemisphere (in the manatee), and in many animals a deep fossa is formed in the temporal bone to lodge this part of the cerebellum.

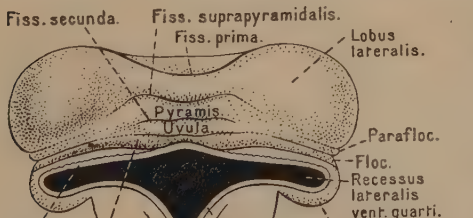

FIG. 474.—THE POSTERIOR ASPECT OF A FŒTAL (FOURTH MONTH) CEREBELLUM, MEDULLA OBLONGATA AND FOSSA RHOMBOIDEA.

The label *Lobus lateralis* refers to the hemisphere.

The evidence of comparative anatomy seems to suggest that the reduction of the parafloccculus in man and the apes is associated with the adoption of the erect attitude (or in the apes the maintenance of equilibrium by the use of the arms). The enormous development of the parafloccculus in all marine mammals is due to the fact that it co-ordinates those muscular movements that maintain equilibrium by controlling the tendency to roll in the lateral direction, that is, around the long axis of the body. The mode of progression in the apes and man restricts this tendency and correspondingly minimises the need for a parafloccculus.

As the cerebellum grows the lateral hemispheres expand much more rapidly

than the median part—the handle of the dumb-bell. But the superficial area of the latter becomes increased by means of transverse folds which begin to make their appearance at the close of the third month. Earlier in that month the median part of the cerebellum presents in sagittal section almost a semicircular outline (Fig. 477, A) with a slight notch near its inferior margin (**fissura postnodularis**) demarcating the **nodulus**. As development proceeds during the third month the nodular region becomes bent forwards upon the rest of the cerebellum (Fig. 477, B), thus starting the posterior diverticulum of the fourth ventricle, which ultimately assumes a tent-like outline (Fig. 451).

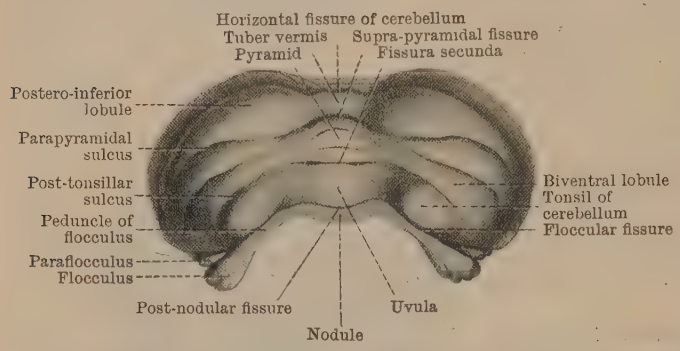

FIG. 475.—INFERIOR SURFACE OF THE CEREBELLUM OF A HUMAN FŒTUS WHICH HAS REACHED THE END OF THE FIFTH MONTH OF DEVELOPMENT.

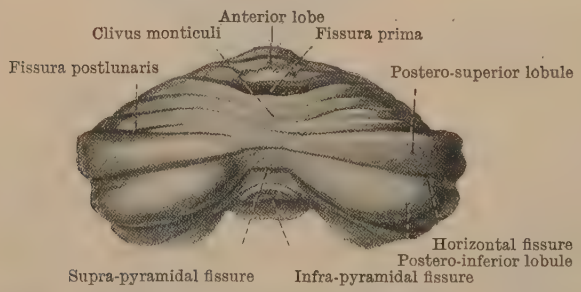

FIG. 476.—CEREBELLUM OF A HUMAN FŒTUS WHICH HAS REACHED THE END OF THE FIFTH MONTH OF DEVELOPMENT. Viewed from above and behind.

At the close of the third month the irregular growth of the surface of the median area of the cerebellum, which from its worm-like appearance in the adult (Fig. 480) is

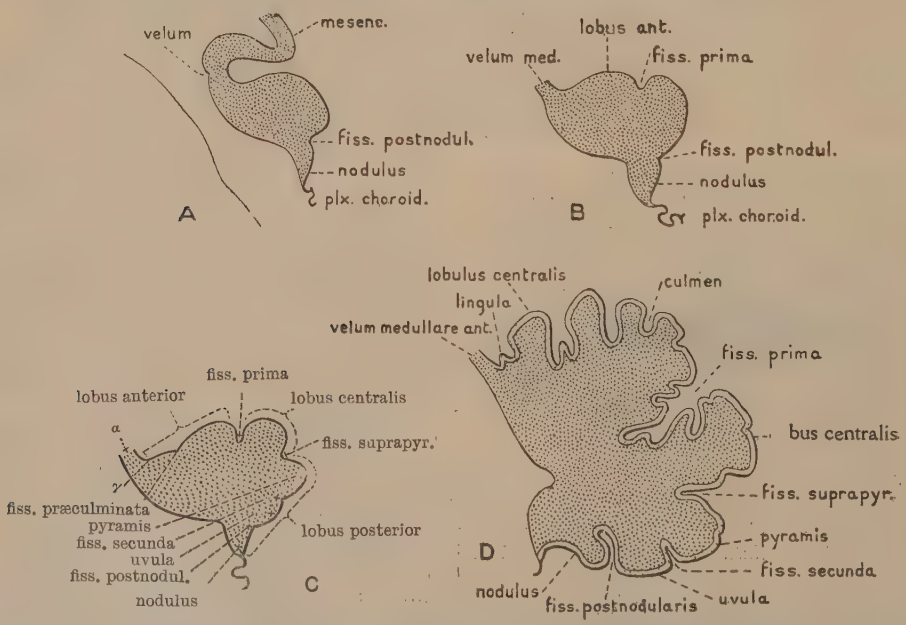

FIG. 477.—MEDIAN SAGITTAL SECTIONS OF FŒTAL CEREBELLA IN FOUR STAGES OF DEVELOPMENT. A and B, third month; C, fourth month; D, fifth month.

called the **vermis**, leads to the appearance of a transverse depression upon the superior surface. This is the **fissura prima** (Fig. 477, B, C, and D), which

becomes the deepest and most complex of all the multitude of fissures that ultimately cut into the cerebellum (Fig. 477). It cuts off a lozenge-shaped area of the front of the cerebellum that is called the **anterior lobe** (Fig. 478), which is believed to be concerned with the co-ordination of those movements that help to maintain equilibrium by preventing the body from falling forward. Soon afterwards two other fissures make their appearance further back, one that is phylogenetically old, the **fissura secunda**, appearing to delimit the uvula (Fig. 477, C and D) posteriorly, and another, which is very precocious in the human fœtus, the **fissura suprapyramidalis** (which might be called **tertia**), intermediate between the first and second fissures.

Other transverse fissures appear in rapid succession until the vermis becomes cut up into a series of folds to which the labels indicated in Fig. 477 D, used to be applied, but there is now no reason for retaining such terms as lobulus centralis, culmen, or declive. It is still useful to retain the terms **pyramid, uvula,** and **nodule.**

The posterior lobe is made up of the three lobules called pyramid, uvula, and nodule respectively (Fig. 477, D), and is supposed to be concerned with the co-ordination of the movements to prevent the body falling backward. Morphologically the pyramid should not be included in the posterior lobe, because the facts of comparative anatomy suggest that it is merely an outgrowth of the central lobe in front of it. But in the human brain it seems to be more intimately related to the uvula and to be precociously cut off (by the suprapyramidal fissure, Fig. 477) from the central lobe. The lateral connexions of the pyramid and the uvula with the parts of the hemispheres labelled (in Fig. 475) biventral lobule and tonsil respectively are quite fortuitous and devoid of any morphological or functional significance. The narrow bridge of vermis labelled central lobe in Fig. 477, D, when traced laterally, expands into an enormous mass forming the greater part of the cerebellar hemisphere. It can be divided into three natural subdivisions, an anterior crescentic strip called the **lobulus lunatus** (Fig. 478), a great feather-like mass forming the major part of the hemispheres that has been called **lobulus ansiformis** by Bolk, and the **tonsil**, a curious appendage packed on the under surface of the cerebellum (Fig. 481) between the pyramid and uvula on its medial side and the ansiform lobule ("biventral") on its lateral side. The tonsil corresponds to the part of the cerebellum of other mammals to which Bolk has given the name **paramedian lobule.** The enormous expansion of the ansiform lobule is the outstanding distinctive feature of the human cerebellum, and is believed to be due to the need for a very much more complex co-ordination of the muscles of the limbs, and more particularly of the arms and hands, not merely for purposes of equilibration but also for the performance of skilled movements.

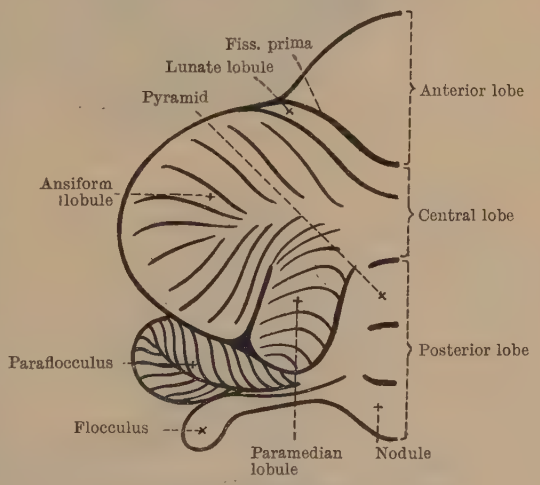

FIG. 478.—DIAGRAM OF LOBULATION OF LEFT HALF OF MAMMALIAN CEREBELLUM.

Only some of the fissures of the vermis become prolonged laterally beyond the limits of the vermis, but as the boss-like lateral lobes begin to expand, their surface becomes folded and a series of independent lateral fissures are formed. [*The anterior lobe, however, is prolonged laterally upon each side into tapering wings and all the fissures in them are merely prolongations of the fissures of the vermis.*]

After the limiting fissures of the flocculus and parafloccul, the first independent fissure to make its appearance is one which develops behind and almost parallel to the lateral prolongations of the fissura prima. The intervening strip of cerebellum

is the **lobulus lunatus** and its posterior boundary, the **fissura postlunaris**. These postlunar fissures begin far out on the lateral swelling in the fourth month and gradually approach the median plane, where they may meet and become confluent on the vermis.

At the end of the fourth or beginning of the fifth month an oval swelling makes its appearance alongside the uvula upon the inferior surface of each lateral lobe (Fig. 475). This is called the **tonsilla cerebelli** or **tonsil**, and the fissure which develops behind it and delimits it is called **post-tonsillar**. As a rule the two post-tonsillar fissures become confluent with the **fissura secunda** upon the vermis, and the whole furrow in the adult may be called **fissura secunda**. The fissure to which most importance is usually attached develops quite late in the human cerebellum, and not at all in that of the great majority of other animals. It is called the **fissura horizontalis cerebelli**. In the adult it begins upon the front, where the brachium pontis plunges into the cerebellum, and the furrow is formed in a more or less mechanical way by the bulging forwards (above and below the cerebellar peduncles) of the exuberant mass of the cerebellar hemispheres. The actual infolding is preceded by the appearance of several irregular depressions (Fig. 479) in the place where the horizontal fissure will develop. This fissure begins in front and passes continuously round the circumference of the organ, cutting deeply into its lateral and posterior margins. In front, its lips diverge to admit the three cerebellar peduncles as they pass into the interior of the cerebellum.

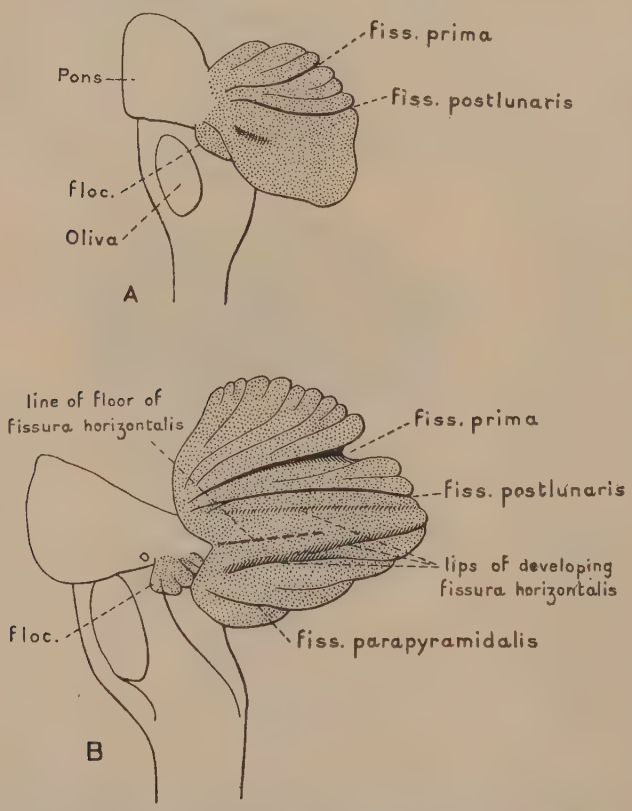

FIG. 479.—THE LEFT LATERAL ASPECT OF THE FŒTAL RHOMBENCEPHALON AT THE FOURTH (A) AND FIFTH (B) MONTHS.

The cerebellum is stippled.

In some cases it meets the corresponding fissure of the other side upon the vermis, but very often such a confluence does not occur.

It used to be the custom to subdivide the cerebellum somewhat arbitrarily into a median portion termed the **vermis**, and two much larger lateral portions called the **hemispheres**. The demarcation between these main subdivisions of the organ is not very evident from every point of view. In front, and also behind, there is a marked deficiency or notch. The **incisura cerebelli posterior** (O.T. **marsupial notch**) is smaller and narrower than the anterior notch. It is bounded at the sides by the hemispheres, whilst its bottom is formed by the axial lobe or vermis. It is occupied by a fold of dura mater called the falx cerebelli. The **incisura cerebelli anterior** (O.T. **semilunar notch**) is wide, and, when viewed from above, it is seen to be occupied by the inferior quadrigeminal bodies and by the brachia conjunctiva. As in the case of the posterior notch, its sides are formed by the hemispheres, and the bottom by the vermis.

On the superior surface of the cerebellum the vermis is not marked off from the hemispheres. It forms a high median elevation, from which the surface slopes gradually downwards on each side to the margin of the hemisphere. The vermis is highest in front, immediately behind the anterior notch, and from this it shows a somewhat sharp descent towards the posterior notch.

On the inferior surface of the cerebellum the distinction between the three main

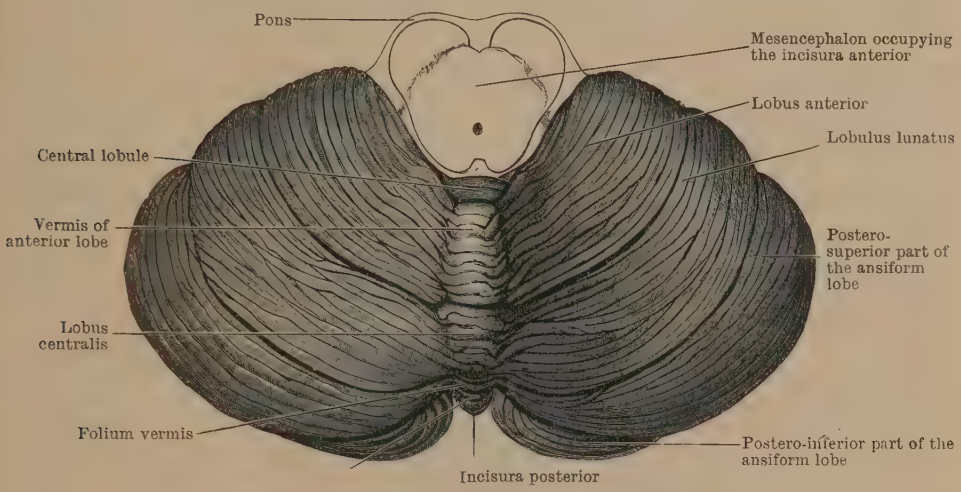

FIG. 480.—SUPERIOR SURFACE OF THE CEREBELLUM.

constituent parts of the organ is much better marked (Fig. 481). On this aspect the hemispheres are full, prominent, and convex, and occupy the cerebellar fossæ in the floor of the cranium. They are separated by a deep median hollow, which is continued forwards from the posterior notch. This hollow is termed the **vallecula cerebelli**, and in its anterior part the medulla oblongata is lodged. When

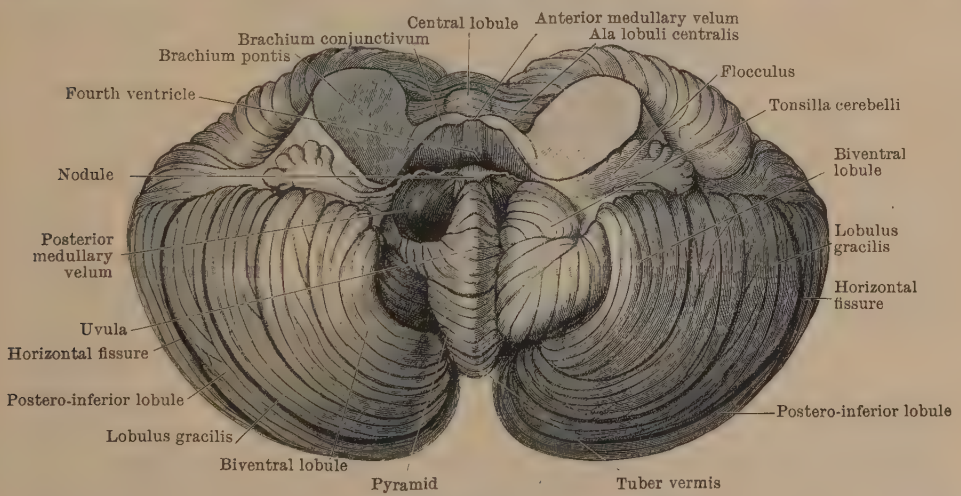

FIG. 481.—INFERIOR SURFACE OF THE CEREBELLUM.

The right tonsil has been removed so as to display more fully the posterior medullary velum and the furrowed band. The structures labelled "biventral lobule," "lobulus gracilis," and "postero-inferior lobule" are all parts of the lobulus ansiformis, the greatly expanded lateral part of the central lobe.

the medulla oblongata is raised and the hemispheres are pulled apart, so as to expose the bottom of the vallecula, it will be seen that this is formed by the **vermis**, which is separated on each side from the corresponding hemisphere by a distinct furrow, termed the **sulcus valleculæ**.

The nodule and the flocculus of each side are linked by a delicate connecting lamina which is formed by the **posterior medullary velum**.

The Structure and Connexions of the Cerebellum.

Arrangement of the Gray and White Matter of the Cerebellum.—The white matter of the cerebellum forms a solid compact mass in the interior, and over this is spread a continuous and uniform layer of gray matter. In each hemisphere the white central core is more bulky than in the vermis, in which the central white matter is reduced to a relatively thin bridge thrown across between the two hemispheres. When sagittal sections are made through the cerebellum, the gray matter on the surface stands out clearly from the white matter in the interior. Further, from all parts of the surface of the central core stout stems of white matter are seen projecting into the lobes of the cerebellum. From the sides of these white stems secondary branches proceed at various angles, and from these again tertiary branches are given off. Over the various lamellæ of white matter thus formed the gray cortex is spread, and the fissures on the surface show a corresponding arrangement, dividing up the organ into lobes, lobules, and folia. When the cerebellum is divided at right angles to the general direction of its fissures and folia, a highly arborescent appearance is thus presented by the cut surface. To this the term **arbor vitæ** is applied.

Nucleus Dentatus and other Gray Nuclei in the White Matter of the Cerebellum.—Embedded in the midst of the mass of white matter which forms the central core of each hemisphere there is an isolated nucleus of gray matter, which presents a strong resemblance to the inferior olivary nucleus of the medulla. It is called the **nucleus dentatus**, and it consists of a corrugated or plicated lamina of gray matter, which is folded on itself so as to enclose, in a flask-like manner, a portion of the central white matter (Figs. 482 and 483). This gray capsule is not completely closed. It presents an open mouth, termed the hilum, which is directed medially and upwards, and out of this stream the fibres of the brachium conjunctivum.

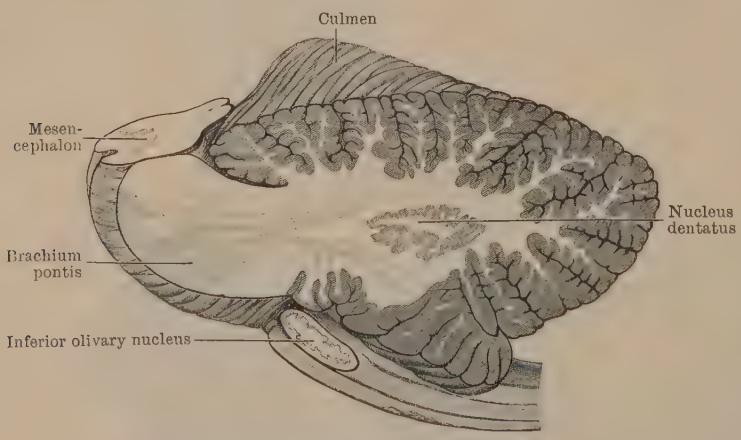

Fig. 482.—Sagittal Section through the Left Hemisphere of the Cerebellum.

Showing the "arbor vitæ" and the nucleus dentatus.

Three small additional masses of gray matter are also present on each side of the median plane in the central white matter of the cerebellum. These are termed the nucleus emboliformis, the nucleus globosus, and the nucleus fastigii. The **nucleus emboliformis** or **embolus** is a small lamina of gray matter which lies just medial to the hilum of the nucleus dentatus, being thus related to it somewhat in the same manner that the medial accessory olivary nucleus is related to the main inferior olivary nucleus. The **nucleus globosus** lies medial to the nucleus emboliformis and on a somewhat deeper horizontal plane. The **nucleus fastigii** or **roof nucleus** is placed in the white substance of the vermis close to the median plane and its fellow of the opposite side. It is, therefore, situated on the medial aspect of the nucleus globosus.

The nucleus dentatus and the emboliform nucleus present a structure very similar to that of the inferior olivary nucleus. In the nucleus globosus and the nucleus fastigii the cells are somewhat larger in size.

Cerebellar Peduncles.—These are three in number on each side, viz., the middle, the inferior, and the superior (Fig. 456, p. 551). The fibres of which they are composed all enter or emerge from the white medullary centre of the cerebellum.

The **middle peduncle** or **brachium pontis** is much the largest of the three,

and has already been described on pp. 456 and 551. It is formed by the transverse fibres of the pons, and it enters the cerebellar hemisphere on the lateral aspect of the other two peduncles. The lips of the anterior part of the horizontal fissure are separated widely from each other to give it admission (Fig. 456). Within the cerebellar hemisphere its fibres are distributed in two great bundles. Of these, one, composed of the superior transverse fibres of the pons, radiates out in the inferior part of the hemisphere; whilst the other, consisting of the inferior transverse fibres of the pons, spreads out in the superior part of the hemisphere.

The **inferior peduncle** is simply the **restiform body** of the medulla oblongata. After leaving the medulla oblongata it ascends for a short distance on the dorsal surface of the pons and then turns sharply backwards, to enter the cerebellum between the other two peduncles.

The **superior peduncle** or **brachium conjunctivum**, as it issues from the cerebellum,

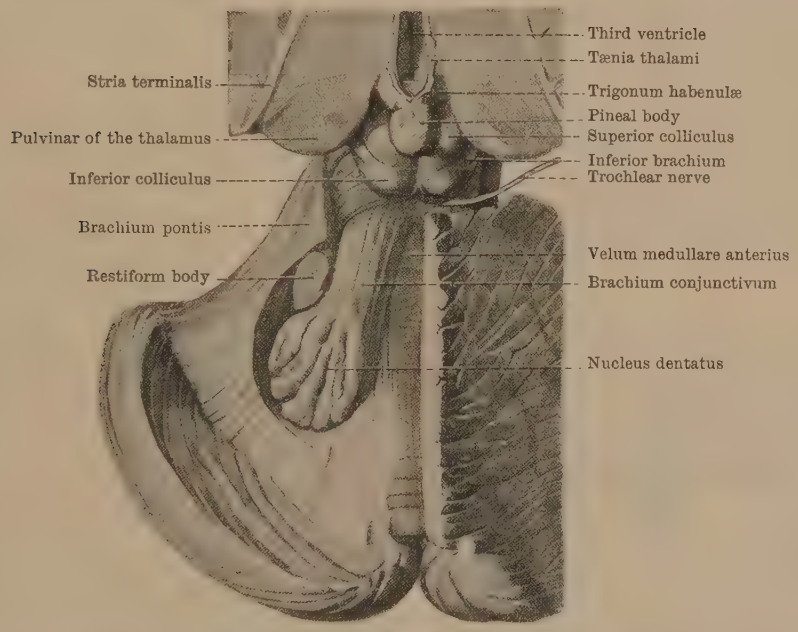

FIG. 483.—From a dissection by Dr. Edward B. Jamieson in the Anatomical Department of the University of Edinburgh. The nucleus dentatus is displayed from above and the brachium conjunctivum has been traced from it to the mesencephalon.

lies close to the medial side of the middle peduncle (Fig. 456). Its further course upwards on the dorsum of the pons to the inferior quadrigeminal body has been previously described (pp. 549 and 550).

Connexions established by the Peduncular Fibres.—The fibres of the **brachium pontis** represent the second stage of the connexion between the cerebral hemisphere of one side and the opposite cerebellar hemisphere. The connexions which they establish in the pons are described on p. 566.

The **restiform body** is also composed of afferent fibres (see p. 548); only the more important connexions which these establish in the cerebellum can be touched on here. The principal afferent strand is the *fasciculus spinocerebellaris* [posterior]. The fibres of this strand end in the cortex of the *superior* vermis on both sides of the median plane, but chiefly on the opposite side. The olivo-cerebellar tract (*fasciculus olivocerebellaris*) are also afferent. It appears that they end in connexion with cells in the cortex of both the vermis and hemisphere, and also with cells in the nucleus dentatus. The numerous *external arcuate fibres* which enter the restiform body establish connexions with cells in the cortex of the hemisphere and of the vermis.

The **brachium conjunctivum** is an efferent tract: its fibres come from the cells of the nucleus dentatus, and pass to the red nucleus and thalamus of the opposite side.

According to Ramon y Cajal collateral branches springing from these fibres descend to the motor nuclei in the medulla oblongata and spinal medulla.

There is, however, a bundle of fibres passing *downwards* alongside the brachium conjunctivum from the tegmentum of the mesencephalon and possibly from the thalamus: these fibres cross in the mid-brain and pass inferiorly to the cerebellum, in contact with the lateral margin of (or intermingled with) the fibres of the brachium. They probably convey to the cerebellum fibres from the visual centres of the opposite side.

The **fasciculus anterolateralis superficialis** of the spinal medulla (O.T. Gowers' tract), for which the better name **fasciculus spinocerebellaris anterior** is now in common use, also enters the cerebellum alongside the emerging brachium conjunctivum. It has been noticed in connexion with the lateral funiculus of the spinal medulla (p. 537). The fibres which compose it are carried upwards through the formatio reticularis grisea of the medulla oblongata and the corresponding part of the tegmental portion of the pons. In this part of its course the fibres are scattered and do not form a compact strand. Reaching the superior end of the pons the tract turns backwards across the brachium conjunctivum, enters the anterior medullary velum, and proceeds downwards in it into the cerebellum.

Roof of the Fourth Ventricle.—In its superior part the roof of the fourth ventricle is formed by the anterior medullary velum as it stretches across between the two brachia conjunctiva, and also, to some extent, by these brachia themselves as they approach the mesencephalon.

In its inferior part the roof of the ventricle is exceedingly thin and is not all formed of nervous matter. The posterior medullary velum is a mere ridge which can hardly be said to enter into its formation: the epithelial lining of the cavity, supported by pia mater, is carried downwards towards the inferior boundaries of the floor of the ventricle. At the lowest part of the calamus scriptorius, and also along each lateral boundary of the floor, the epithelial roof becomes thickened at its attachment to the parts of the medulla oblongata. The small semilunar lamina which stretches across between the inferior parts of the two clavæ at the calamus scriptorius and overhangs the opening of the central canal is termed the **obex** (Fig. 456, p. 551). A downwardly directed protrusion of the epithelial roof is often found behind the obex.

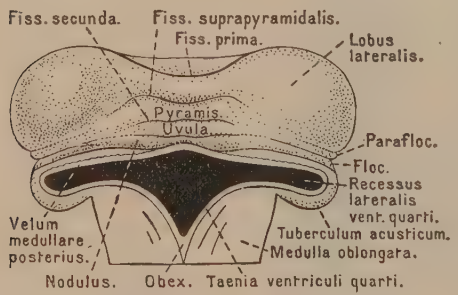

FIG. 484.—THE POSTERIOR ASPECT OF A FŒTAL CEREBELLUM AND MEDULLA OBLONGATA.

THE HISTOGENESIS AND MINUTE STRUCTURE OF THE CEREBELLUM.

The developmental history of the cerebellum presents certain peculiar features which seem quite enigmatic unless considered from the point of view of the evolution of the connexions and functions of the organ. The cerebellum is derived from part of the alar lamina of the rhombencephalon, and at an early stage of its development the rudiment shows the regular lamination into ependyma, mantle layer, and marginal layer, which has already been described as distinctive of the corresponding place of development in the whole nervous system. The cells of this mantle layer are to be looked upon as an outlying (superior) part of the receptive nucleus of the vestibular nerve, the cells to which information concerning the position and movements of the body as a whole or of the head will be transmitted from the semicircular ducts of the internal ear. But, if such information is to be put to any use in influencing behaviour, it is obvious that the activity of these cerebellar cells must, firstly, be correlated with visual impressions, which also supply information concerning the position and movements of the body, and with all those nerves which are bringing into the encephalon or spinal medulla impressions of touch, pressure, or any other information concerning the state of the muscles, tendons, joints, or other structures which are concerned in movements; and, secondly, they must be brought to bear upon the various motor nuclei and other motor regulating parts of the brain (such as the red nucleus, tectum, mesencephali, basal ganglia, and cerebral cortex) to which the co-ordinating influence of the cerebellum is essential for the properly adjusted performance of complex actions.

The neuroblasts which receive all these extrinsic sensory impulses, visual, tactile, musculo-

sensory, et cetera, collect at the threshold of what was originally the vestibular cerebellar rudiment; and they can be seen during the latter part of the second month migrating from the rhombic lip into the marginal layer of the cerebellum, until eventually its whole surface has been invaded by these alien neuroblasts, so that the originally non-nucleated marginal layer becomes a densely packed granular layer (**stratum marginale embryonale**). When this stage is reached the cerebellum consists of an inner ependymal layer, a mantle layer crowded with locally developed neuroblasts, a clear layer (the inner part of the original marginal layer), and the superficial layer of neuroblasts which have invaded the outer part of the marginal layer. As development proceeds in the mantle layer the axons of its neuroblasts are directed mainly towards the ventricular surface—the reverse of what happens in the spinal medulla; and as these fibre-masses increase in quantity the main part of the mantle layer becomes pushed farther and farther away from the ependyma by the accumulation of their own (and other) axons. Some of the neuroblasts, however, do not become pushed out into the line of the embryonic cerebellar cortex, but remain behind amidst the fibre-mass and receive the axons that come from the cortical cells. These neuroblasts left amidst the fibres gradually assume the form of the dentate, fastigial, globose, and emboliform nuclei already described; and their axons pass out (as the brachia conjunctiva) to the thalamus, mesencephalon, and pons. In the meantime many of the neuroblasts of the mantle layer have been converted into the large pear-shaped **Purkinje-cells**.

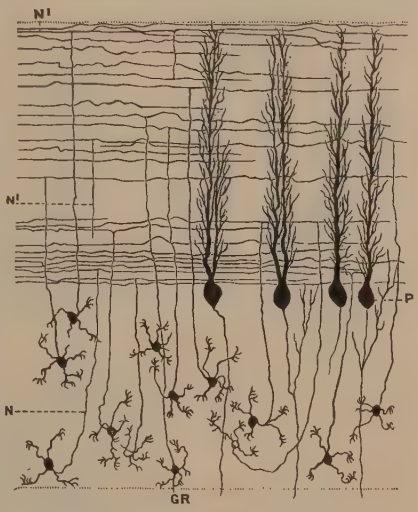

FIG. 485.—SECTION THROUGH THE MOLECULAR AND GRANULAR LAYERS IN THE LONG AXIS OF A CEREBELLAR FOLIUM. (After Kölliker.)

Treated by the Golgi method.

P. Cell of Purkinje.
GR. Granule cells.
N. Axon of a granule cell.
N¹. Axons of granule cells in molecular layer.

While these events have been occurring in the true mantle layer a peculiar process has been taking place in the superficial layer of immigrant cells. One by one they begin to leave their places upon the surface and dip into the mantle layer; many of them pass between the Purkinje-cells to a deeper plane, where they cease their wanderings and form a densely packed layer of granule cells (Fig. 485), the axons of which indicate the course of these migrations.

MINUTE STRUCTURE OF A CEREBELLAR FOLIUM.

A cerebellar folium is composed of a central core of white matter, covered with a layer of gray matter. The gray cortex is arranged in two very evident layers, viz., a superficial **molecular layer** and a subjacent rust-coloured **granular layer**. Between these strata a single layer of large cells, termed the **cells of Purkinje**, is disposed in the form of a very nearly continuous sheet. The cells of Purkinje constitute the most characteristic, and probably the most essential, constituents of the cerebellar cortex.

The **cells of Purkinje** are most numerous on the summit of the folium. At the bottom of the sulci which intervene between the folia they become fewer in number, and, therefore, looser in their arrangement. Each consists of a large flask-shaped or piriform cell body, the narrow end of which projects into the molecular layer, whilst the thicker, deeper end rests on the granular layer. From the latter arises a **single axon**, which passes into the granular layer and presents the peculiarity of almost immediately assuming its medullary sheath. From this axon a few collateral branches soon arise, which, taking a recurrent course, enter the molecular layer, to end in connexion with certain of the adjoining cells of Purkinje. They would seem to have the function of binding together adjacent cells, and thus enabling them to carry on their operations in harmony with each other.

The **dendritic processes** spring from the narrow end of the cell in the form of either one or perhaps two stout stalks. These ascend into the molecular layer, branching and rebranching until an arborescent arrangement of extraordinary richness and extent results. The dendritic branches extend throughout the entire thickness of the molecular layer, and the branching takes place in one plane only, viz., in a plane which is transverse to the long axis of the folium. Consequently, it is only when transverse sections through a folium are made that the full dendritic effect is obtained (Fig. 486); in sections made parallel to the long axis of the folium the cells are seen in profile, and are observed to occupy quite a narrow area (Fig. 485). The branching of the dendrites of a cell of Purkinje may, therefore, be compared to that which takes place in the case of a fruit-tree which is trained against a wall.

In the **molecular layer** the cells are not very numerous, and of these the most characteristic are the **basket-cells** which lie in the deeper part of the layer. In addition to numerous dendrites the basket-cell gives off an axon which runs transversely, as regards the long axis of the folium, between the planes of adjacent dendritic arborisations of the cells of Purkinje. At first very fine, these axons gradually become coarse and thick, and at intervals they give off collaterals which

run towards the bodies of the cells of Purkinje. Reaching these, they break up into an enormous number of fine terminal branches, which enclose the cells of Purkinje, as well as the short non-medullated portions of their axons, in a close basket-work of fine filaments.

M¹. Basket-cells.
ZK. Basket-work around the cells of Purkinje.
GL. Neuroglial cell.
N. Axon of an association cell.

The **granular layer** is, for the most part, composed of large numbers of small granule-like bodies closely packed together. Each of these possesses a somewhat large nucleus, with a very small amount of surrounding protoplasm. From the cell body three or four, or perhaps five, dendrites and one axon proceed. The **dendrites** are short and radiate out from different aspects of the cell body. They end in tufts of claw-like twigs, which either embrace or are otherwise in contact with neighbouring granule cells. The whole multitude of granule cells, therefore, are brought into intimate connexion with each other. The **axon** passes into the molecular layer, in which it ends, at a varying distance from the surface, by dividing into two branches. These diverge so sharply from each other that they form almost a right angle with the parent stem, and they run parallel to the long axis of the folium, threading their way among the branches of the various dendritic planes of the cells of Purkinje and entering into contact association with them. When it is borne in mind that the number of granule cells is very great, and that each sends an axon into the molecular layer, the important part which these fibres, with their longitudinal branches, take in building up the molecular layer will be understood. They are found pervading its entire thickness—from the surface down to the bodies of the cells of Purkinje.

THE MESENCEPHALON.

The **mesencephalon** or **mid-brain** is the short, narrow part of the brain-stem which occupies the aperture of the tentorium cerebelli (incisura tentorii), and connects the cerebrum, which lies above, with the parts which occupy the posterior cranial fossa. It is about three-quarters of an inch in length, and it consists of a dorsal part, composed of the **corpora quadrigemina**, and a much larger ventral part, which is formed by the two **pedunculi cerebri**.

The pedunculi cerebri can be seen to some extent on the base of the brain, where they bound the posterior part of the interpeduncular fossa. Encircling the upper end of each cerebral peduncle, where it emerges from the cerebrum, is the optic tract (Fig. 497, p. 592).

The mesencephalon is tunnelled from below upwards by a narrow passage, called the **aquæductus cerebri**, which connects the fourth ventricle with the third ventricle (Fig. 451, p. 543). This channel lies much nearer the dorsal aspect than the ventral aspect of the mesencephalon.

Corpora Quadrigemina.—This name is applied to four rounded eminences or

colliculi on the dorsal aspect of the mesencephalon (Figs. 451 and 487). The **superior pair** are larger and broader than the **inferior pair**, but they are not so well defined nor are they so prominent. A longitudinal and a transverse groove separate the colliculi from each other. The longitudinal groove occupies the median plane and extends upwards to the posterior commissure of the brain. The superior end of this groove widens out into a shallow depression, in which the **pineal body**, a small conical structure which belongs to the diencephalon, rests. From the lower end of the same groove a short but well-defined and projecting band, the **frenulum veli**, passes to the anterior medullary velum, which lies immediately below the inferior colliculi. The transverse groove curves round below each of the superior pair of colliculi and separates them from the inferior pair. It is also continued in an upward and ventral direction on the lateral aspect of the mesencephalon.

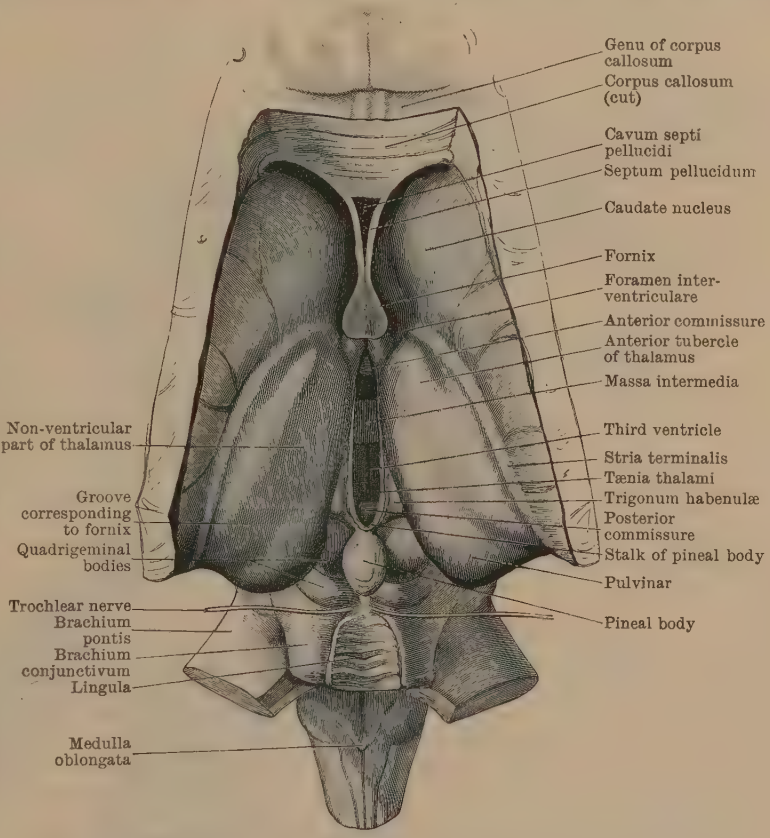

FIG. 487.—THE CORPORA QUADRIGEMINA AND THE NEIGHBOURING PARTS.

The quadrigeminal bodies are not marked off laterally from the sides of the mesencephalon, but each has in connexion with it, on this aspect, a prominent strand, which is prolonged superiorly and ventrally towards the thalamic region. These strands are called the **brachia of the corpora quadrigemina**, and they are separated from each other by a continuation, on the side of the mesencephalon, of the transverse groove which intervenes between the two pairs of colliculi.

The **corpus geniculatum mediale** is closely associated with the brachia, although it does not form part of the mesencephalon, but belongs to the prosencephalon. It is a small, sharply defined oval eminence, which lies on the lateral side of the superior part of the mesencephalon under shelter of the posterior end of the thalamus.

The **brachium quadrigeminum inferius**, proceeding upwards from the colliculus inferior, advances towards the corpus geniculatum mediale and disappears from view under cover of this prominence.

The **brachium quadrigeminum superius** is carried upwards and ventrally between the overhanging thalamus and the corpus geniculatum mediale. A superficial examination of the mesencephalon is sufficient to show that, while a large part of this strand enters the corpus geniculatum laterale, a considerable portion is a continuation of the lateral root of the optic tract.

Pedunculi Cerebri.—The **cerebral peduncles** (Figs. 488 and 497) appear upon the ventral or basal aspect of the mesencephalon as two large rope-like strands which emerge from the cerebral hemispheres and disappear below by plunging

into the pars basilaris of the pons. At the place where each peduncle emerges from the corresponding side of the cerebrum it is encircled by the optic tract.

Each pedunculus cerebri is composed of two parts, viz., a dorsal tegmental part (**tegmentum**), which is prolonged upwards into the region below the thalamus (hypothalamus), and a ventral portion (**basis pedunculi**), which, when traced upwards into the cerebrum, is seen to take up a position on the lateral side of the thalamus and to be continuous with the internal capsule of the brain; and an intermediate part, the **substantia nigra.** When the base of the brain is examined, it is the basis pedunculi which is seen, and it is observed to be white in colour and

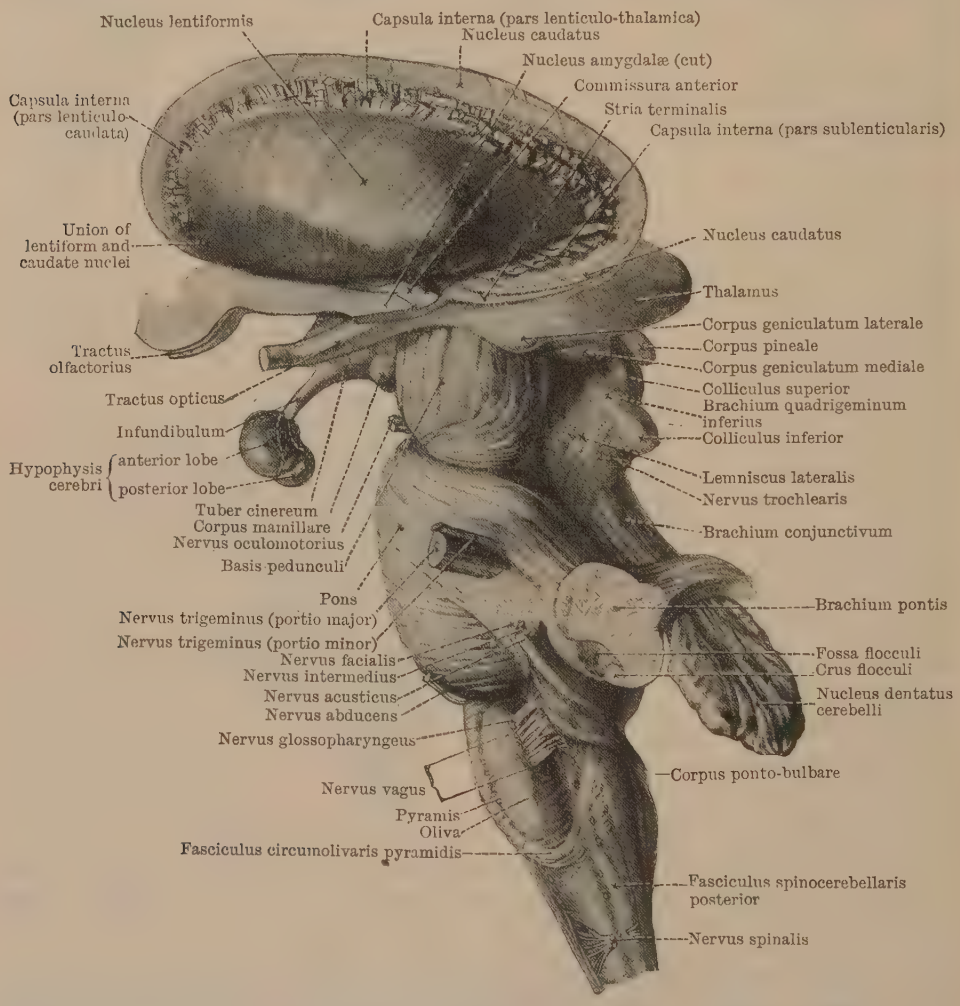

FIG. 488.—THE LEFT LATERAL ASPECT OF THE BRAIN-STEM AFTER THE CEREBRAL HEMISPHERE (EXCEPT THE CORPUS STRIATUM) AND THE CEREBELLUM (EXCEPT THE NUCLEUS DENTATUS) HAVE BEEN REMOVED

streaked in the longitudinal direction. In the tegmentum the longitudinally-arranged fibres are, in large part, *corticipetal*, or, in other words, fibres which are ascending towards the cortex of the cerebrum; the basis pedunculi, on the other hand, is composed entirely of longitudinal strands of fibres which are *corticifugal*, or fibres which descend from the cerebral hemisphere.

On the surface of the mesencephalon the separation between the tegmental and basal portions of the pedunculus cerebri is clearly indicated by a medial and a lateral groove. The medial furrow is the more distinct of the two. It looks into the interpeduncular fossa, and from it emerge the fila of the oculomotor nerve. It is termed, therefore, the **sulcus n. oculomotorii.** The lateral groove, which is placed on the lateral aspect of the mesencephalon, is called the **sulcus lateralis**

[**mesencephali**]. Its lower end becomes continuous with the furrow between the brachium pontis and brachium conjunctivum of the cerebellum.

A close inspection of the lateral surface of the tegmental part of the pedunculi cerebri, below the level of the brachia, will reveal some faintly-marked bundles of fibres curving obliquely upwards and backwards to reach the inferior colliculus (Fig. 488, p. 582). These are fibres of the **lateral lemniscus**, coming to the surface at the sulcus lateralis and sweeping over the subjacent brachium conjunctivum to gain the inferior colliculus, inferior brachium, and medial geniculate body.

INTERNAL STRUCTURE OF THE MESENCEPHALON.

When transverse sections are made through the mesencephalon the aquæductus cerebri is seen to be surrounded by a thick layer of gray matter, which receives the name of the **stratum griseum centrale** or the **central gray matter of the aqueduct**. On the dorsal aspect of this gray matter the corpora quadrigemina form a layer which separates it from the surface, and to which the term **lamina quadrigemina** is applied. On the anterior and lateral aspects of the central gray matter are the tegmental portions of the cerebral peduncles; whilst, intervening between each of the tegmenta and the corresponding basis pedunculi, there is a conspicuous mass of dark pigmented matter, termed the **substantia nigra**.

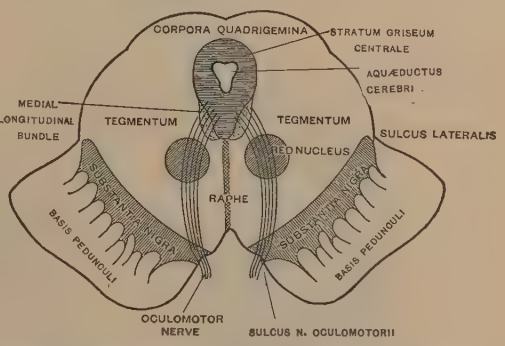

FIG. 489.—DIAGRAMMATIC VIEW OF THE CUT SURFACE OF A TRANSVERSE SECTION THROUGH THE SUPERIOR PART OF THE MESENCEPHALON.

Aquæductus Cerebri and **Stratum Griseum Centrale.**—The aqueduct is the canal which leads from the fourth ventricle below, upwards through the mesencephalon, to the third ventricle above. It is not quite three-quarters of an inch in length, and it lies much nearer the dorsal than the ventral surface of the mesencephalon. When examined in transverse section, it presents a triangular outline as it passes into the fourth ventricle and a T-shaped outline close to the third ventricle. In the intermediate part of its course it assumes different outlines, and not always the same form at the same level in different specimens.

The aqueduct is lined with ciliated epithelium, and outside this is the thick layer of central gray matter, which is directly continuous below with the gray matter spread out on the floor of the fourth ventricle, and above with gray matter on the floor and sides of the third ventricle. Scattered more or less irregularly throughout the central gray matter are numerous nerve-cells of varying forms and sizes, whilst in addition to these there are three definite collections or clusters of cells, which constitute the nuclei of origin of the trochlear nerve, the oculomotor nerve, and the mesencephalic root of the trigeminal nerve. The position and relations of these will be given at a later stage.

Substantia Nigra.—When seen in transverse section, the **substantia nigra** presents a semilunar outline. It consists of a mass of gray matter, in the midst of which are large numbers of deeply pigmented nerve-cells. It is only when this substance is examined in bulk that it appears dark; in thin sections it does not differ much in colour from ordinary gray matter, although, under the microscope, the brown-coloured cells stand out very conspicuously, even under low powers. The substantia nigra is disposed in the form of a thick layer, interposed between the tegmental and basal portions of the cerebral peduncle. It begins below at the superior border of the pons and extends upwards into the hypothalamus. The margins of this layer of dark-coloured substance come to the surface at the oculomotor and the lateral sulci of the mesencephalon, and its medial part is traversed by the emerging fila of the oculomotor nerve. It is not equally thick throughout. Towards the lateral sulcus it becomes thin, whilst it thickens

considerably near the medial aspect of the pedunculus cerebri. The surface of the substantia nigra, which is turned towards the tegmentum, is concave and uniform; the opposite surface is convex and rendered irregular by the presence of numerous slender prolongations of the substance into the basis pedunculi.

The morphological and physiological significance of the substantia nigra is not fully understood, and the connexions established by its cells are imperfectly known.

Bechterew, however, is of the opinion that fibres arising in the motor area of the cerebral cortex end in relationship with the cells of the substantia nigra, the axons of which proceed to the motor trigeminal nucleus for the purpose of co-ordinating the muscles of mastication.

Colliculi Inferiores (or **inferior quadrigeminal bodies**).—Each **inferior colliculus** is composed largely of a mass of gray matter which, in transverse section, presents an oval outline (Fig. 520, p. 584). This central nucleus is, to a large extent, encapsulated by white matter. Numerous cells of various sizes are scattered throughout it, and the whole mass is pervaded by an intricate interlacement of fine fibres, which are derived, to a large extent, from the lateral lemniscus.

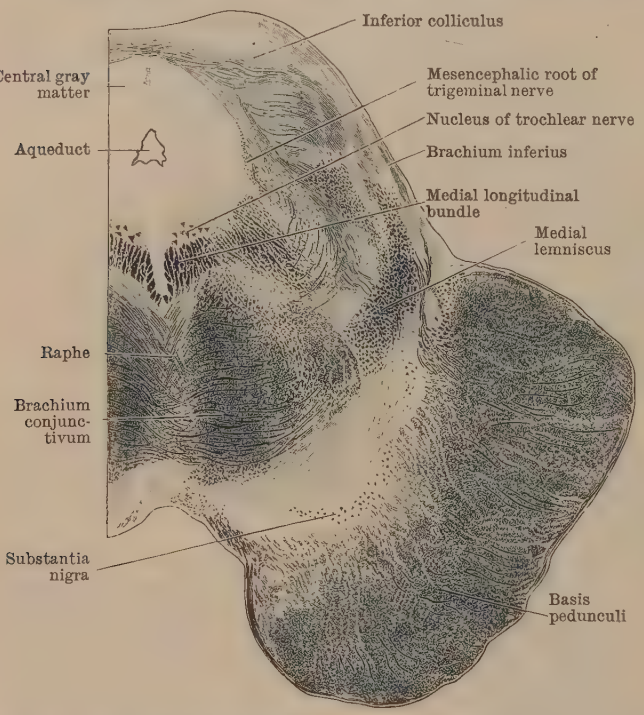

FIG. 490.—TRANSVERSE SECTION THROUGH THE MESENCEPHALON AT THE LEVEL OF THE INFERIOR COLLICULUS.

In transverse sections through this region, the lateral lemniscus is seen to abut against the lateral margin of the central nucleus. Many of the fibres of this tract enter it at once and become dispersed amongst its cells; others sweep over its dorsal surface, so as to give it a superficial covering; whilst a third group is carried medially, in the form of a thin layer, on its ventral aspect, so as to mark it off from the subjacent central gray matter of the aqueduct (Fig. 499, p. 584). In this manner, therefore, the inferior colliculus becomes partially circumscribed by the fibres of the lateral lemniscus. Several of the lateral lemniscus fibres, which proceed over the superficial or dorsal aspect of the nucleus, reach the median plane and form a loose decussation with the corresponding fibres of the opposite side.

The intimate connexion which is thus exhibited between the fibres of the lateral lemniscus and the nucleus of the inferior colliculus is very significant. The lateral lemniscus, to a large extent, comes from the nuclei of termination of the cochlear nerve of the opposite side. We must associate, therefore, the inferior colliculus, and also the corpus geniculatum mediale, which likewise receives fibres from the lateral lemniscus, with the organ of hearing.

This view regarding the inferior colliculi is supported both by experimental and by morphological evidence. Speaking broadly, it may be stated that the inferior colliculi become prominent only in mammals, and then they are invariably correlated with a spirally wound and well-developed cochlea. That they have nothing to do with sight is shown by the fact that, when the eyeballs are extirpated in a young animal, the inferior colliculi remain unaffected, whilst the superior colliculi after a time atrophy (Gudden). When, on the other hand, the cochlear terminal nuclei are destroyed, fibres which have undergone atrophy may be followed to the inferior colliculi of both sides, but particularly to that of the opposite side (Baginski, Bumm, and Ferrier and Turner). A very considerable tract of ascending fibres takes origin within the inferior colliculus and passes upwards, in the inferior brachium, into the tegmentum subjacent to

the medial geniculate body. Within the tegmentum they proceed up to the thalamus (Ferrier and Turner).

Colliculi Superiores (or **superior quadrigeminal bodies**).—The **superior colliculus** presents a more complicated structure (Fig. 491). Superficially, it is coated with a very thin layer of white matter, which is termed the **stratum zonale.** Underneath this there is a gray nucleus, called the **stratum griseum,** which, in transverse section, exhibits a crescentic outline and rests in a cap-like manner upon the subjacent part of the eminence. The succeeding two strata, which respectively receive the names of **stratum opticum** and the **stratum lemnisci,** present this feature in common, that they are composed of gray matter, traversed by numerous fibres. The source from which the fibres are derived is different, however, in each case.

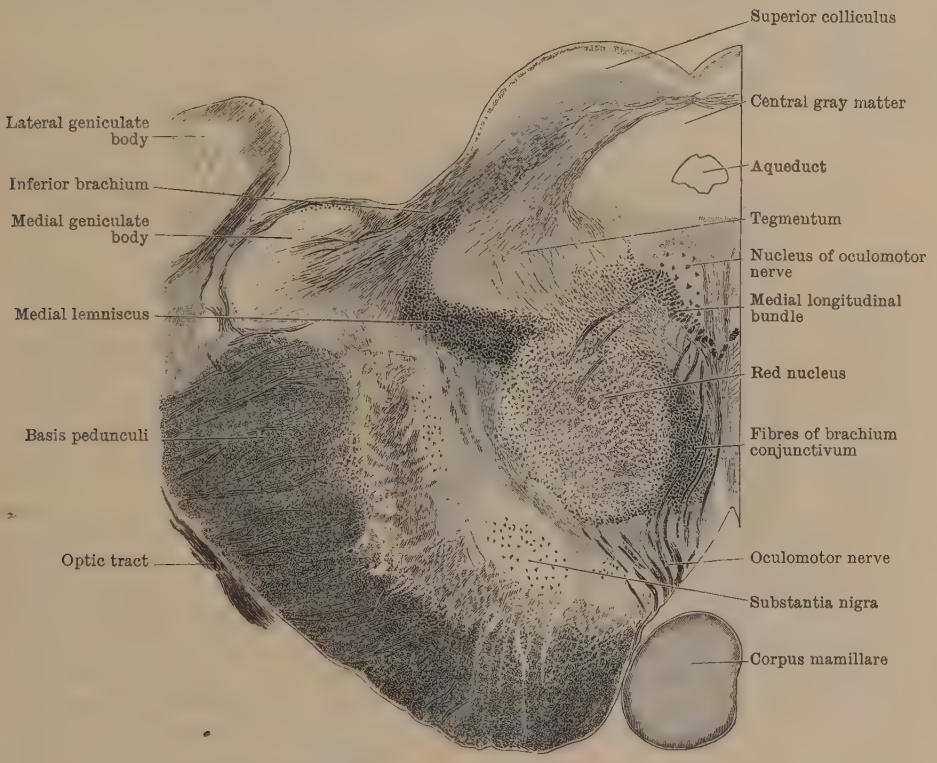

FIG. 491.—TRANSVERSE SECTION THROUGH THE MESENCEPHALON AT THE LEVEL OF THE SUPERIOR COLLICULUS.

Nerve-fibres reach the superior colliculus through—(1) the lemnisci and (2) the superior brachium.

The fibres of the lemnisci constitute the **stratum lemnisci.** The **superior brachium** contains fibres of two different kinds, viz., fibres from the optic tract and fibres from the cortex of the occipital lobe of the cerebrum. By the former it is connected with both retinæ, and by the latter with the visual centre in the occipital region of the cerebral cortex. The great majority of these fibres pass into the margin of the colliculus superior and form a layer—**stratum opticum**—underneath the stratum griseum, in which they ultimately terminate.

Tegmentum.—The tegmentum of the pedunculus cerebri may be regarded as the continuation upwards of the formatio reticularis of the medulla oblongata and the dorsal or tegmental portion of the pons into the mesencephalon. It consists, therefore, of fine bundles of longitudinal fibres intersected by arching fibres, which take a transverse and curved course. The interstices between these nerve-bundles is occupied by gray matter containing irregularly scattered nerve-cells. On its dorsal aspect the tegmentum is continuous, at the side of the central gray matter, with the bases of the corpora quadrigemina, whilst, ventrally, it is separated from the basis pedunculi by the substantia nigra. The tegmenta of opposite sides are,

to some extent, marked off from each other in the median plane by a prolongation upwards of the median raphe of the pons and medulla oblongata, although, in the inferior part of the mesencephalon, this is much obscured by the decussation of the brachia conjunctiva. The two longitudinal strands, termed the **medial longitudinal bundle** and the **medial lemniscus**, are prolonged upwards throughout the entire length of the mesencephalon; and they present the same relations to the tegmentum as in the inferior parts of the brain. The medial longitudinal fasciculus is placed in relation to its dorsal aspect, whilst the lemniscus is carried up in its ventral part.

The tegmentum of the mesencephalon may be considered as presenting two parts: viz. (1) an inferior part, which is placed subjacent to the inferior colliculi and is largely occupied by the decussation of the brachia conjunctiva (Fig. 490); and (2) a superior part, subjacent to the superior colliculi, which is traversed by the emerging bundles of the oculomotor nerve. The superior part contains a large and striking nuclear mass, termed the **nucleus ruber** or the red tegmental nucleus (Fig. 491). In the inferior part of the central gray matter of the mesencephalon is the nucleus of the trochlear nerve; in the superior part, the nucleus of the oculomotor nerve is situated.

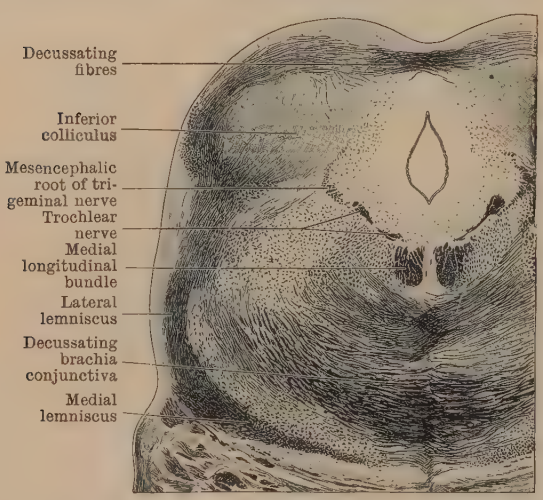

FIG. 492.—SECTION THROUGH THE INFERIOR COLLICULUS AND THE TEGMENTUM OF THE MESENCEPHALON BELOW THE LEVEL OF THE NUCLEUS OF THE TROCHLEAR NERVE. (The decussation of the brachia conjunctiva and the course of the trochlear nerve in the central gray matter are seen.)

Brachia Conjunctiva.—As the **brachia conjunctiva** leave the pons and sink into the tegmentum of the mesencephalon, they undergo a complete decussation, subjacent to the inferior colliculi and the central gray matter (Figs. 490, 491, pp. 584, 585; and Fig. 492). In this manner each brachium is transferred from one side across the median plane, to the opposite side. The decussation is completed at the level of the superior borders of the inferior colliculi, and then each brachium proceeds upwards into the superior part of the tegmentum, where it encounters the red nucleus. Into this a large proportion of its fibres plunge, and come to an end in connexion with the nuclear cells. Many of the fibres, however, are carried around the nucleus so as to form for it a capsule, which is thicker on the medial than on the lateral side (Fig. 491). These are prolonged into the thalamus, and end ultimately in connexion with the ventral thalamic cells. The brachium conjunctivum is, therefore, a great efferent tract which issues from the nucleus dentatus of the cerebellum, crosses the median plane in the inferior part of the mesencephalon, and ends in the red nucleus and the ventral part of the thalamus.

Nucleus Ruber.—The **red nucleus** is a rounded nuclear mass, of a reddish tint in the fresh brain, which lies in the superior part of the tegmentum, and in the path of the brachium conjunctivum. In transverse section it presents a circular outline. It begins at the level of the inferior border of the superior colliculus and it extends upwards into the hypothalamus. At first it is small and is placed at a little distance from the median plane; but, as it proceeds upwards, it increases in bulk and approaches more nearly to the median raphe, and to its fellow of the opposite side. The curved emerging bundles of the oculomotor nerve pass through it on their way to the surface. The relation which the fibres of the opposite brachium conjunctivum present to it has been described. These fibres traverse its inferior part in such numbers that in Weigert-Pal specimens it presents a very dark colour; but higher up, as the fibres gradually end in the

nuclear mass, they become less numerous in its midst, and the nucleus assumes a paler tint.

Numerous fibres which descend from the cerebral cortex, and others from the corpus striatum, enter the red nucleus. It also sends out fibres which proceed in two directions: (1) upwards into the thalamus; (2) downwards to the spinal medulla. The thalamic fibres may be regarded as carrying on the continuity of the path of the brachium conjunctivum after its nodal interruption in the red nucleus. The fibres to the spinal medulla, called the **rubro-spinal tract** and first described by Monakow, cross to the opposite side and then descend in the tegmentum to reach the lateral funiculus of the spinal medulla (Fig. 448, p. 536).

Fasciculus Longitudinalis Medialis.—The **medial longitudinal fasciculus** is a very conspicuous tract of longitudinal fibres which extends throughout the whole length of the medulla oblongata, pons, and mesencephalon, in the formatio reticularis or tegmental part of each. Below, at the level of the decussation of the pyramids, it becomes continuous with the fasciculus anterior proprius of the spinal medulla (p. 537), whilst, by its opposite or superior end, it establishes intricate connexions in the region immediately above the mesencephalon. Throughout its whole length it lies close to the median plane and its fellow of the opposite side. In the mesencephalon it is applied to the ventral aspect of the central gray matter, whilst in the pons and medulla oblongata it is situated immediately subjacent to the gray matter of the floor of the fourth ventricle. One of its most salient features is the intimate association which it presents with the three motor nuclei from which the nerves for the supply of the muscles of the eyeball take origin, viz., the oculomotor nucleus, the trochlear nucleus, and the abducent nucleus. The first two of these are closely applied to its medial and dorsal aspect, whilst the abducent nucleus is placed on its lateral side. Into each of these nuclei it sends many collaterals, and probably also some of its constituent fibres, and these end around the nuclear cells. It would appear, therefore, that one of the most important functions of this strand is to bind together these nuclei, and thus enable them to act in harmony one with the other. Fibres also enter the medial longitudinal fasciculus from the vestibular nucleus of the acoustic nerve system. The results obtained by degeneration would seem to indicate that, to a large extent, it is formed of fibres which run a short course within it.

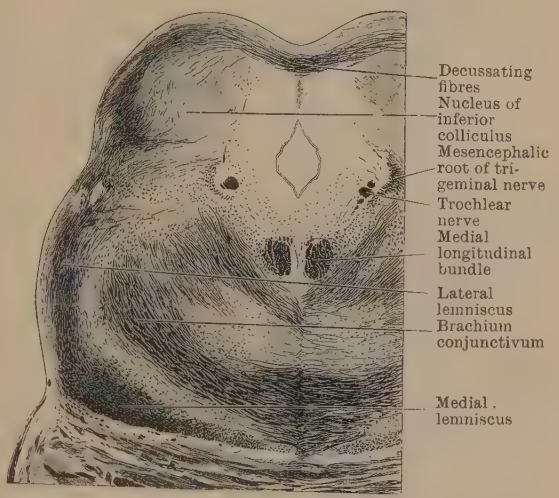

Fig. 493.—Section through the Inferior Colliculus and the Tegmentum of the Mesencephalon, at a slightly Lower Level than Fig. 492.

It is evident that it is a brain tract of high importance, from the fact that it is present in all vertebrates, and, further, that its fibres assume their medullary sheaths at an extremely early period. In fishes, amphibians, and reptiles, it is one of the largest bundles of the medulla oblongata. In man, its fibres medullate between the sixth and seventh months of fœtal life, and at the same time as the fibres of the fasciculus anterior proprius of the spinal medulla, with which it stands in connexion.

According to van Gehuchten and Edinger, it extends upwards beyond the level of the oculomotor nucleus, and in the thalamic region its fibres take origin from a special nucleus of its own in the gray matter of the third ventricle, immediately behind the level of the corpora mamillaria. Fibres also enter the medial longitudinal bundle from a nucleus common to it and the posterior commissure of the brain. This nucleus is placed in the anterior part of the central

gray matter of the mid-brain. Held asserts that numerous fibres, arising from cells in the superior colliculus, curve in an arcuate manner in the tegmentum outside the central gray matter, to take part on the ventral aspect of this in what is called the **fountain decussation**. Reaching the opposite side, these fibres turn downwards and join the medial longitudinal bundle. The same authority considers that fibres from the ventral part of the posterior commissure can also be traced downwards into the medial longitudinal bundle. Edinger, on the other hand, places these fibres as a distinct tract on the ventral and lateral aspect of the medial longitudinal bundle, although in apposition with it.

Mendel believed that fibres from the oculomotor nucleus are carried down in

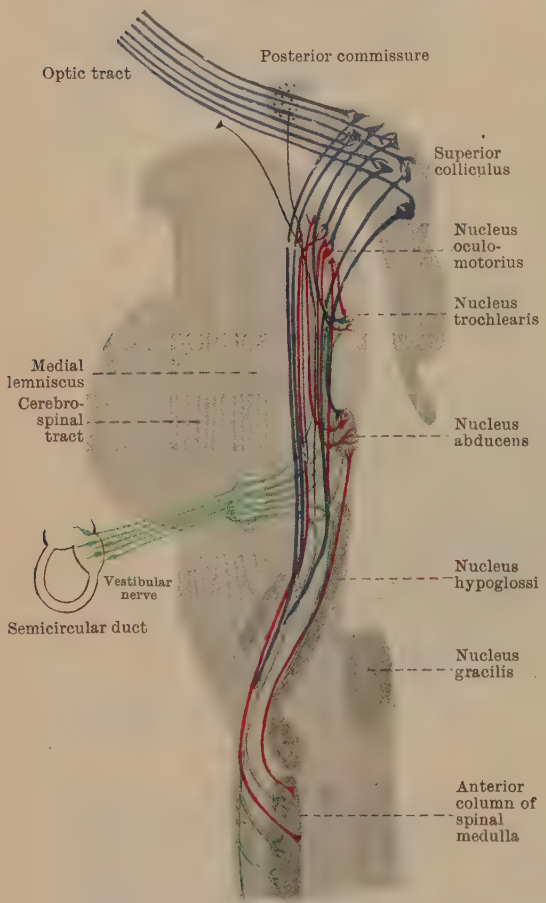

FIG. 494.—DIAGRAM REPRESENTING SOME OF THE CONSTITUENT ELEMENTS OF THE FASCICULUS LONGITUDINALIS MEDIALIS.

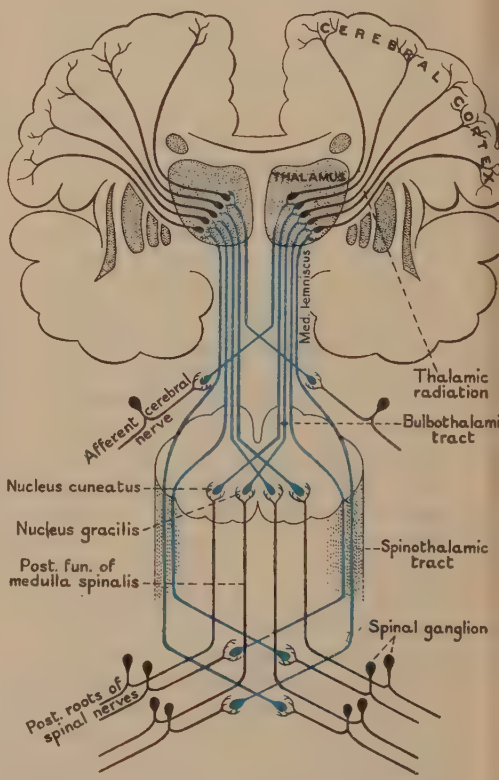

FIG. 495.—DIAGRAM OF THE CONNEXIONS OF THE MEDIAL LEMNISCUS AND ALSO OF CERTAIN OF THE THALAMO-CORTICAL FIBRES.

the medial longitudinal bundle, and, from this, into the facial nerve for the supply of the orbicularis oculi and the corrugator supercilii, bringing these muscles, therefore, under the control of the same nucleus as the levator palpebræ superioris muscle. This view was adopted by many clinicians because this upper group of facial muscles is often spared in cases of facial paralysis; but Harman has adduced reasons in support of the view that there is a superior prolongation of the facial nucleus which innervates these muscles. It has been suggested further that fibres from the hypoglossal nucleus may, by the medial longitudinal bundle, reach the facial nerve, and through it the orbicularis oris. In this manner the same nucleus would hold sway over the tongue and the sphincter muscle of the lips. The close relation which exists between the ascending part of the intrapontine portion of the facial nerve and the medial longitudinal bundle would render the passage of

fibres from one to the other a circumstance which could easily be understood. But the balance of evidence now available inclines us to regard the facial nucleus as the origin of the fibres innervating all the facial muscles. Another interchange of fibres through the medial longitudinal bundle has been described by Duval and Laborde. According to these authorities, fibres from the abducens nucleus ascend in the medial longitudinal bundle into the mesencephalon, and establish connexions with that part of the oculomotor nucleus from which the nerve for the medial rectus of the opposite side derives its fibres. If this view is correct, it affords a ready and simple anatomical explanation of the harmonious action of the lateral and medial recti muscles in producing movements of the two eyeballs simultaneously to the right and to the left. From the investigations of E. H. Fraser it would appear that no fibres from the abducens nucleus go directly into the oculomotor nerve. The same observer has shown that many fibres from Deiters' nucleus, a part of the vestibular nucleus of the acoustic nerve to be described later in this account, enter the oculomotor and the trochlear nuclei through the path afforded by the medial longitudinal bundle.

Lemniscus Lateralis.—The **lateral lemniscus** is a definite tract of longitudinal fibres, which extends upwards through the lateral part of the tegmental substance of the superior portion of the pons and the mesencephalon. It is formed by the fibres of the corpus trapezoideum and striæ medullares in the inferior part of the pons, turning abruptly upwards and taking a course towards the quadrigeminal region. But the details of the arrangement and connexions of this important fasciculus must be left for fuller consideration when we are discussing the central connexions of the acoustic nerve.

Lemniscus Medialis.—The **medial lemniscus** has already been followed through the medulla oblongata and pons, and its position in each of these portions of the brain-stem has been defined (pp. 561 and 562). In the tegmentum of the inferior part of the mesencephalon it is carried up in the form of a more or less flattened band on the ventral aspect of the decussating brachia conjunctiva. To its lateral side, and forming an angle with it (as seen in transverse section), is the lateral lemniscus (Figs. 492 and 493), and at this level there is no clear demarcation between these two tracts. In the superior part of the mesencephalon the appearance of the red nucleus in the tegmentum causes the medial lemniscus to take up a more lateral and dorsal position, so that it now comes to lie subjacent to the corpus geniculatum mediale (Fig. 491, p. 585). At this level it exhibits a crescentic outline in transverse section, and the lateral lemniscus has to a large extent disappeared from its lateral side.

A part of the medial lemniscus, which is called the **fasciculus bulbothalamicus,** takes origin in the inferior part of the medulla oblongata from the gracile and cuneate nuclei of the opposite side (p. 561). Seeing that the posterior funiculus of the spinal medulla ends in these nuclei, the medial lemniscus may be considered to continue that funiculus upwards into the brain. Other fibres arise from the terminal nuclei of the various sensory cerebral nerves of the opposite side. The rest of the tract consists of the superior part of the **fasciculus spinothalamicus** from the spinal medulla. In the mesencephalon a considerable contribution of fibres is given by the medial lemniscus to the superior colliculus, and then the remainder of the tract proceeds into the lateral (ventro-lateral) nucleus of the thalamus. Here its fibres end amidst the thalamic cells.

Ganglion Interpedunculare and Fasciculus Retroflexus. — Immediately above the pons a small collection of nerve-cells is found in the median plane, wedged in between the two cerebral peduncles. It is all that is found in the human brain to represent a large nucleus projecting into the interpeduncular fossa in most other animals, especially those with a highly developed sense of smell. In this **interpeduncular ganglion** ends the **fasciculus retroflexus,** a tract of fibres which comes from the nucleus habenulæ of the epithalamus. We shall return to the consideration of this tract later.

Fountain Decussation. — If the region ventral to the medial longitudinal bundles is examined in the superior part of the mesencephalon a very close decussation of fibres in the median plane will be observed in the interval between the two

red nuclei. This is the "**fountain decussation.**" According to Held, the fibres which take part in the dorsal portion of the fountain decussation (decussation of Meynert) come from the superior colliculi, and, after they have gained the opposite side, they turn downwards in the medial longitudinal fasciculus.

Many of the fibres that cross in this decussation enter a descending tract (*fasciculus tecto-bulbaris et spinalis*) which connects the corpora quadrigemina with the motor nuclei on the other side of the medulla oblongata and spinal medulla.

Basis Pedunculi.—The **basis pedunculi** presents a somewhat crescentic outline when seen in transverse section, and it stands quite apart from its fellow of the opposite side. It is composed of a compact mass of longitudinally directed fibres, all of which, as Déjerine has shown, arise in the cortex of the cerebrum and pursue an unbroken corticifugal course into and through the pedunculus cerebri. These fibres may be classified into two distinct sets, viz., cerebro-pontine and pyramidal or cerebro-spinal.

The **cerebro-pontine fibres** possess this leading character: in their course downwards they are all arrested in the ventral part of the pons, and end amidst the cells of the nuclei pontis. These tracts would appear to hold a very definite position within the crus. Thus, it has been satisfactorily established that the fibres coming from the temporal area of the cerebral cortex (*temporo-pontine strand*) form the lateral fifth of the basis pedunculi, whilst those coming from the frontal area (*fronto-pontine strand*) hold a similar position in the medial part of the basis pedunculi.

The **pyramidal fibres** constitute the great motor tract from the cerebral cortex. They occupy a position corresponding to the middle three-fifths of the basis. The pyramidal tract differs from the cerebro-pontine strands in being carried downwards through the ventral part of the pons and on the ventral aspect of the medulla oblongata into the spinal medulla, which it enters in the form of the fasciculi cerebrospinales lateralis and anterior. On its way through the pons and medulla oblongata it sends fibres across the median plane to the various motor nuclei on the opposite side of those sections of the brain-stem.

Development of the Mesencephalon.

Even in the early embryo the mesencephalon is the smallest section of the brain-tube, although the disproportion in size between it and the other primitive subdivisions of the brain is not nearly so marked as in the adult. Owing to the cephalic flexure, the mid-brain for a time occupies the summit of the head. Later it becomes completely covered over by the expanding cerebral hemispheres.

The corpora quadrigemina are derived from the alar laminæ of the side walls of the brain-tube, whilst the basal laminæ thicken and ultimately form the tegmenta. The original cavity of the mid-brain is retained as the aqueduct.

For a considerable time the cavity of the mesencephalon remains relatively large, and the lower part of its dorsal wall is carried downwards in the form of a diverticulum or recess, which overlaps the cerebellar plate. About this time, also, the dorsal wall shows a median fold or ridge. Both of these conditions are transitory. As the corpora quadrigemina take shape, the median ridge disappears and is replaced by the median longitudinal groove, which separates the quadrigeminal bodies. Only its inferior part is retained, and this is represented by the frenulum veli of the adult brain. The diverticulum of the cavity gradually becomes reduced, and finally disappears as the aqueduct assumes form.

The precise mode of origin of the red nucleus is not known.

Later in this account reasons will be given for the belief that the representatives of the neural crests in the region of the mesencephalon become absorbed and assimilated in the walls of the neural tube as it closes in.

THE DEEP CONNEXIONS OF THE CEREBRAL NERVES ATTACHED TO THE MEDULLA OBLONGATA, PONS, AND MESENCEPHALON.

There are twelve pairs of cerebral nerves, of which the inferior eight are attached to the medulla oblongata and pons. From above downwards these are named the trigeminal (fifth), the abducens (sixth), the facial (seventh), the acoustic (eighth), the glossopharyngeal (ninth), the vagus (tenth), the accessory (eleventh), and the hypoglossal (twelfth). Two others, the trochlear (fourth) and oculomotor (third) spring

from the mesencephalon. The hypoglossal, the accessory, the greater part of the facial, the abducens, the motor root of the trigeminal, the trochlear and the oculomotor are efferent nerves; the acoustic, the nervus intermedius (sensory root of the facial) and the sensory root of the trigeminal are purely afferent nerves; whilst the vagus and the glossopharyngeal are composed of both efferent and afferent fibres. In all these cases (with a possible reservation in the case of part of the trigeminal) afferent fibres arise from ganglionic cells placed outside the brain and penetrate the brain-stem, to end in connexion with the cells of certain **nuclei of termination.** Efferent fibres, on the other hand, take origin within the brain as the axons of cells which are grouped together in certain places in the form of **nuclei of origin.**

Nuclei of Origin, or Motor Nuclei. — In the spinal medulla the nuclei of origin are represented by elongated columns of cells which run more or less con-

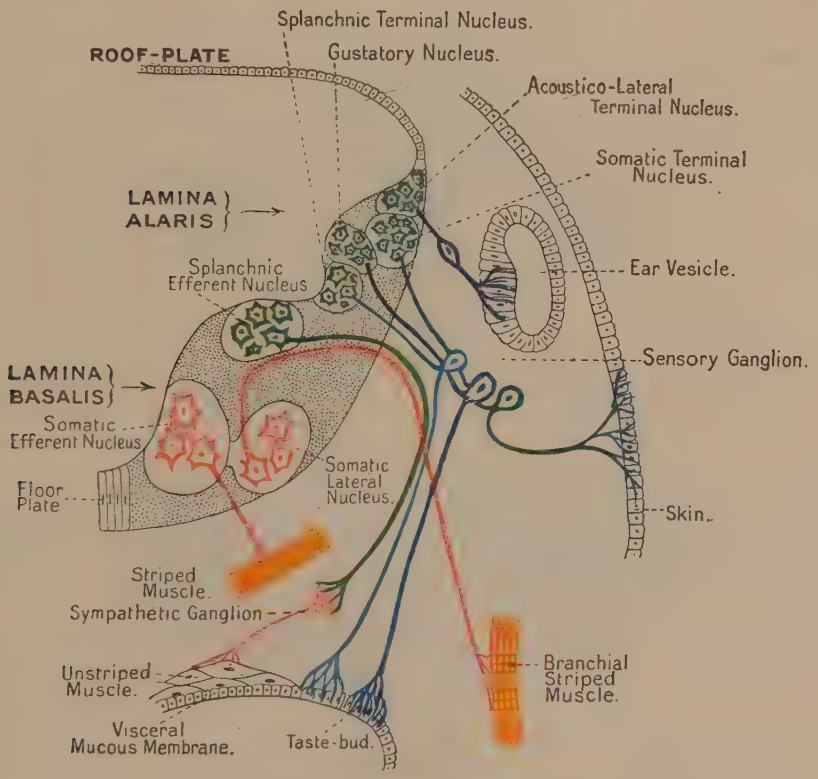

FIG. 496.—DIAGRAM REPRESENTING THE DIFFERENT KINDS OF COMPONENTS FOUND IN THE CEREBRAL NERVES AND OF THEIR NUCLEI OF ORIGIN OR TERMINATION.

tinuously in the anterior column of gray matter of successive spinal segments, and from these the series of efferent anterior nerve-roots take origin. In the medulla oblongata, pons, and mesencephalon the nuclei of origin, or, in other words, the motor nuclei of the individual nerves, become, for the most part, discontinuous, and are represented by certain isolated clumps of compact gray matter, in which are placed the clusters of cells from which the fibres of the efferent nerves arise. The nucleus ambiguus, however, which consists of a column of cells from which root-fibres of the bulbar part of the accessory, of the vagus, and also of the glossopharyngeal are derived, is an exception to this rule. At the decussation of the pyramids, the anterior column of gray matter of the spinal medulla is broken up by the intercrossing bundles into a detached head and a basal part which remains in relation with the ventrolateral aspect of the central canal. Certain of the efferent nuclei of the medulla oblongata, pons, and mesencephalon lie in the line of the basal portion of the anterior column of gray matter of the spinal medulla, and, thus, close to the median plane. These are termed **medial somatic nuclei**, and are met with at different levels in the

brain-stem. This group comprises the hypoglossal nucleus, the abducens nucleus and, in the mesencephalon, the trochlear nucleus and part of the oculomotor nucleus. Other motor nuclei of origin are present in the form of isolated clumps or columns of gray matter, which lie at different levels in the medulla oblongata and pons in a more lateral and deeper situation. They are the nucleus ambiguus of the accessory, vagus and glossopharyngeal, the facial nucleus, and the nucleus of the motor root of the trigeminal nerve. From their position in the substantia reticularis of the medulla oblongata and pons they constitute a group to which the name of **lateral somatic nuclei** is applied.

In addition to these two columns of motor nuclei there is a third efferent column of **splanchnic nuclei** represented by the dorsal nucleus of the vagus and

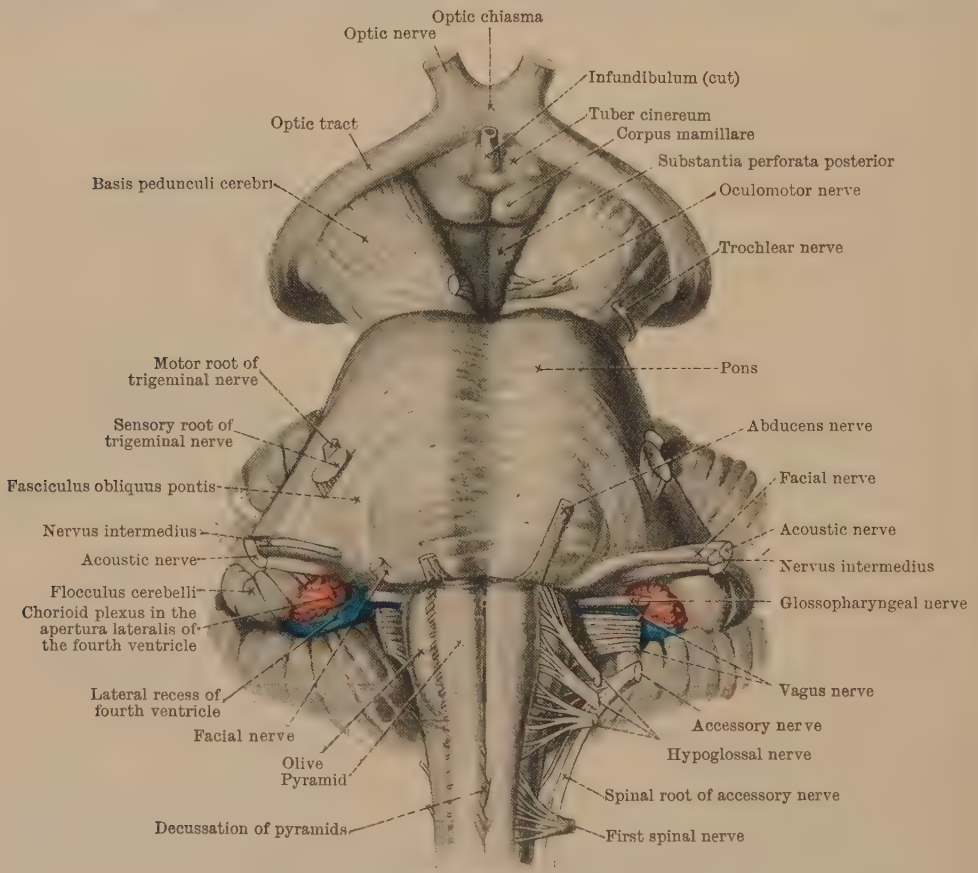

FIG. 497.—THE VENTRAL ASPECT OF THE MEDULLA OBLONGATA, PONS, AND MESENCEPHALON, showing the nerve roots.

glossopharyngeal nerves, and similar nuclei emitting sympathetic fibres into the facial and oculomotor nerves. It is possible some splanchnic efferent fibres may pass into the trigeminal nerve.

The different nuclei of origin of the efferent fibres which belong to the various cerebral nerves, both medial and lateral, are connected with the motor area of the cerebral cortex by fibres of the cerebro-spinal tract of the other side, which enter the nuclei and end in association with their cells.

Nuclei Terminales.—The general scheme of arrangement of the **terminal nuclei** has already been explained (Fig. 496); its details will be further elucidated as the various nerves are considered seriatim.

The axons of many of the cells of the nuclei of termination enter the substantia reticularis as arcuate fibres, and, crossing the median plane, are carried upwards in the substantia reticularis of the opposite side, to establish direct connexions with the thalamus and, indirectly through it, with the cerebral cortex (Fig. 495).

Others pass to the nuclei of motor nerves, to the cerebellum or other groups of nerve-cells, to form connexions necessary for the performance of reflex actions.

Nervus Hypoglossus.—The nucleus of origin of the **hypoglossal nerve**, the motor nerve of the tongue, lies in the substance of the medulla oblongata. It is composed of several groups of large multipolar cells, which closely resemble the cells in the anterior column of gray matter in the spinal medulla, and is pervaded by an intricate network of fine fibrils. In form it is elongated and rod-like, and in length it is about 18 mm. It extends from a point immediately above the decussation of the pyramids up to the level of the striæ medullares. The inferior portion of the nucleus is thus placed in the closed part of the medulla oblongata (Fig. 465, p. 561), whilst its superior part is situated in the open part (Fig. 466, p. 562). The former lies in that part of the central gray matter which is continuous with the basal part of the anterior column of gray matter of the spinal medulla. It is thus placed on the anterior and lateral aspect of the central canal, close to the median plane and the corresponding nucleus of the opposite side. The superior part of the nucleus occupies a position in the gray matter on the floor of the fourth ventricle, subjacent to the medial part of the surface area, which has been described under the name of the **trigonum hypoglossi.** Within the nucleus the axons of the cells arrange themselves in converging bundles of fine fibres, which come together and leave the ventral aspect of the nucleus as the fila radicularia of the nerve. The nerve bundles thus formed traverse the entire antero-posterior thickness of the medulla oblongata, between the substantia reticularis grisea and the substantia reticularis alba, and emerge on the surface, in linear order, at the bottom of the furrow between the olive and the pyramid. After they emerge these fibres collect to form three definite bundles like the anterior nerve-roots of three spinal nerves (Fig. 497). In the substance of the medulla oblongata the fila radicularia of the hypoglossal pass between the main inferior olivary nucleus and the medial accessory olivary nucleus, and many of them on their way to the surface pierce the ventral lamina of the main olivary nucleus.

No decussation between the nerves of opposite sides takes place in the medulla oblongata, but commissural fibres pass between the two nuclei (Kölliker). Further, numerous fibres from the opposite pyramidal tract enter the nucleus and end in connexion with its cells. The nucleus is thus brought into connexion with the motor area of the opposite side of the cerebral cortex.

Nervus Accessorius.—The **accessory nerve** also is a motor nerve, and it is generally described as consisting of a spinal and a cerebral or accessory part.

The **spinal part** of the nerve emerges by a series of roots which issue from the surface of the lateral column of the superior part of the spinal medulla as low down as the fifth cervical nerve. These take origin in a column of cells situated in the anterior column of gray matter of the spinal medulla, close to its lateral margin, and immediately behind the nerve-cells which give rise to the fibres of the anterior roots of the upper five cervical nerves. The cells of the accessory nucleus are large, multipolar, and in every respect similar to the motor cells of the spinal nerves. The axons from these cells leave the dorsal aspect of the nucleus in converging groups to form the fila radicularia or root-bundles of the nerve. These, in the first place, proceed straight backwards in the anterior column of gray matter. Reaching the bay between the two columns of gray matter, they turn sharply laterally into the white matter and traverse the lateral funiculus to gain their points of exit from the spinal medulla. At the decussation of the pyramids, fila, which join the accessory nerve, are seen to proceed from the detached head of the anterior column of gray matter.

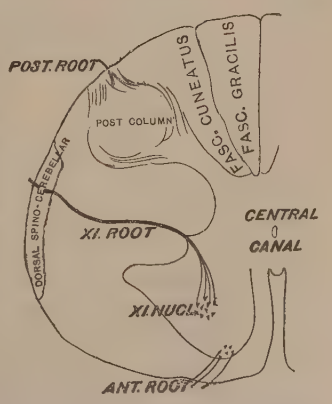

Fig. 498.—Diagram of the Spinal Origin of the Accessory Nerve. (After Bruce.)

The **cerebral part** of the accessory nerve has its nucleus of origin in the medulla oblongata; and its fila, as they proceed laterally from this, can be distinguished by the fact that they pursue a course on the ventral side of the tractus spinalis of the trigeminal nerve, whereas the vagus roots, with which they are apt to be confused, pass through or lie on the dorsal aspect of the trigeminal root (Kölliker). The nucleus of origin of the cerebral part of the accessory nerve is formed by the same column of cells which constitutes the **nucleus ambiguus**, and which, at a higher level, gives motor fibres to the vagus and glossopharyngeal nerves.

The part of the accessory nerve which takes origin in the spinal medulla supplies the sterno-mastoid and trapezius muscles. The cerebral portion joins the vagus, and through the external laryngeal and recurrent nerves it supplies the muscles of the larynx. The portion of the nucleus ambiguus from which it arises has thus been termed the laryngeal nucleus (Edinger) but it is not certain whether it is vagal or accessory.

Collaterals and fibres of the opposite lateral cerebro-spinal tract end in connexion with the cells of origin of the accessory nerve, and thus bring its nucleus into connexion with the motor area of the cerebral cortex. Fibres also from the posterior roots of the spinal nerves (afferent or sensory fibres) end in the nucleus.

Nervus Vagus, Nervus Glossopharyngeus.—The **vagus and glossopharyngeal nerves** present similar connexions with the brain, and they may therefore be studied together. The greater part of both nerves is composed of afferent fibres, which arise outside the brain-stem from ganglionic cells placed in relation to the nerve-trunks. Both nerves possess efferent fibres also, which spring from two special nuclei of origin situated within the medulla oblongata and termed respectively the **dorsal** or **splanchnic nucleus** and the **nucleus ambiguus**, which is the **somatic nucleus**. The afferent ganglionic fibres of the vagus and glossopharyngeal enter the brain by a series of roots which penetrate the medulla oblongata along the ventral side of the restiform body. Within the medulla oblongata they separate into two sets, viz., a series of bundles (composed chiefly of vagus fibres, *i.e.* afferent splanchnic), which end in the **dorsal nucleus of termination** of the vagus and glossopharyngeal nerves, and another series of bundles (composed chiefly of glossopharyngeal fibres, *i.e.* taste fibres), which join a conspicuous longitudinal tract of fibres called the **tractus solitarius**.

The **dorsal nucleus** (Figs. 461, p. 587, and 496, p. 591) of the vagus and glossopharyngeal nerves is mixed, and contains both motor cells which give origin to efferent fibres, and cells around which afferent fibres of the vagus, and possibly also of the glossopharyngeal nerve, break up into terminal arborisations. It very nearly equals in length the nucleus of the hypoglossal nerve, with which it is closely related. Above, it reaches as high as the striæ medullares, whilst, below, its inferior end falls slightly short of that of the hypoglossal nucleus. In specimens stained by the Weigert-Pal method the two nuclei offer a marked contrast. The hypoglossal nucleus presents a dark hue, owing to the enormous numbers of fine fibres which twine in and out amidst its cells; the vago-glossopharyngeal dorsal nucleus is pale, from the scarcity of such fibres within it. Its cells, like those of all splanchnic efferent nuclei, are much smaller than the somatic cells of the nucleus ambiguus. In the closed part of the medulla oblongata the dorsal vago-glossopharyngeal nucleus lies in the central gray matter immediately behind the hypoglossal nucleus, and upon the lateral aspect of the central canal; in the open part of the medulla oblongata it lies in the gray matter of the floor of the fourth ventricle, immediately to the lateral side of the hypoglossal nucleus and subjacent to the surface area termed the trigonum vagi or ala cinerea.

All the fibres which arise from this dorsal or splanchnic efferent nucleus are very fine, and in sections of the vagus nerve can readily be distinguished from the much coarser somatic fibres, which come from the nucleus ambiguus, and also from the medium-sized sensory fibres, which spring from the ganglia placed upon the nerves. The fine fibres from the dorsal nucleus are distributed (probably indirectly, *i.e.* after being interrupted in a peripheral ganglion), to the involuntary striped muscle of the œsophagus and heart, and the unstriped muscle of the œsophagus, stomach and respiratory system (van Gehuchten and Molhant, *La Névraxe*, June 15, 1912, p. 55).

The **nucleus ambiguus** (Figs. 461, 499, 496) gives origin to the somatic

motor fibres of the glossopharyngeal and vagus nerves. All the fibres from this nucleus which pass into the glossopharyngeal nerve end in the stylo-pharyngeus muscle; the vagal branches are distributed to the striated muscles of the pharynx and larynx. The cells of the nucleus ambiguus are large, multipolar, and similar in every respect to the large cells in the anterior column of the spinal medulla. These cells are arranged in a slender column which is best developed in the open part of the medulla oblongata. Here the nucleus can easily be detected, in transverse sections, as a small area of compact gray matter which lies in the substantia

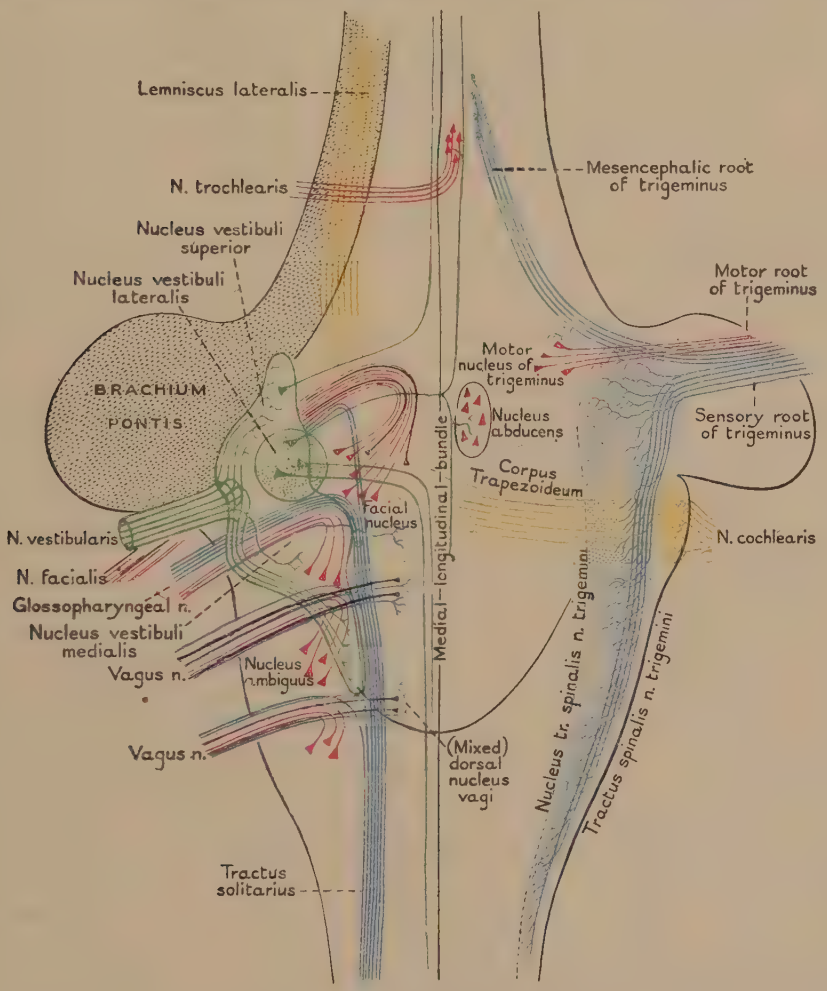

FIG. 499.—DIAGRAM, showing the brain connexions of the vagus, glossopharyngeal, acoustic, facial, abducens, and trigeminal nerves.

reticularis grisea, midway between the dorsal accessory olive and the nucleus tractus spinalis nervi trigemini. It therefore lies more deeply in the substance of the medulla oblongata than the dorsal vago-glossopharyngeal nucleus. Kölliker states that it can be traced downwards as low as the level of the decussation of the medial lemniscus, and upwards as high as the place of entrance of the cochlear root of the acoustic nerve. From its dorsal aspect the axons of the cells proceed, and in the first instance they pass backwards towards the floor of the fourth ventricle; then, bending suddenly laterally and forwards, they join the afferent roots of the vagus and the glossopharyngeal nerves, and emerge from the brain in company with these.

Sensory or Terminal Nuclei of the Glossopharyngeal and Vagus. Splanchnic and Gustatory Components.—The cells in the portion of the dorsal

nucleus which acts as a *nucleus of termination* are spindle-shaped in form and similar to those found in the posterior column of gray matter in the spinal medulla. In connexion with these cells, the greater number of the afferent fibres of the vagus nerve, and a small proportion of the afferent fibres of the glossopharyngeal nerve, end in fine terminal arborisations. A small part of the superior portion of the nucleus may be said to belong to the glossopharyngeal nerve and the remainder of the nucleus to the vagus nerve.

The **tractus solitarius** (Figs. 465, p. 561; 466, p. 562; and 499) is a round bundle of longitudinal fibres which forms a very conspicuous object in transverse sections through the medulla oblongata. It begins at the superior limit of the medulla oblongata, and can be traced downwards through its whole length. Its precise point of termination is not known, but some authorities believe that it is carried for some distance downwards into the superior part of the spinal medulla, and, according to Kölliker, to the level of the fourth cervical nerve. Most modern writers, however, limit it to the medulla oblongata. The relations of the tractus solitarius are not the same in all parts of its course. It lies immediately to the lateral side of the dorsal vago-glossopharyngeal nucleus; but, whereas in the superior part of the medulla oblongata it is situated somewhat on the ventral side of that nucleus, in the inferior, closed part of the medulla oblongata it is placed on its dorsal aspect. Throughout its entire length it is intimately associated with a column of gelatinous gray substance called the **nucleus tractus solitarii**, which constitutes the nucleus of termination in which its fibres end. When traced from above downwards, the tractus solitarius is observed to become gradually smaller owing to the loss of fibres which it thus sustains. The great bulk of the tractus solitarius is formed of fibres derived from the glossopharyngeal nerve; only a few of the afferent fibres of the vagus enter it, but fibres of the sensory root (**nervus intermedius**) of the facial also enter it. As the fibres of the three nerves join the fasciculus they immediately turn downwards, and at different levels come to an end in the associated nucleus tractus solitarii.

As the afferent root-bundles of the vagus and the glossopharyngeal nerves traverse the substance of the medulla oblongata in a backward and medial direction to reach the tractus solitarius and the dorsal nucleus of termination, they pass through the tractus spinalis of the trigeminal nerve and the nucleus of that tract. As the afferent root of the vagus passes through the trigeminal tractus spinalis and its nucleus, which is somatic sensory in nature, it gives off to this nucleus its own somatic sensory branches, the peripheral ends of which constitute the auricular branch, distributed to the skin on the back of the auricle. The other afferent fibres in the glossopharyngeal and vagus nerves include taste fibres, sensory fibres from the pharynx, larynx, and other parts of the respiratory and alimentary systems, and other splanchnic afferent fibres. Although there is no sharp demarcation between the terminal nuclei of these various components, it is probable that the taste fibres proceed to the nucleus tractus solitarii, the splanchnic afferent fibres to the dorsal nucleus, and the somatic afferent fibres to the nucleus of the spinal trigeminal tract.

Nervus Acusticus.—As this is a nerve of special sense it will be left for consideration after the rest of this series.

Nervus Facialis (Figs. 499 and 500).—The **facial nerve** is composed of two distinct parts, viz., a large efferent (mainly motor) portion, the **facial nerve proper**, and a small afferent sensory portion termed the **nervus intermedius**.

The facial nerve proper emerges from the brain at the inferior border of the pons, to the medial side of the acoustic nerve, whilst the nervus intermedius sinks into the superior part of the medulla oblongata between the facial and acoustic nerves, but alongside the latter, rather than the former, from which it is separated by the fasciculus obliquus pontis (Fig. 497). The three nerves, therefore, lie in intimate relation with each other, where they are attached to the surface of the brain, and they pass in company into the internal acoustic meatus.

The fibres of the **nervus intermedius** arise from the cells of the ganglion geniculi of the facial nerve. These, like the cells of a spinal ganglion, are unipolar, the single process in each case dividing into a peripheral and a central branch. The group of peripheral fibres represent parts of the greater superficial petrosal nerve

and chorda tympani branch of the facial nerve, whilst the central fibres form the nervus intermedius. The central fibres penetrate the brain, and, passing either through or on the dorsal side of the tractus spinalis of the trigeminal nerve, they finally reach the superior part of the column of gray matter in connexion with the tractus solitarius, and in this they end. The nervus intermedius presents, therefore, the same terminal connexions within the brain as the glossopharyngeal nerve.

The motor nucleus of the facial nerve contains elements serially homologous with both the somatic (nucleus ambiguus) and splanchnic (nucleus dorsalis) efferent nuclei of the glossopharyngeal and vagus. It is composed partly of the larger cells characteristic of the former and the smaller cells distinctive of the latter. The axons of the somatic cells innervate the striated muscles of the face, whereas the splanchnic efferent fibres pass to the spheno-palatine, otic and submaxillary ganglia (as their white rami communicantes), and are largely concerned with the regulation of the secretory activity of the large salivary glands and other glands around the mouth.

The facial nucleus is situated close to the place where the nerve emerges from the brain, but the nerve does not at once pass to this point of exit. It pursues a long and devious path within the pons before it finally reaches the surface. This intrapontine part of the nerve may be divided into three parts, viz.: (1) a radicular part, (2) an ascending portion, and (3) an emergent part.

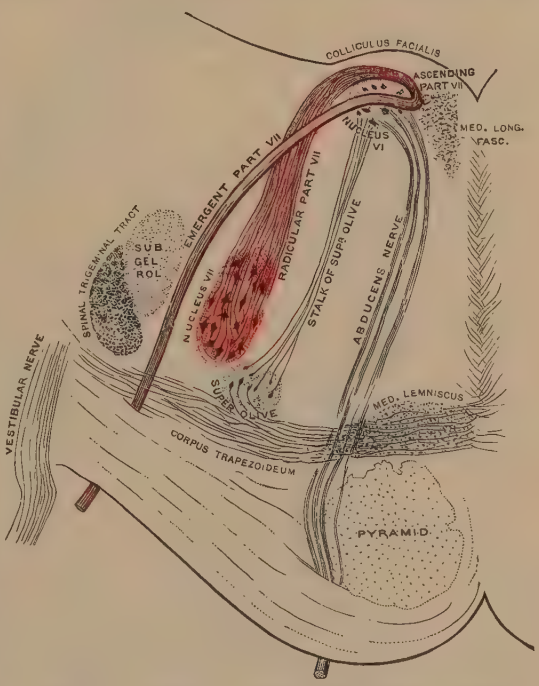

FIG. 500.—DIAGRAM OF THE INTRAPONTINE COURSE OF THE FACIAL NERVE.

Sub. gel. rol. refers to the nucleus of the spinal trigeminal tract.

The **radicular part of the facial nerve** (Fig. 500) is composed of a large number of fine, loosely arranged bundles of fibres, which issue from the lateral and dorsal aspect of the nucleus and proceed backwards and slightly medially through the pons. Reaching the floor of the fourth ventricle they curve medially, and the bundles which lie highest up sweep over the lateral and dorsal aspect of the inferior part of the nucleus of the sixth nerve. Close to the median plane they turn sharply upwards and are collected into a single solid nerve-bundle, which constitutes the **ascending part of the facial nerve** (Figs. 499 and 500). This proceeds upwards immediately beneath the ependyma of the ventricular floor on the dorsal aspect of the medial longitudinal bundle, and along the medial side of the abducent nucleus for a distance of about five millimetres. Then the nerve bends laterally at a right angle, and curves a second time over the dorsal aspect of the abducent nucleus. This gives rise to a prominent hemispheral projection in the floor of the fourth ventricle, the **colliculus facialis** (Fig. 500 and Fig. 456, p. 551). The nerve now passes straight to the place of exit from the brain, and this part of the intrapontine trunk may be termed the emergent portion (Figs. 468 and 500). The facial nerve thus forms a curved loop over the dorsal aspect of the abducent nucleus. The **emergent part** of the nerve takes an oblique course through the pons to reach the surface. It inclines laterally and downwards as it proceeds towards the ventral aspect of the pons, and on its way it passes between its own nucleus and the tractus spinalis of the trigeminal nerve.

Entering the facial nucleus, and ending in fine terminal arborisations around its cells, are many fibres from the opposite pyramidal tract; fibres from the spinal tract of the fifth nerve; fibres from the corpus trapezoideum, etc. The nucleus is thus brought into connexion with the motor area of the cerebral cortex, with the trigeminal nerve or sensory nerve of the face, and with the acoustic nerve.

The peculiar course of the efferent fibres of the facial nerve within the pons is to be explained in accordance with the general principle regulating migrations of nerve-cells, to which reference has already been made (p. 555). In the embryo the nucleus facialis develops alongside the nucleus abducens. The latter, controlling one of the eye-muscles, receives most of its afferent impulses from the medial longitudinal bundle (descending from the optic centres in the superior colliculus), and therefore it remains alongside the medial longitudinal bundle and perhaps moves slightly upwards, *i.e.* towards the mesencephalon. The facial nucleus, however, receives most of its stimuli from the nucleus tractus spinalis nervi trigemini, and therefore, as the walls of the metencephalon thicken during their growth, this nucleus retains its proximity to the trigeminal nucleus (Fig. 500), and so migrates along a course which remains mapped out by its emerging fibres. Streeter, working with human embryos, and Ariëns-Kappers, on comparative and therefore broader lines, have elucidated the meaning of this peculiar intracentral course of the facial nerve.

Nervus Abducens (Figs. 468 and 500). — The **abducens nerve** is a small motor nerve which emerges from the brain at the inferior border of the pons above the lateral side of the pyramid of the medulla oblongata. It is the nerve of supply to the lateral rectus muscle of the eyeball. Its **nucleus** of origin is a small spherical mass of gray matter, containing large multipolar cells, which lies in the dorsal part of the tegmental portion of the pons, close to the median plane and immediately subjacent to the gray matter of the floor of the fourth ventricle. Its position can be easily indicated on the ventricular floor, seeing that it is placed subjacent to the colliculus facialis and immediately above the level of the striæ medullares. Its peculiar and intimate relation to the intrapontine portion of the facial nerve has already been indicated. It lies on the ventral aspect of, and within the concavity formed by, the two limbs of the loop of that nerve.

The axons of the multipolar cells of this nucleus emerge from the medial aspect of the nucleus in the form of several bundles, which proceed through the whole dorso-ventral thickness of the pons towards the place of exit. As they pass forwards they incline downwards and slightly laterally. In the dorsal part of the pons they proceed forwards on the medial side of the nucleus olivaris superior, whilst in the basilar part of the pons they keep for the most part to the lateral side of the pyramidal bundles, although several of the nerve fila pierce these on their way to the surface.

It would appear probable that certain of the axons of the cells of the abducens nucleus enter the medial longitudinal fasciculus and proceed upwards in it to end in the oculomotor nucleus of the opposite side. Fibres and collaterals from the basis pedunculi of the opposite side enter the nucleus, and, ending around the cells, bring the nucleus into connexion with the motor area of the cerebral cortex. The pedicle of the nucleus olivaris superior ends partly within the nucleus of the abducent nerve (Fig. 499).

Nervus Trigeminus.—The **trigeminal nerve** strikes its roots deeply into the brain and establishes a connexion with it which extends from the upper part of the mesencephalon above to the level of the second cervical nerve below. No other cerebral nerve presents so extensive a connexion (Fig. 499, p. 595). It is composed of two roots—a large afferent or sensory root and a small efferent or motor root. Both roots appear close together on the surface of the pons, rather nearer its superior than its inferior border, and in the same line as the facial, and glossopharyngeal and vagus nerves (Fig. 497, p. 592).

The **sensory root of the trigeminal nerve** is composed of fibres which arise outside the brain from the cells of the semilunar ganglion. They end within the brain in a somewhat tadpole-shaped terminal nucleus, the swollen body of which is situated in the pons and is termed the main sensory nucleus of the trigeminal nerve:

the tail is a long column of gray matter which is directly continuous below with the substantia gelatinosa of the spinal medulla.

The **main sensory nucleus** (Fig. 501) is an oval mass of gray matter placed half-way up the pons in the lateral part of its dorsal or tegmental portion. It lies close to the lateral surface of the pons and immediately subjacent to the ventral submerged margin of the brachium conjunctivum. It is directly continuous with the substantia gelatinosa, and may be regarded as being merely the enlarged superior end of that column of gray matter.

The fibres of the sensory root of the trigeminal nerve, on reaching the sensory nucleus, divide, in the same way as the fibres of the entering posterior roots of the spinal nerves, into a system of ascending and descending branches (Fig. 499, p. 595). The ascending fibres are short, and almost immediately enter the sensory nucleus and end within it; the descending fibres turn sharply downwards and form the

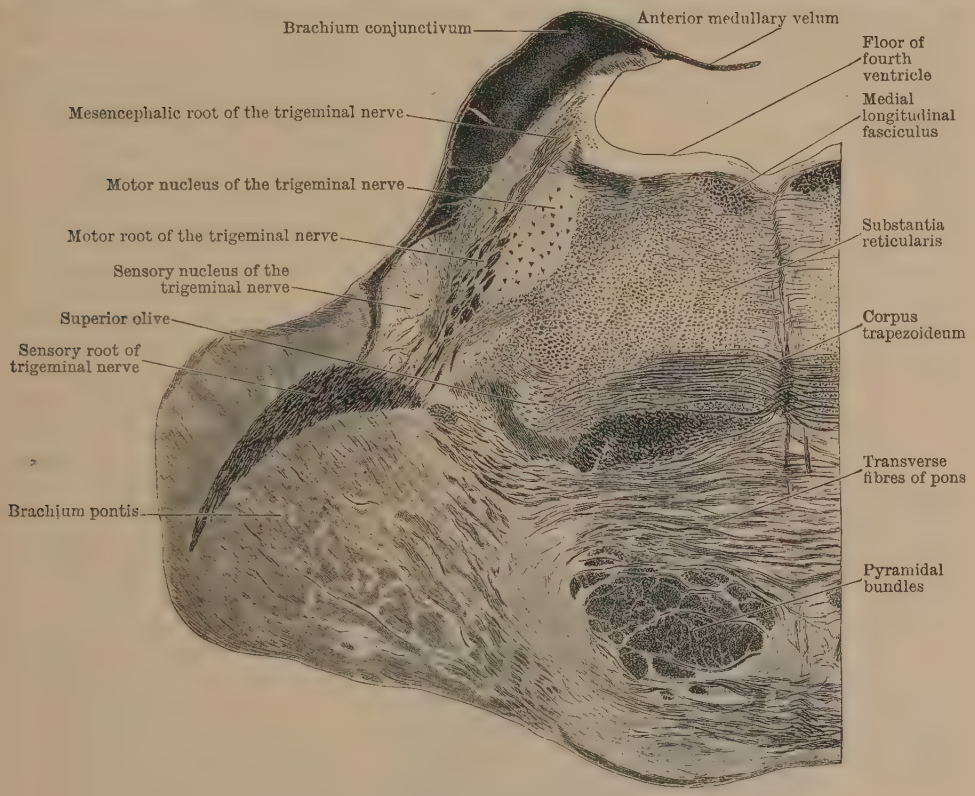

FIG. 501.—SECTION THROUGH THE PONS AT THE LEVEL OF THE NUCLEI OF THE TRIGEMINAL NERVE.

tractus spinalis. This tract descends on the lateral side of the column of gray matter formed by the substantia gelatinosa, which constitutes its terminal nucleus, **nucleus tractus spinalis nervi trigemini.** Fibres constantly leave it to enter the nucleus, so that the lower it gets the smaller does the spinal tract become until, in the upper part of the spinal medulla, about the level of the first or second spinal nerve, it disappears altogether.

The large spinal tract of the trigeminal nerve is a conspicuous object in sections through the pons and medulla oblongata. In the pons it traverses the dorsal or tegmental part, first, between the emergent part of the facial nerve and the vestibular nerve; and then lower down, between the restiform body and the nucleus of the facial nerve (Fig. 468, p. 565). In cross sections it presents a well-defined semi-lunar or curved piriform outline. In the superior part of the medulla oblongata it lies on the ventral aspect of the restiform body, and therefore nearer the surface than in the pons (Fig. 466, p. 562). Here it is traversed and broken up into separate bundles by the olivo-cerebellar fibres and the roots of the glossopharyngeal and vagus nerves.

Finally, it comes to the surface and its fibres are spread over the area on the side of the medulla oblongata known as the tuberculum cinereum of Rolando (Fig. 465, p. 561).

The small **motor part of the trigeminal nerve** is distributed chiefly to the muscles of mastication, and derives its fibres from the motor nucleus.

The **motor nucleus** (Fig. 501) lies in the lateral part of the tegmental portion of the pons, close to the medial side of the main sensory terminal nucleus, but somewhat nearer the floor of the fourth ventricle. It is serially homologous with the motor nuclei of the lateral somatic group, namely, the facial and nucleus ambiguus. It does not become displaced so far forwards as these nuclei, because its chief source of sensory impulses—the terminal nucleus of the trigeminal afferent fibres—is placed alongside it, and there is no need for any definite migration (Fig. 501).

The **mesencephalic root** or **radix descendens nervi trigemini** takes origin from a column of loosely arranged pear-shaped unipolar cells which are placed in the extreme lateral part of the gray matter surrounding the aquæductus cerebri. As this root is traced downwards it gradually increases in size by the accession of new fibres, and it assumes a crescentic form in transverse section (Figs. 471, p. 569; 501, p. 599; 502; and 503, p. 601). In the inferior part of the mesencephalon it lies on the medial side of the brachium conjunctivum; and the trochlear nerve, on its way to the surface, runs downwards in its concavity and on its medial aspect. In the superior part of the pons it continues its course downwards on the lateral and deep aspect of the gray matter in the floor of the fourth ventricle. Finally, reaching the level of the nuclei of the trigeminal nerve, the fibres of the mesencephalic root turn forwards and are said to join the *sensory* part (Johnston) of the trigeminal nerve. Otto May and Horsley, however, confirm the usual description, viz., that it passes into the *motor* root; but, according to them, it cannot be traced beyond the semilunar ganglion.

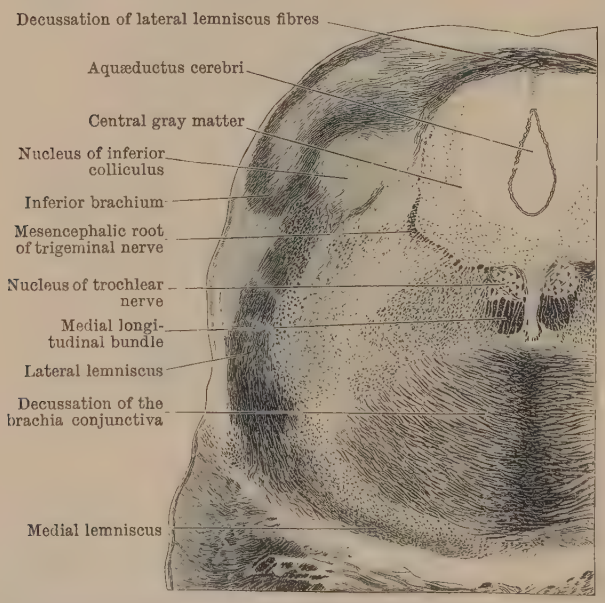

Fig. 502.—Section through the Inferior Colliculus and the Tegmentum of the Mesencephalon at the Level of the Middle Part of the Nucleus of the Trochlear Nerve.

It is customary to describe this mesencephalic root as belonging to the motor division of the trigeminal nerve; but Johnston has recently questioned this and claimed: (1) that its fibres become associated at their exit from the central nervous system with the sensory, and not with the motor, root; (2) that its nucleus develops in the alar and not in the basal lamina; and (3) that the pear-shaped unipolar cells, from which its fibres arise, conform to the sensory and not to the motor type.

The reason why its sensory nature has not been suspected hitherto is no doubt the fact that its fibres arise not in some **ganglion** outside the central nervous system, like other sensory nerves, but from cells in the tectum mesencephali. If Johnston's view is correct, the neural crest in the mesencephalic region must have been drawn into the neural tube during development and given rise to this sensory nucleus of origin (*not* a terminal nucleus) within the central nervous system.

Otto May and Sir Victor Horsley have shown that the mesencephalic root is a mixture of ascending and descending fibres, but there is no evidence to show that the latter may not be sensory like the former. These fibres are supposed to transmit to the brain-stem afferent impulses from the muscles of mastication.

Nervus Trochlearis.—The **trochlear nerve** supplies the superior oblique muscle of the eyeball. It emerges from the brain, on its dorsal aspect, at the superior part of the anterior medullary velum, immediately below the lower border of the inferior colliculus (Fig. 488, p. 582). The **nucleus** from which it arises is a small oval mass of gray matter, placed in the ventral part of the central gray matter, at the level of the superior part of the inferior colliculus. The close association of this nucleus with the medial longitudinal bundle has already been referred to. It is sunk deeply in a bay which is hollowed out on the dorsal and medial aspect of that tract. The nerve has a course of some length within the mesencephalon. The axons of the cells leave the lateral aspect of the nuclear mass, and curve backwards and laterally in the central gray matter until they reach the concave medial surface of the mesencephalic root of the trigeminal nerve. Here they are gathered together into one or two round bundles, which, bending sharply, turn downwards at a right angle and descend on the medial side of the trigeminal root. When the region below the inferior colliculus is reached, the nerve makes another sharp bend. This time it turns medially, enters the superior end of the anterior medullary velum, in which it decussates with its fellow of the opposite side. Having thus crossed the median plane, the trochlear nerve emerges at the medial border of the brachium conjunctivum. The course pursued by the trochlear nerve within the central gray matter may be traced by examining in succession Fig. 502; Fig. 503; Fig. 472, p. 570; and Fig. 483, p. 577.

Nervus Oculomotorius.—The **oculomotor nerve** supplies the levator palpebræ superioris, all the ocular muscles, with the exception of the superior oblique and the lateral rectus, and also two muscles within the eyeball, viz., the sphincter iridis and the musculus ciliaris. The **nucleus** of origin is placed in the ventral part of the central gray matter subjacent to the superior colliculus (Fig. 491, p. 585). In length it measures from 5 to 6 mm. Its inferior end is partially continuous with the nucleus of the trochlear nerve, whilst its superior end extends upwards for a short distance beyond the mesencephalon into the gray matter on the side wall of the third ventricle. Its relation to the medial longitudinal bundle is even more intimate than that of the trochlear nucleus. It is closely applied to the dorsal and medial aspect of this strand; many of its cells occupy a position in the intervals between the nerve-bundles of the tract, and some even are seen on its ventral or tegmental aspect. The axons of the nuclear cells leave the nucleus in numerous bundles, which describe a series of curves as they proceed forwards through the medial longitudinal bundle, the tegmentum, red nucleus, and medial margin of the substantia nigra, to emerge finally from the brain-stem along the bottom of the sulcus oculo-motorius on the medial aspect of the basis pedunculi.

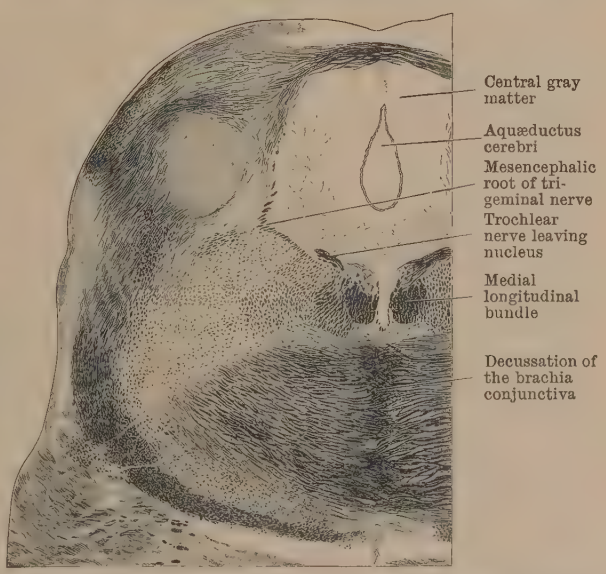

Fig. 503.—Section through the Inferior Colliculus and the Tegmentum of the Mesencephalon at the Level of the Inferior Part of the Nucleus of the Trochlear Nerve.

The cells of the oculomotor nucleus are not uniformly distributed throughout it. They are grouped into several more or less distinct collections or clumps, some of which possess cells which differ in size and appearance from the others. These cell-clusters are very generally believed to possess a definite relation to the several branches of the nerve and the muscles which they supply. Perlia

recognises no less than seven such cell-clusters in each nucleus, with a small median nucleus placed accurately on the median plane, and from which fibres for both nerves spring. Whilst the majority of the fibres in the oculomotor nerve arise from the cell-groups which lie on its own side of the median plane, it has been satisfactorily established that a certain proportion of its fibres are derived from the nucleus of the opposite side, thus forming a crossed connexion and giving rise to a median decussation. These crossed fibres are supposed by some to supply the medial rectus muscle; and we have seen that there is reason to believe that the part of the nucleus from which these fibres are derived stands in connexion through the medial longitudinal fasciculus with the abducens nucleus from which proceeds the nerve of supply for the lateral rectus muscle. The harmonious action of the medial and lateral recti in producing the conjugate movements of the eyeballs is thus explained.

The oculomotor nucleus is connected—(1) with the occipital part of the cerebral cortex by fibres which reach it through the optic radiation; (2) with the vestibular, trochlear and abducent nuclei (and probably with other nuclei) by fibres which come to it through the medial longitudinal bundle; (3) possibly with the facial nerve by fibres which pass out from it into the medial longitudinal bundle (p. 587); (4) with the visual system by fibres which enter it from the cells of the superior colliculus.

It is important to recognise that although the main part of the oculomotor nucleus belongs to the medial somatic group, which also includes the trochlear, abducent and hypoglossal nuclei, it also includes a representative (the Edinger-Westphal group of small cells) of the column of splanchnic efferent nuclei in series with those of the facial, glossopharyngeal, and vagus nerves. Its axons pass out along with the other fibres of the oculomotor nerve and enter the ciliary ganglion, where they end in relationship with the cells that innervate the ciliary muscle and the circular muscle of the iris.

Nervus Acusticus.—This large nerve enters the brain at the inferior border of the pons. Its fibres spring from bipolar ganglionic cells in the immediate neighbourhood of the labyrinth or internal ear (see section dealing with the Organs of Sense). One group of these forms the **spiral ganglion**, the peripheral branches of which are distributed to the organ of Corti in the cochlea: another group constitutes the **vestibular ganglion** (often called **Scarpa's**), which distributes fibres to the ampullæ of the semicircular ducts, the utricle, and the saccule. Although the central processes of the cells in these two ganglia accompany one another and are known collectively as the acoustic nerve they really remain distinct throughout, in their mode of termination in the brain as well as in their peripheral distribution. Reaching the brain the acoustic nerve divides into two parts, viz., the nervus cochlearis and the nervus vestibularis, which present totally different connexions, corresponding to their distinct functions. In their further course these two divisions deviate from each other so as to embrace the restiform body — the vestibular part entering the pons on the medial aspect of the restiform body, whilst the cochlear part sweeps round its lateral surface. Special nuclei of termination require to be studied in connexion with each part of the nerve.

The **cochlear nerve** is composed of finer fibres than the vestibular nerve, and its fibres acquire their medullary sheaths at a later period. It is the true nerve of hearing, and its fibres end in a nucleus which lies in intimate relation to the restiform body. It may be described as consisting of two parts. Of these one, called the **dorsal cochlear nucleus**, is a piriform mass which is placed on the dorsal aspect of the restiform body—between it and the flocculus of the cerebellum. The second part, termed the **ventral cochlear nucleus**, is placed on the ventral aspect of the restiform body in the interval between the cochlear and vestibular divisions of the acoustic nerve, after they have separated from each other. The fibres of the cochlear nerve enter these two ganglia and end around the cells in arborisations, which are finer, closer, and more intricate than those met with in any other nerve-ending in the brain.

The **vestibular nerve** enters the brain at a slightly higher level than the cochlear nerve and on the medial aspect of the ventral cochlear nucleus. It proceeds backwards through the pons between the restiform body, which lies on its lateral

side, and the spinal tract of the trigeminal nerve, which is placed on its medial side. Its fibres end in a series of terminal nuclei (Fig. 499, p. 595), viz.: (1) the **nucleus vestibularis dorsalis**, often known as the principal nucleus, (2) its inferior prolongation, **nucleus tractus descendentis**, (3) the **nucleus vestibularis lateralis** (*Deiters'*), (4) the **nucleus vestibularis superior** (*Bechterew's*), and (5) the cerebellar cortex.

The **principal nucleus** (Figs. 468, p. 565, and 504, p. 603) is a large diffuse nuclear mass, which lies in the floor of the fourth ventricle subjacent to the surface district known as the **area acustica** (Fig. 456, p. 551). It is situated, therefore, in both the pons and the medulla oblongata to the lateral side of the fovea superior and the fovea inferior. In transverse section it is prismatic in outline, and crossing the surface of its upper or pontine part immediately under the ependyma of the ventricle are the striæ medullares.

When the nervus vestibularis, as it traverses the brain, reaches the medial aspect of the dorsal portion of the restiform body, its fibres bifurcate to form ascending and descending tracts. The latter pass vertically downwards in separate bundles and form the descending tract of the vestibular nerve (Figs. 468, p. 565; 466, p. 562; and 499, p. 595). This proceeds through the inferior part of the pons into the medulla oblongata, in which it may be traced as far as the level of the decussation of the medial lemniscus. Associated with the descending tract there is a column of gray matter, with nerve-cells strewn sparsely throughout it. This is the **nucleus of the descending tract**, and the fibres end in fine arborisations around these nerve-cells.

Some of the ascending fibres of the vestibular nerve end in the **nucleus lateralis**. This nucleus is composed of a number of large and conspicuous multipolar nerve-cells, which are scattered amidst the bundles of the vestibular nerve. As it is traced upwards into the pons the nucleus gradually inclines backwards, and finally it occupies a place in the side wall of the fourth ventricle. It attains its greatest development at the level of the emerging part of the facial nerve and this upper part is sometimes termed the **nucleus superior.**

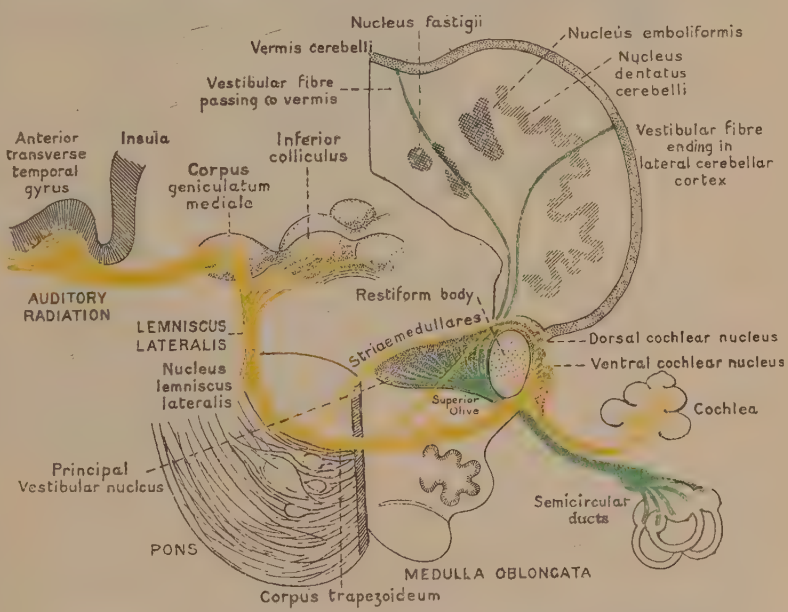

FIG. 504.—CENTRAL CONNEXIONS OF THE COCHLEAR AND VESTIBULAR DIVISIONS OF THE ACOUSTIC NERVE.

Vestibular fibres green. Cochlear fibres yellow.

Other ascending fibres pass without interruption into the cerebellum to terminate in the cortex of the vermis and hemisphere. In their course many of these fibres pass through the nucleus fastigii, and many writers describe them as terminating in this nucleus; but according to Ramon y Cajal they merely traverse it on their way to the cerebellar cortex.

From the large-celled **nucleus lateralis**—best known as **Deiters' nucleus**—a strand of fibres passes medially to reach the medial longitudinal fasciculus, of which it forms one of the most important constituent elements. Some of these fibres pass

upwards to the nuclei of the oculomotor, trochlear, and abducens nerves; others downwards, probably to the nucleus of the accessory nerve, which are concerned in regulating the movements of the eyes and the head respectively, because they need to be thus closely linked to the receptive nucleus of the nerve (vestibular), which is concerned with the appreciation of movements of the head and the position of the body in space. Other fibres arise from the lateral nucleus and pass directly to the spinal medulla without passing through the medial longitudinal bundle; they form the **fasciculus vestibulospinalis**, which passes downwards in the funiculus anterior and distributes fibres to the various motor nuclei in the anterior column of the spinal medulla (Fig. 494, p. 588, and Fig. 448, p. 535).

The **nucleus superior (Bechterew's nucleus)** likewise emits a group of fibres

which pass directly to the mid-brain (**fasciculus vestibulomesencephalicus**), chiefly to the oculomotor and trochlear nuclei (Fig. 494, p. 588).

Central Connexions of the Cochlear Nerve.—The cochlear nuclei are brought into connexion with the inferior colliculus and the medial geniculate body of the opposite side by the fibres of the corpus trapezoideum and the lateral lemniscus.

The fibres of the cochlear nerve end in the ventral cochlear nucleus and in the dorsal cochlear nucleus (tuberculum acusticum). From the cells of these nuclei two tracts arise, viz., a **ventral tract**, composed of the fibres of the corpus trapezoideum, and a **dorsal tract**, which is represented by the striæ medullares.

The **corpus trapezoideum** (Figs. 500 and 501) is formed of the axons of the cells of the ventral cochlear nucleus, as well as certain of the axons of the cells of the dorsal nucleus. In the midst of the corpus trapezoideum are lodged large cells which are known as the *nucleus trapezoideus*, and these give off axons which join the strand with which they are associated. Many of the fibres of the corpus trapezoideum end in a large mass of gray matter called the **nucleus olivaris superior**, which is placed immediately behind the

trapezoid body. The trapezial fibres cross the median plane and decussate with the corresponding fibres of the opposite side. Reaching the opposite superior olivary nucleus, more fibres leave the trapezoid body, and almost immediately after this the strand bends upwards and forms the **lemniscus lateralis** (Figs. 504, p. 603; 506, p. 605). But still another nucleus is interposed in its path, viz., the **nucleus lemnisci lateralis.** Here some fibres are dropped, whilst from the nuclear cells others are acquired, and the lateral lemniscus then proceeds upwards until it reaches the inferior colliculus and the medial geniculate body, in which its fibres end.

Other fibres arise from the cells of the dorsal cochlear nucleus, and arrange themselves in the conspicuous bundles which sweep round the dorsal aspect of the restiform body and proceed medially across the floor of the fourth ventricle, often immediately

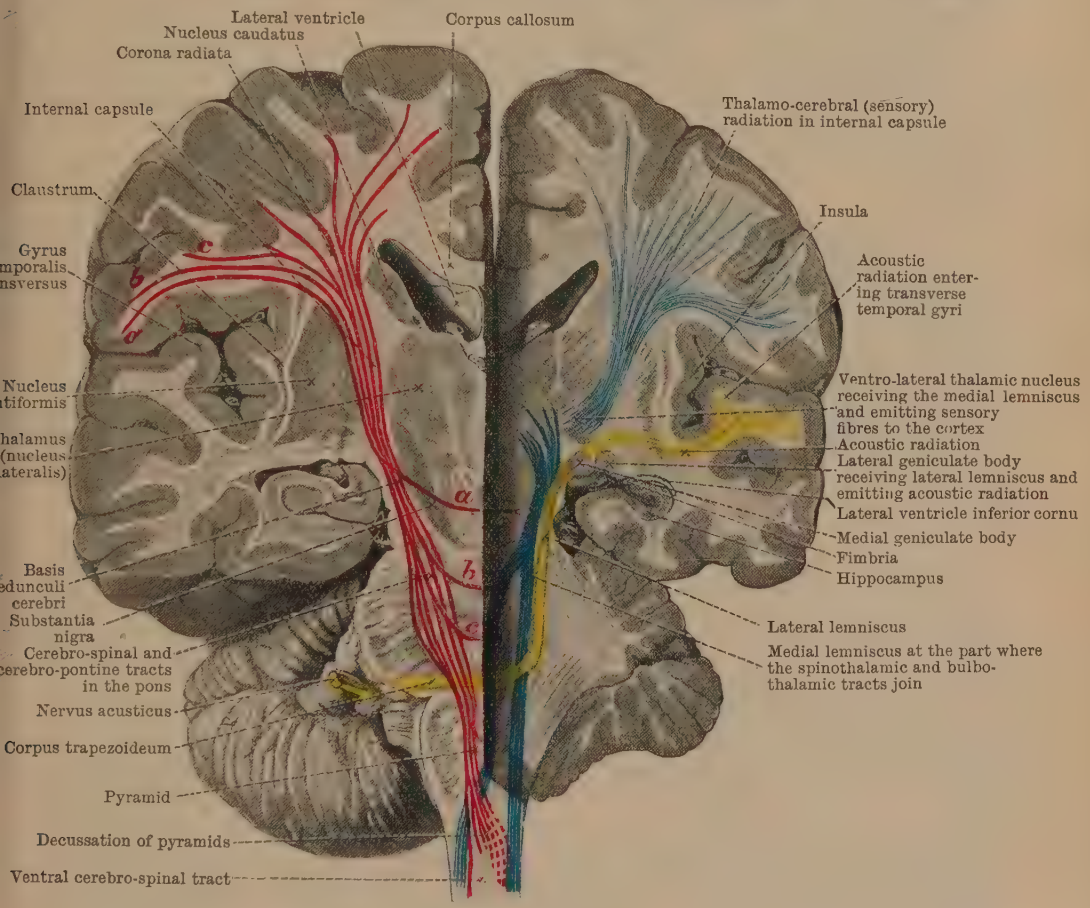

FIG. 506.—A VERTICAL TRANSVERSE SECTION OF THE BRAIN TO SHOW THE WHOLE OF THE CENTRAL ACOUSTIC PATH. The left hemisphere (right side of the figure) is cut on a plane posterior to that of the right. Motor fibres red. Sensory fibres blue. Acoustic fibres yellow.

beneath the ependyma (Fig. 456, p. 551). Reaching the median plane they dip forwards into the substance of the pons, and, crossing the median plane, they join the lateral lemniscus. It is important to remember that the striæ medullares are not always visible in the floor of the fourth ventricle (Fig. 504), but are often buried more or less deeply.

The connexion between the terminal cochlear nuclei and the inferior colliculus is not altogether with that of the opposite side, as the foregoing description and the diagram (Fig. 503) might lead one to infer. A few fibres pass directly to the inferior colliculus of the same side, but none to the corresponding medial geniculate body: the connexion with the latter is entirely *crossed* (Ferrier and Turner).

From the medial geniculate body there proceeds a tract to the cerebral cortex of the transverse temporal gyri (Heschl's). The whole nervous apparatus is thus linked on to the cerebral cortex, and the succession of neurones which build up the entire chain are therefore: (1) in the cochlea of the internal ear, the bipolar cells of the spiral

ganglion emit axons that terminate in the brain; in (2) the cochlear nuclei, from the nerve-cells of which fibres arise and cross to the lateral lemniscus of the opposite side, proceeding to (3) the medial geniculate body, from which fibres pass to the cerebral cortex.

It must be borne in mind that all the axons of the cells of the superior olive do not join the trapezoid strand. Many leave its dorsal aspect and pass backwards in a group called the **pedicle of the superior olive**, to end in the nucleus of the abducens nerve, and, through the medial longitudinal bundle, in the nuclei of the trochlear and oculomotor nerves. In this way the organ of hearing is brought into connexion with the nuclei which preside over the movements of the eyeballs (Figs. 500, p. 597, and 505, p. 604).

PROSENCEPHALON OR FORE-BRAIN.

The fore-brain vesicle in the embryo has been subdivided, somewhat arbitrarily, into two parts—an anterior, termed the **telencephalon**, and a posterior, called the **diencephalon**, which forms the greater part of the walls of the third ventricle. The extreme anterior part of the third ventricle belongs to the telencephalon, and this includes the anterior wall of the neural tube, which is known as the **lamina terminalis**.

Development of Parts derived from Fore-Brain.

The alar part of each side wall of the telencephalon is pushed out to form a diverticulum, which ultimately constitutes the cerebral hemisphere, and thus, from a very early period, the primitive position of this part of the side wall is indicated by the wide **foramen interventriculare**, or aperture of communication between the cavity of the cerebral hemisphere and the third ventricle (Fig. 507).

The alar part of the side wall of the diencephalon is utilised for the development of the thalamus, the epithalamus, and the metathalamus. Of these the thalamus is derived from the anterior and by far the greatest part of the alar wall. It arises as a large oval swelling, which gradually approaches its fellow of the opposite side, and thus diminishes the width of the third ventricle. Finally, the two bodies sometimes come into contact in the median plane and cohere over an area corresponding to the massa intermedia. This may occur about the end of the second month.

From that section of the side wall to which the name of metathalamus is given the two geniculate bodies arise. Each of these shows, in the first place, as a depression on the inside, and a slight elevation on the outside, of the wall of the diencephalon. As the thalamus grows backwards, it encroaches greatly upon the territory occupied by the geniculate bodies. It thus comes about that in the adult brain the medial geniculate body seems to hold a position on the lateral aspect of the mesencephalon, whilst the lateral geniculate body, viewed from the surface, appears to be a part of the thalamus.

From the epithalamic region of the wall of the diencephalon are developed the pineal body, its peduncle, and the habenular region. These parts are relatively much more evident in the embryonic than in the adult brain. The pineal body appears to be developed as a diverticulum of the posterior part of the roof of the diencephalon, but in reality it is a derivative of the alar lamina. Viewed from the dorsal aspect of the brain-tube, this diverticulum shows, in the first instance, as a rounded elevation, from each side of which a broad ridge runs forwards. This ridge becomes the tænia thalami, whilst in the region of its junction with the pineal elevation the trigonum habenulæ takes shape. The pineal diverticulum ultimately becomes solid, but a small portion of the original cavity is retained as the recessus pinealis of the third ventricle.

The part of the diencephalon and telencephalon which represents the basal lamina (*i.e.* lies below the level of the sulcus hypothalamicus) retains its primitive form, and undergoes only slight change. Consequently, when this region in the adult brain is compared with the corresponding region in the embryonic brain, the resemblance between the two is very striking.

In the fore-brain, therefore, it is the alar lamina which plays the predominant part in the formation of the cerebrum. The value, also, of the basal part of the wall of this portion of the neural tube is still further reduced by the fact that it no longer contains the nuclei of origin of efferent nerves. The highest of these nuclei (the oculomotor) is placed in the mesencephalon. [Johnston has recently announced the discovery of a sensory nerve (*nervus terminalis*) attached to the fore-brain in human embryos; and of course the optic and olfactory nerves enter the fore-brain.]

The region of the fore-brain which lies below the sulcus hypothalamicus is termed the hypothalamus. The part of this which corresponds to the diencephalon is called the pars mamillaris hypothalami, whilst the part in front, which belongs to the telencephalon, receives the name of pars optica hypothalami. From the pars mamillaris hypothalami are derived the corpus mamillare and a portion of the tuber cinereum. With the pars optica hypothalami are associated the following parts, viz., the tuber cinereum, with the infundibulum and the cerebral part of the hypophysis, the optic chiasma, the optic recess, and the lamina terminalis. The corpora mamillaria form, in the first instance, a relatively large ventral bulging of the floor of the brain-tube. As development goes on this bulging becomes relatively small, and about the

fourth month the single projection becomes divided into the two tubercles. The infundibulum and posterior or cerebral lobe of the hypophysis are developed as a hollow downward diverticulum of the floor of the telencephalon (Fig. 507). A portion of the original cavity is retained in the upper part of the infundibulum, and constitutes the infundibular recess in the floor of the third ventricle.

The optic nerve is formed chiefly by the passage of fibres backwards from the retina in the wall of the original optic stalk, whilst the chiasma takes form by the transit of fibres across the median plane in front of the infundibulum and behind the optic recess. To a large extent these fibres are derived from the optic nerve. The optic recess of the third ventricle marks the spot where the hollow optic vesicle was originally attached to the inferior and lateral part of the fore-brain, and in the adult it therefore represents a portion of the primitive cavity of the tubular stalk of the optic vesicle. In the course of development the optic nerve fibres, which appear in the stalk of the optic vesicle to form the optic nerve, seek an attachment much further back, and through the optic tract they are even carried as far as the mesencephalon.

The **roof of the fore-brain** remains thin, and does not proceed to the development of nervous elements, although its posterior part becomes invaded by nervous tissue to form the pineal body and the posterior commissure. In front of these structures the roof of the fore-brain is epithelial, and remains so during life. It constitutes the epithelial roof of the third ventricle, and it becomes involuted along the median plane into the cavity to form the chorioid plexuses of the ventricle (Fig. 517, p. 619). The posterior commissure appears as a transverse thickening at the bottom of a transverse groove which appears in the roof of the early brain-tube, behind the pineal diverticulum.

M, Mamillary eminence; Tc, Tuber cinereum; Hp, Hypophysis (hypophyseal diverticulum from buccal cavity); Opt, Optic stalk; TH, Thalamus; Tg, Tegmental part of mesencephalon; Ps, Pars hypothalamica; Cs, Corpus striatum; FM, Foramen interventriculare; L, Lamina terminalis; RO, Recessus opticus; Ri, Recessus infundibuli.

PARTS DERIVED FROM THE DIENCEPHALON.

Under this heading we have to consider: (1) the **thalamus**; (2) the **epithalamus**, which comprises the pineal body and the habenular region; (3) the **metathalamus**, or the corpora geniculata; and (4) the **hypothalamus**.

The hypothalamus consists of two portions, viz., the **pars mamillaris hypothalami**, which comprises the corpus mamillare and the portion of the central gray matter which forms the floor of the third ventricle in its immediate vicinity; and the **pars optica hypothalami**, which embraces the tuber cinereum, the infundibulum, the hypophysis (O.T. pituitary body), and the lamina terminalis. Strictly speaking, the optic part of the hypothalamus does not belong to the diencephalon, but it is convenient to study the parts which it represents at this stage.

The original cavity of that part of the brain-tube which forms the diencephalon is represented by the greater part of the third ventricle of the brain.

Thalamus.—The thalamus is the principal object in this section of the brain

(Fig. 507). It is a large ovoid mass of gray matter, which lies obliquely across the path of the cerebral peduncle as it descends from the cerebral hemisphere. The smaller anterior end of the thalamus lies close to the median plane, and is separated from the corresponding part of the opposite side only by a very narrow interval. The enlarged posterior ends of the two thalami are placed more widely apart, and in the interval between them the corpora quadrigemina are situated.

The two thalami, in their anterior two-thirds, lie close together, one on each side of the deep median cleft which receives the name of the third ventricle of the brain. The inferior and lateral aspects are in apposition with, and, indeed, directly connected with, adjacent parts of the brain, and on this account it is customary to study them by means of sections through the brain. The superior and medial surfaces are free.

The *lateral surface* of the thalamus is applied to a thick layer of white matter interposed between it and the lentiform nucleus, called the **internal capsule**, and composed of fibres passing both upwards towards and downwards from the cerebral cortex. A large proportion of these fibres descend to form the basis pedunculi. From the entire extent of the lateral surface of the thalamus large numbers of fibres stream out and enter the internal capsule, to reach the cerebral cortex. They constitute what is termed the **thalamic radiation**. As the fibres leave the thalamus, over the whole of the lateral surface of the ganglionic mass they form a very distinct reticulated zone or stratum, which is termed the **external medullary lamina**.

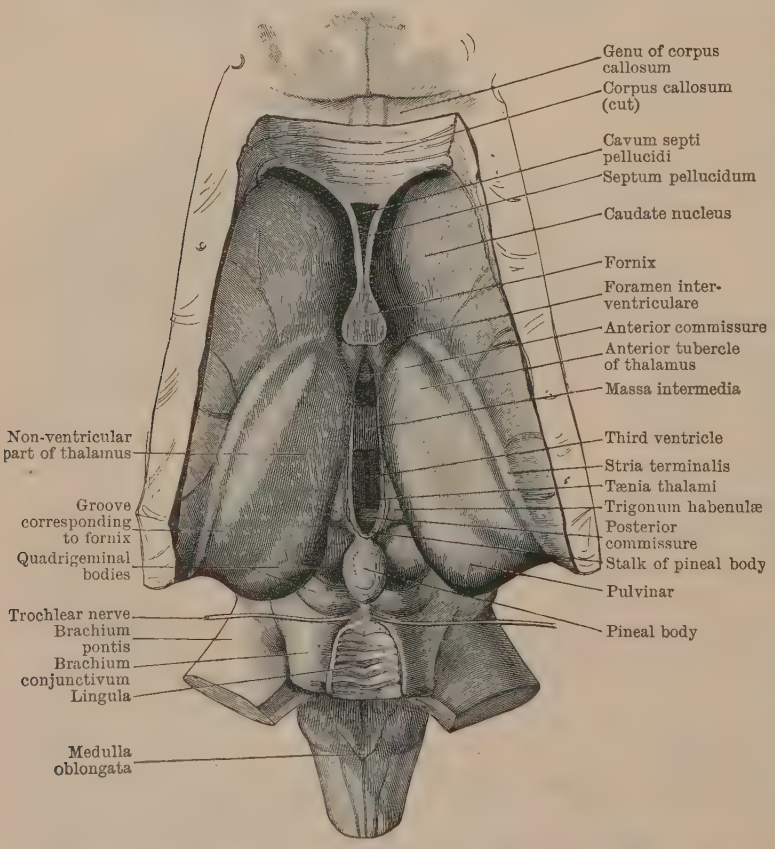

FIG. 508.—THE THALAMI AND THE PARTS OF THE BRAIN SURROUNDING THEM. Superior aspect.

The *inferior surface* of the thalamus rests on the hypothalamus. From the latter region many fibres enter the thalamus on its inferior aspect, whilst other fibres leave this surface of the thalamus to take part in the thalamic radiation.

The *superior surface* of the thalamus is free. Laterally it is bounded by a groove, which traverses the floor of the lateral ventricle of the brain and intervenes between the thalamus and the caudate nucleus. In this groove is placed a slender band of longitudinal fibres, termed the stria terminalis, and in its forepart the vena terminalis. Medially, the superior surface of the thalamus is separated from the medial surface in its anterior half by a sharp edge or prominent ledge of the ependyma of the third ventricle. This is termed the **tænia thalami**, and the ridge which it forms is accentuated by the

presence of a subjacent longitudinal strand of fibres called the **stria medullaris**. When these two structures, viz., the ependymal ridge and the subjacent stria, are traced backwards, they are seen to turn medially and become continuous with the stalk or peduncle of the pineal body. Behind the portion of the tænia thalami which turns medially towards the pineal body a small depressed triangular area, the **trigonum habenulæ**, situated in front of the superior colliculus, forms a very definite medial boundary for the posterior part of the superior surface of the thalamus.

The superior surface of the thalamus is slightly bulging or convex, and is of a whitish colour, owing to the presence of a thin superficial covering of nerve-fibres, termed the **stratum zonale**. It is divided into two areas by a faint oblique groove, which begins in front at the medial border, a short distance behind the anterior extremity of the thalamus, and extends laterally and backwards to the lateral part of the posterior extremity. This groove corresponds to the edge of the fornix. The two areas which are thus mapped out are very differently related to the ventricles of the brain, and also to the parts which lie above the thalamus. The *lateral area*, which includes the anterior extremity of the thalamus, forms a part of the floor of the lateral ventricle. It is covered with ependyma, overlapped by the chorioid plexus of this ventricle, and lies immediately subjacent to the corpus callosum. Along the line of the groove the epithelial lining of the lateral ventricle is reflected over the chorioid plexus of this cavity. The *medial area*, which includes the posterior end of the thalamus, intervenes between the lateral and third ventricles of the brain, and takes no part in the formation of the walls of either. It is covered by a fold of pia mater, termed the tela chorioidea of the third ventricle, above which is the fornix, and these two structures intervene between the thalamus and the corpus callosum.

The *anterior extremity* of the thalamus, called the **tuberculum anterius thalami**, forms a marked bulging. It projects into the lateral ventricle, behind and to the lateral side of the free portion of the column of the fornix. The foramen interventriculare, a narrow aperture of communication between the lateral and third ventricles of the brain, is bounded in front by the column of the fornix and behind by the anterior tubercle of the thalamus.

The *posterior extremity* of the thalamus is very prominent and forms a cushion-like projection, which overhangs the brachia of the corpora quadrigemina. This prominence is called the **pulvinar**. Another oval bulging on the posterior part of the thalamus receives the name of the **corpus geniculatum laterale**. It is situated below, and to the lateral side of, the pulvinar, and presents a very intimate connexion with the optic tract.

The *medial surfaces* of the two thalami are placed close together, and are covered not only by the lining ependyma of the third ventricle, but also by a moderately thick layer of gray matter, continuous below with the central gray substance which surrounds the aquæductus cerebri in the mesencephalon. A band of gray matter, termed the **massa intermedia**, crosses the third ventricle and joins the medial surfaces of the two thalami together.

Intimate Structure and Connexions of the Thalamus.—The upper surface of the thalamus is covered by the **stratum zonale**, a thin coating of white fibres derived to some extent from the optic tract, and probably also from the optic radiation. The medial surface has a thick coating of central gray matter, whilst intervening between the internal capsule and the lateral surface is the **lamina medullaris externa**. The lower surface merges into the hypothalamus.

The gray matter of the thalamus is marked off into three very apparent parts —termed the anterior, the medial, and the lateral thalamic nuclei—by a thin vertical sheet of white matter, continuous with the stratum zonale, termed the **lamina medullaris interna**. The **lateral nucleus** (nucleus lateralis thalami) is by far the largest of the three. It is placed between the medial and the lateral medullary laminæ, and it stretches backwards beyond the medial nucleus, and thus includes the whole of the pulvinar (Fig. 510). The **medial nucleus** (nucleus medialis thalami) reaches only as far back as the habenular region. It is placed between the central gray matter of the third ventricle and the internal medullary lamina. The lateral nucleus is more extensively pervaded by fibres than the medial nucleus.

From the lateral nucleus by far the greatest number of the fibres which form the **radiatio thalami** pass, and these are seen crossing it in various directions towards the lamina medullaris externa. The **anterior nucleus** (nucleus anterior thalami) is the smallest of the three thalamic nuclei. It forms the prominent anterior tubercle, and is prolonged in a wedge-shaped manner, for a short distance, downwards and backwards between the anterior parts of the medial and lateral nuclei. The internal medullary lamina splits into two parts and partially encloses the anterior nucleus. In connexion with its large cells a very conspicuous bundle of fibres, the **fasciculus thalamomamillaris**, comes to an end. [As this bundle arises in the corpus mamillare, it ought to be called "fasciculus mamillo-thalamicus."]

A diffuse gray mass, imperfectly marked off from the inferior surface of the lateral nucleus, receives the name of the *ventral nucleus*. Its inferior part is composed of the **central nucleus of Luys** and the **nucleus arcuatus**. In section the former appears as a circular mass of gray matter, which comes into view immediately behind the point where the internal medullary lamina disappears. It would seem to be intimately connected with fibres which reach it from the red nucleus and from the posterior commissure. These fibres pass round it so as to mark it off from the rest of the thalamus, and in front of the nucleus many of them enter the internal medullary lamina. The **nucleus arcuatus** is a small semilunar mass of gray matter placed below and to the lateral side of the central nucleus of Luys.

The **connexions of the thalamus** are of an extremely intricate kind. It would appear to be a ganglionic mass interposed between the tegmental corticipetal tracts and the cerebral cortex. In its posterior part, and through its stratum zonale, it also has important connexions with the optic tract. The corticipetal tegmental tracts, which enter it from below, will be noticed in connexion with the hypothalamic region. Suffice it to say, for the present, that these fibres end in the midst of the thalamus in connexion with the thalamic cells. In addition to these, enormous numbers of fibres, arising within the thalamus as the axons of its cells, stream out from its lateral and inferior surfaces to form the thalamic radiation. These **thalamo-cortical fibres** pass to every part of the cortex; and although there is no separation of them into distinct groups as they leave the thalamus, it is customary to regard them as constituting a frontal stalk, a parietal stalk, an occipital stalk, and a ventral stalk. But fibres from the cortex, **cortico-thalamic fibres**, likewise stream into the thalamus in large numbers, and end in fine arborisations around its cells. A double connexion with the cerebral cortex is thus established by the thalamus.

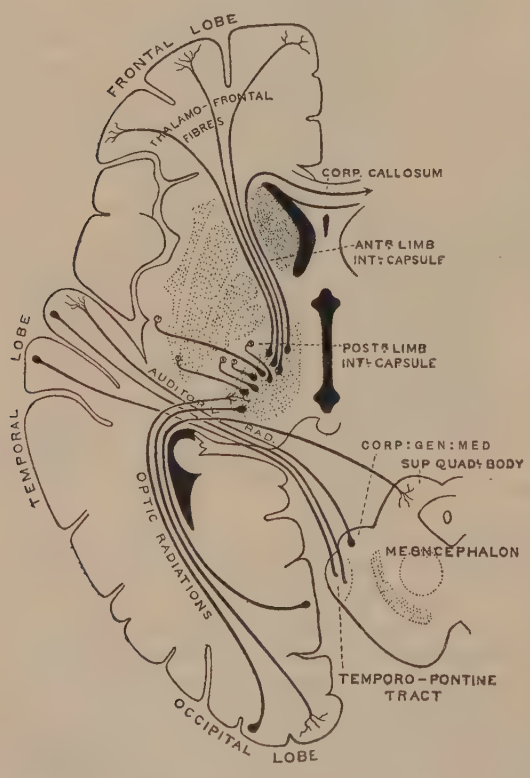

FIG. 509.—SCHEMA. Founded on the observations of Flechsig, and Ferrier and Turner.

The **frontal stalk** of the thalamic radiation emerges from the anterior part of the lateral surface of the thalamus and passes through the anterior limb of the internal capsule, to reach the cortex of the frontal lobe. Many of these fibres end in the caudate and lentiform nuclei, between which they proceed. The **parietal stalk** issues from the lateral surface of the thalamus, and, passing through the internal capsule (and to some extent, also, through the lentiform nucleus and the external capsule), gains the cortex of the posterior part of the frontal lobe and of the parietal lobe. The **occipital stalk** emerges from the lateral aspect of the pulvinar and constitutes the so-called optic radiation. These fibres sweep laterally and backwards round the lateral side of the posterior horn of the lateral ventricle to gain the cortex of the occipital lobe. The

ventral stalk streams out from the under aspect of the anterior part of the thalamus, in front of the hypothalamic tegmental region and the corpus mamillare. Its fibres arise in both the medial and lateral nuclei, and sweep downwards and laterally to reach the region below the lentiform nucleus. One very distinct band which lies dorsal to the other fibres **(ansa lenticularis)** comes from the lentiform nucleus to the thalamus, whilst the remainder **(ansa peduncularis)** proceed in a lateral direction from the thalamus below the lentiform nucleus and gain the cortex of the temporal lobe and of the insula.

Flechsig divides the thalamo-cortical fibres of ordinary sensation into three sensory systems. These he has been able to distinguish by studying the order in which they assume their sheaths of myelin in the fœtus and infant.

Ferrier and Turner, by the degenerative method of investigation, corroborate Flechsig's results. They confirm the observation of Flechsig that, while thalamic fibres are distributed to the several regions of the cerebral cortex to an almost equal extent, there is one district, viz., the frontal pole, to which the supply is scanty. Another very important result has been obtained by these authors. They have established the fact that many of the thalamic fibres cross the median plane in the corpus callosum, and thus gain the cortex of the opposite cerebral hemisphere. Hamilton's crossed callosal tract thus receives confirmation.

Intimate Structure of the Corpus Geniculatum Laterale.—Sections through the lateral geniculate body reveal the fact that it is composed of a series of alternately placed gray and white curved laminæ. This gives it a very characteristic appearance. The white laminæ are composed of fibres which enter the body from the optic tract. The connexions of the geniculate bodies will be studied with the optic tract.

Hypothalamic Region.—The tegmental part of the pedunculus cerebri is prolonged upwards and assumes a position below the posterior part of the thalamus. The **red nucleus** is a conspicuous object in sections through the lower part of this region (Fig. 510). It presents the same appearance as lower down in the mesencephalon, and, gradually diminishing, it disappears before the level of the corpus mamillare is reached. Carried up around it are the same longitudinal tracts of fibres which have been studied in relation to it in the tegmental part of the mesencephalon. Certain of these fibres, placed in immediate relation to the red nucleus, form a coating or capsule for it. This coating is partly derived from those fibres of the brachium conjunctivum which pass directly up into the thalamus and also partly from fibres which issue from the nucleus itself. The **medial lemniscus**, also, which in the superior part of the mesencephalon is observed to take up a position on the lateral and dorsal aspect of the red nucleus, maintains a similar position in the hypothalamic region. When the red nucleus comes to an end these various fibres are continued onwards and form, in the position previously occupied by the nucleus, a very evident and dense mass of fibres. The fibres of the medial

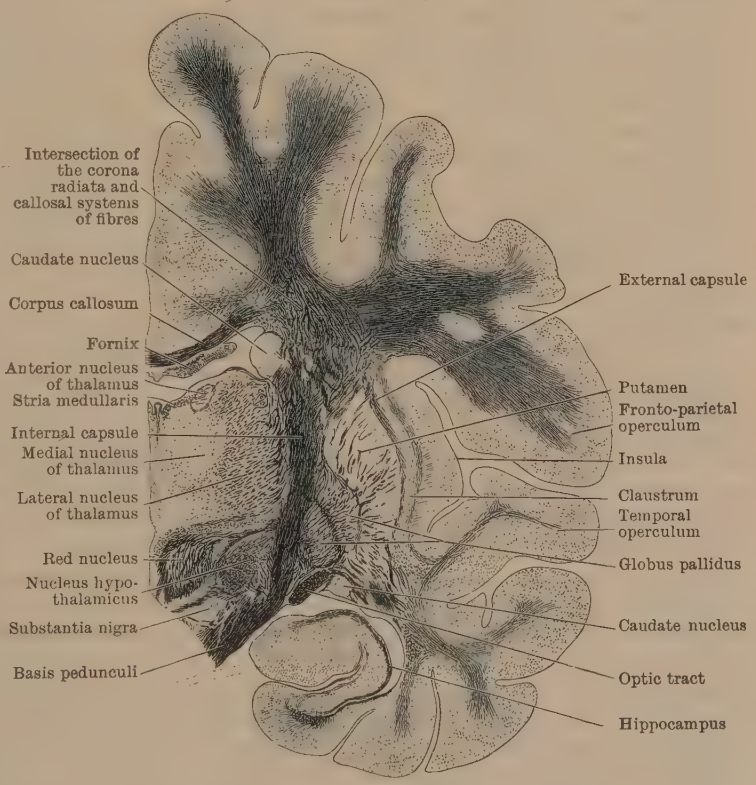

FIG. 510.—FRONTAL SECTION THROUGH THE CEREBRUM OF AN ORANG PASSING THROUGH THE HYPOTHALAMIC TEGMENTAL REGION.

lemniscus, of the brachium conjunctivum, and of the red nucleus are prolonged upwards into the ventral part of the thalamus, where they end in connexion with the thalamic cells (ventro-lateral nucleus).

The **substantia nigra** is likewise carried into the hypothalamic region, where it maintains its original position on the dorsal aspect of the basis pedunculi. As it is traced upwards, it is seen gradually to diminish in amount. It shrinks from the medial to the lateral side, and finally disappears when the posterior part of the corpus mamillare is reached.

In frontal sections through the hypothalamic region, the most conspicuous object which comes into view is the **nucleus hypothalamicus** or the **nucleus of Luys** (Fig. 510). It is a small mass of gray matter, shaped like a biconvex lens, which makes its appearance on the dorsal aspect of the basis pedunculi immediately to the lateral side of the substantia nigra. At first it lies in an angle which is formed by the meeting of the cerebral peduncle and the internal capsule; but, rapidly enlarging in a medial direction, it takes the place of the diminishing substantia nigra on the dorsal surface of the basis pedunculi at the level of the inferior part of the corpus mamillare. The nucleus hypothalamicus is rendered all the more evident by the fact that it is sharply defined by a thin capsule of white fibres. On its medial aspect these fibres proceed medially and form a very evident decussation across the median plane in the floor of the third ventricle, immediately above the posterior ends of the corpora mamillaria.

The nucleus hypothalamicus, in the fresh condition, presents a brownish colour, partly from the fact that its cells are pigmented, and partly also on account of the numerous capillary blood-vessels which pervade its substance.

Corpus Pineale.—This is a small, dark, reddish body, about the size of a cherry-stone and shaped after the fashion of a fir-cone. Placed between the posterior ends of the two thalami, it occupies the depression on the dorsal aspect of the mesencephalon, which intervenes between the two superior colliculi. Its base, which is directed upwards, is attached by a hollow stalk or peduncle. This stalk is separated into a dorsal and a ventral part by the prolongation backwards into it of a small pointed recess of the cavity of the third ventricle. The dorsal part of the stalk curves laterally and forwards, and, on each thalamus, becomes continuous with the tænia thalami; the ventral part is folded round a narrow but conspicuous cord-like band of white matter, which crosses the median plane immediately below the base of the pineal body and receives the name of the **posterior commissure** of the cerebrum (Fig. 451, p. 543).

The pineal body is not composed of nervous elements. The only nerves in its midst are the sympathetic filaments which enter it, with its blood-vessels. It is composed of spherical and tubular follicles, filled with epithelial cells, and containing a variable amount of gritty, calcareous matter.

The pineal body is a rudimentary structure, but in certain vertebrates it attains a much higher degree of development than in man. In the lamprey, lizard, etc., it is present in the form of the so-called pineal eye. In structure it resembles, in these animals, an invertebrate eye, and it possesses a long stalk, in which nerve-fibres are developed. Further, it is carried through an aperture in the cranial wall, and consequently lies close to the surface on the dorsum of the head between the parietal bones.

Trigonum Habenulæ.—The small, triangular, depressed area which receives this name is placed immediately in front of the superior colliculus in the interval between the peduncle of the pineal body and the posterior end of the thalamus (Fig. 508, p. 608). It marks the position of an important collection of nerve-cells, which constitute the **ganglion habenulæ**. The axons of these cells are collected on the ventral aspect of the ganglion into a bundle, called the **fasciculus retroflexus**, which takes a curved course downwards and forwards in the tegmentum of the mesencephalon. The fasciculus retroflexus lies close to the medial side of the red nucleus, and finally comes to an end in a group of cells termed the **ganglion interpedunculare**, situated in the inferior part of the substantia perforata posterior (see p. 589).

The ganglion habenulæ is likewise intimately connected with the striæ medullares (tænia thalami) and the dorsal part of the stalk of the pineal body.

As previously stated, the **stria medullaris**—a very evident band of white

matter—lies on the thalamus, subjacent to the ependymal ridge termed the tænia thalami. When traced backwards, many of the fibres of the stria medullaris are observed to end amongst the cells of the ganglion habenulæ, whilst others are continued past the ganglion to enter the peduncle of the pineal body, and, through it, to reach the ganglion habenulæ of the opposite side, in connexion with the cells of which they terminate. The stria medullaris, therefore, ends partly in the ganglion habenulæ of its own side and partly in the corresponding ganglion of the opposite side. The decussation of fibres across the median plane forms the dorsal part of the pineal stalk or peduncle, and is termed the **commissura habenularum**.

When the stria medullaris is traced in the opposite direction, it is noticed to split into dorsal and ventral parts near the column of the fornix. The *dorsal part* arises from cells in the hippocampus: these fibres pass into the fornix and when they reach its column they turn abruptly backwards to enter the stria medullaris. The *ventral part* springs from a collection of cells in the gray matter on the base of the brain close to the optic chiasma. The striæ medullares are believed to form a part of the olfactory apparatus.

Commissura Posterior.—The posterior commissure is a slender band of white matter, which crosses the median plane under cover of the stalk of the pineal body and overlies the entrance of the aqueduct of the brain into the third ventricle. The fibres which enter into the formation of the posterior commissure are believed to arise in a special nucleus, which is placed in the central gray matter immediately above the oculo-motor nucleus. They decussate with each other across the median plane and thus the commissure is formed. The other connexions of this little band are not satisfactorily established, but Held believes that some of its ventral fibres pass downwards into the medial longitudinal bundle.

Substantia Perforata Posterior.—This has already been described on p. 542. Some delicate bands of white matter, termed the **tænia pontis**, may frequently be seen emerging from the gray matter of this region; they then curve round the pedunculus cerebri in close relation to the superior border of the pons, with which they enter the cerebellum to end in the nucleus dentatus (Horsley).

Corpora Mamillaria.—The corpora mamillaria are two round white bodies, each about the size of a pea, which lie side by side in the interpeduncular fossa on the base of the brain, immediately in front of the substantia perforata posterior.

Each corpus mamillare is coated on the outside by white matter derived from the column of the fornix, and contains, in its interior, a composite gray nucleus with numerous nerve-cells. Several important strands of fibres are connected with the corpus mamillare: (1) The **column of the fornix** curves downwards in the side wall of the third ventricle to reach the corpus mamillare, and its fibres end amidst the cells of that body. (2) A bundle of fibres, the **fasciculus mamillo-thalamicus**, takes origin in the midst of each corpus mamillare and extends upwards into the thalamus, to end in fine arborisations around the large cells in the anterior thalamic nucleus. (3) Another bundle of fibres, the **pedunculus corporis mamillaris**, takes form within the corpus mamillare and extends downwards in the gray matter of the floor of the third ventricle, to reach the tegmentum of the mesencephalon. These tracts, together with the striæ medullares (thalami) and the fasciculi retroflexi, are amongst the most ancient fibre-systems in the brain. They represent the paths by which olfactory impulses may reach the brain-stem, and perhaps the spinal medulla also, and so influence the muscles of the body.

Tuber Cinereum and Infundibulum.—The tuber cinereum is a small, slightly prominent field of gray matter, which occupies the anterior part of the interpeduncular fossa between the corpora mamillaria behind and the optic chiasma in front. From its anterior part the **infundibulum**, or stalk of the hypophysis, projects downwards and connects the hypophysis with the base of the brain. In its upper part the infundibulum is hollow, a small, funnel-shaped diverticulum of the cavity of the third ventricle being prolonged downwards into it.

Hypophysis (O.T. **Pituitary Body**).—This is a small oval structure, flattened from above downwards, and with its long axis directed transversely, which occupies the fossa hypophyseos in the floor of the cranium. It is composed of two

lobes—a large anterior lobe and a smaller posterior lobe, which are closely applied the one to the other. The infundibulum, which extends downwards from the tuber cinereum, is attached to the posterior lobe.

The infundibulum and posterior lobe of the hypophysis are developed in the form of a hollow diverticulum, which grows downwards from the floor of that part of the embryonic brain which afterwards forms the third ventricle. The original cavity of this diverticulum becomes obliterated, except in the superior part of the infundibulum. In structure, the posterior lobe of the hypophysis shows little trace of its origin from the wall of the brain-tube. It is chiefly composed of connective tissue and blood-vessels, with branched cells scattered throughout it (see Ductless Glands).

The anterior lobe has quite a different origin, and may be regarded as the functional part of the hypophysis. It is derived from a tubular diverticulum which grows upwards from the primitive buccal cavity or stomatodæum. Its connexion with the latter (canalis craniopharyngeus) is in the course of time cut off, and the diverticulum becomes encased within the cranial cavity in intimate association with the cerebral portion of the organ. Structurally, it consists of tubules or alveoli, lined with epithelial cells and surrounded by capillary vessels. Its structure is in some respects not unlike that of the parathyreoid bodies. In the disease known as acromegaly, the hypophysis is usually greatly enlarged.

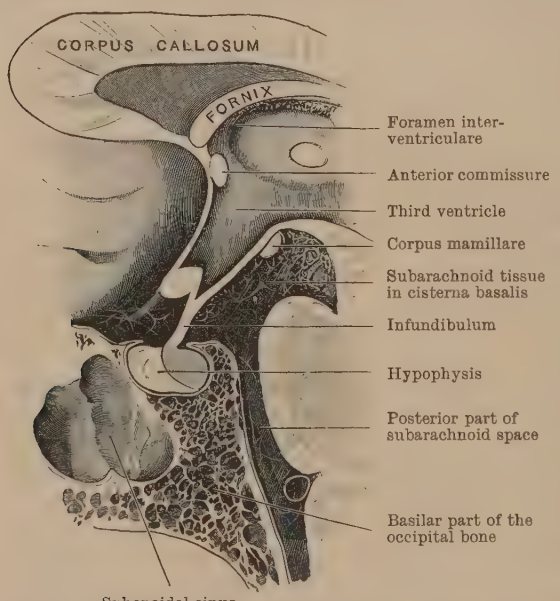

FIG. 511.—MEDIAN SECTION THROUGH THE HYPOPHYSEAL REGION.

Lamina Terminalis.—This is a thin, delicate lamina which may be seen on the basal aspect of the brain, stretching from the upper aspect of the optic chiasma in an upward direction to become connected with the anterior end of the corpus callosum.

Anterior Commissure of the Cerebrum.—In the anterior part of the cleft between the two thalami, and immediately in front of the columns of the fornix, a round bundle of fibres crosses the median plane. This is the anterior commissure.

Ventriculus Tertius. — The **third ventricle** is the narrow cleft which separates the two thalami. Its depth rapidly increases from behind forwards, and it may be said to extend from the pineal body behind to the lamina terminalis in front. Its *floor* is formed by the tuber cinereum and the corpora mamillaria: the gray matter of the substantia perforata posterior, and the tegmenta of the cerebral peduncles may also be looked upon as forming part of the floor (Figs. 511 and 512). It is interesting to note that the central gray matter which surrounds the aqueduct is directly continuous with the gray matter of the substantia perforata posterior and tuber cinereum, and in this way it comes to the surface in the base of the brain. The optic chiasma crosses the floor in front and marks the place where the latter becomes continuous with the anterior wall of the cavity. The *anterior wall* of the third ventricle is formed by the lamina terminalis, which extends upwards from the optic chiasma. The anterior commissure, as it crosses from one side to the other, projects into the ventricle, but, of course, it is excluded from the cavity by the ventricular epithelial lining. It may be taken as indicating the place where the roof joins the anterior wall. The *roof* of the third ventricle is formed by a thin epithelial layer which stretches across the median plane from one tænia thalami to the other, and is part of the thin epithelial lining of the cavity. Applied to the superior surface of the epithelial roof is the fold of pia mater, termed the tela chorioidea, and the roof is invaginated

into the cavity along its whole length by two delicate chorioid plexuses, which hang down from the under surface of this fold. When the pia mater is removed the thin epithelial roof is torn away with it, leaving only the lines of attachment in the shape of the tænia thalami (Fig. 512).

The *side wall* of the third ventricle is formed for the greater part of its extent by the medial surface of the thalamus, covered by a thick layer of central gray matter continuous with the central gray matter of the mesencephalon. A little in front of the middle of the ventricle the cavity is often crossed by the **massa intermedia**, which connects the thalami one with the other, and in front of this the columna fornicis is seen curving downwards and backwards in the side wall. At first the bulging which it forms is distinctly prominent, but it gradually subsides as the strand, on its way to end in the corpus mamillare, becomes more and more sunk in the gray matter on the side of the ventricle.

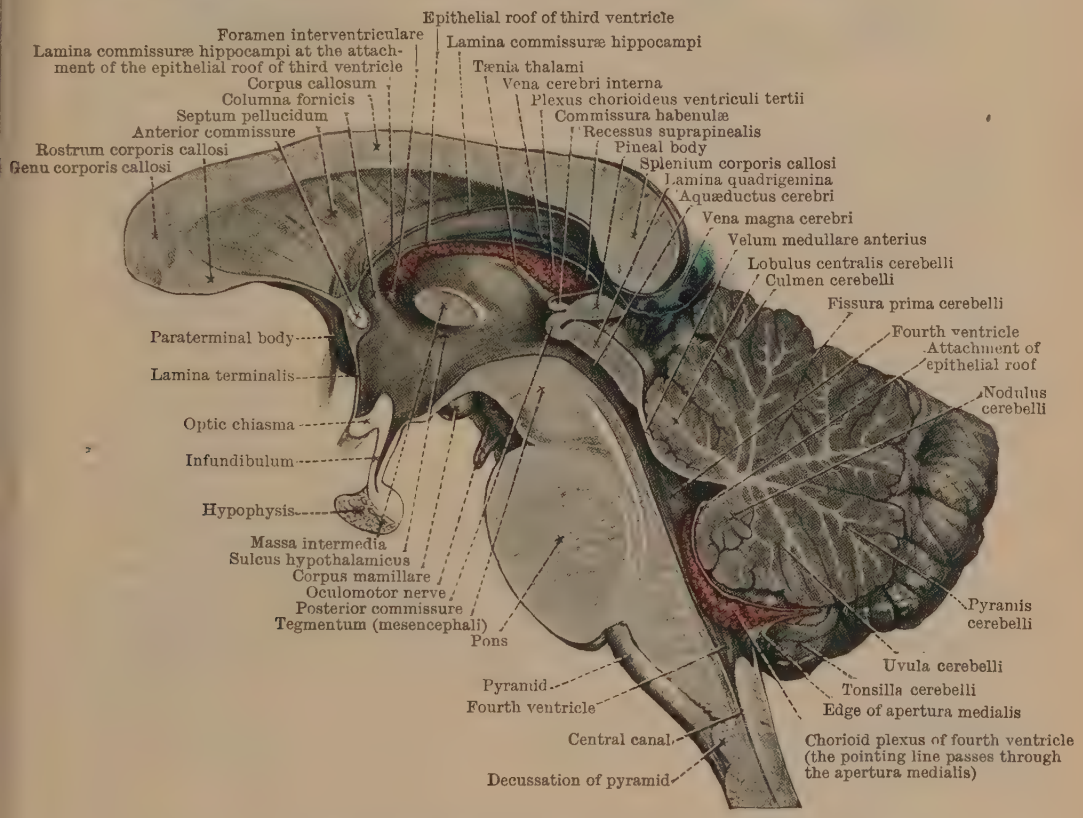

FIG. 512.—THE PARTS OF THE BRAIN CUT THROUGH IN A MEDIAN SAGITTAL SECTION. The side walls of the ventricular cavities are also shown.

The third ventricle communicates with both of the lateral ventricles, and also with the fourth ventricle. The **aquæductus cerebri**, the narrow channel which tunnels the mesencephalon, brings it into communication with the fourth ventricle. The opening of this aqueduct is placed at the posterior part of the floor of the third ventricle, immediately below the posterior commissure. The **foramina interventricularia** bring it into communication with the lateral ventricles. These apertures are placed at the upper and anterior parts of the side walls, and lead laterally and slightly upwards between the most prominent parts of the columns of the fornix and the anterior tubercles of the thalami. They are just large enough to admit a crow-quill, and through these passages the epithelial lining of the three ventricles becomes continuous. From the foramen a distinct groove on the side wall of the ventricle leads backwards towards the mouth of the aqueduct. It is termed the **sulcus hypothalamicus**, and is of interest, inasmuch as

it is considered by His to represent in the adult brain the furrow which divides the side wall of the embryonic brain-tube into an alar and a basal lamina.

The outline of the third ventricle, when viewed from the side in a median section through the brain (Fig. 512), or as it is exhibited in a plaster cast of the ventricular system of the brain (Fig. 513), is seen to be very irregular. It presents several diverticula or recesses. Thus, in the anterior part of the floor there is a funnel-shaped pit or recess, leading

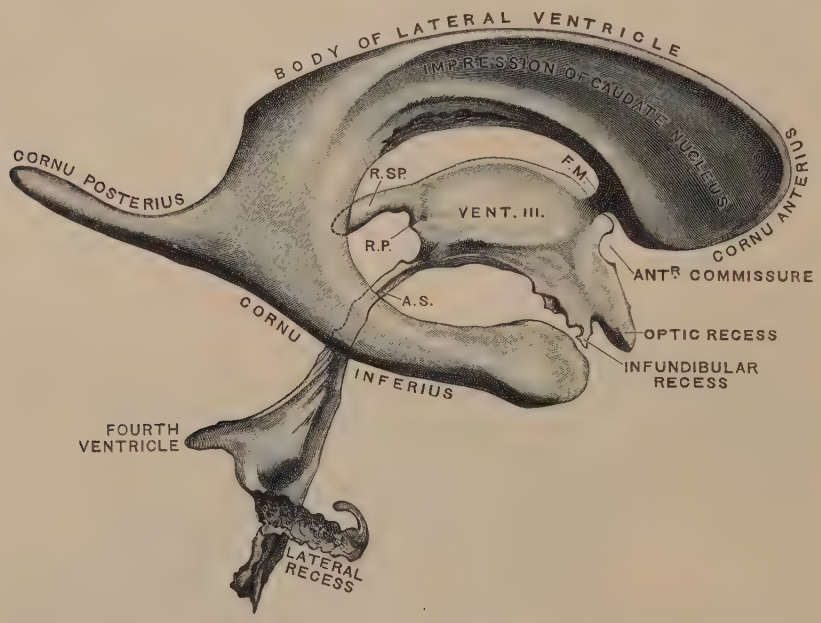

Fig. 513.—Profile View of a Cast of the Ventricles of the Brain. (From Retzius.)

This figure faces in the direction opposite to that of Fig. 512.

R.P. Recessus pinealis. F.M. Foramen interventriculare.

down through the tuber cinereum into the infundibulum of the hypophysis. Another recess, the *recessus opticus*, leads forwards immediately in front of this, above the optic chiasma. Posteriorly two diverticula are present. One, the *recessus pinealis*, passes backwards above the posterior commissure and the mouth of the aquæductus cerebri for a short distance into the stalk of the pineal body. The second is placed above this and is carried backwards for a greater distance. It is a diverticulum of the epithelial roof, and, therefore, is difficult to demonstrate. It is termed the *recessus suprapinealis*.

Cerebral Connexions of the Optic Tract.

At the optic chiasma the optic nerves of the two sides are joined together and a partial decussation of fibres takes place. The fibres which arise in the medial half of each retina cross the median plane and join the optic tract of the opposite side. The optic tract proceeds backwards round the cerebral peduncle, and in the neighbourhood of the geniculate bodies appears to divide into two roots, viz., a lateral and a medial (Fig. 514), but only the former is really part of the tract.

Commissure of Gudden.—The so-called medial root disappears under cover of the medial geniculate body and a large proportion of its fibres arise or end in this nuclear body. The medial root, although it is composed of fibres which are intermingled with those of the optic tract, has nothing to do with the optic nerve. These fibres, when traced forwards, cross the median plane in the posterior angle of the optic chiasma and are carried backwards alongside the opposite optic tract. The fibres constitute a bond of union, called the **commissure of Gudden**, between the medial geniculate body of one side and the colliculus inferior of the other (Fig. 515).

The Optic Tract.—The optic tract is composed of fibres which come—(1) from the lateral half of the retina of its own side; and (2) from the medial half of the retina of the opposite side, which have crossed the median plane in the optic chiasma. But in addition to the afferent retinal fibres there are a certain number of efferent fibres in the optic tract—fibres which take their origin in the brain and end in the retina. These are distinguished from the afferent retinal fibres by their exceeding fineness.

The fibres of the optic tract end in the superior colliculus, in the lateral geniculate body, and in the pulvinar of the thalamus (Fig. 514). The fibres to the **superior colliculus** reach it through the superior brachium (p. 585), and for the most part sink into its substance to end in terminal arborisations around its cells. The

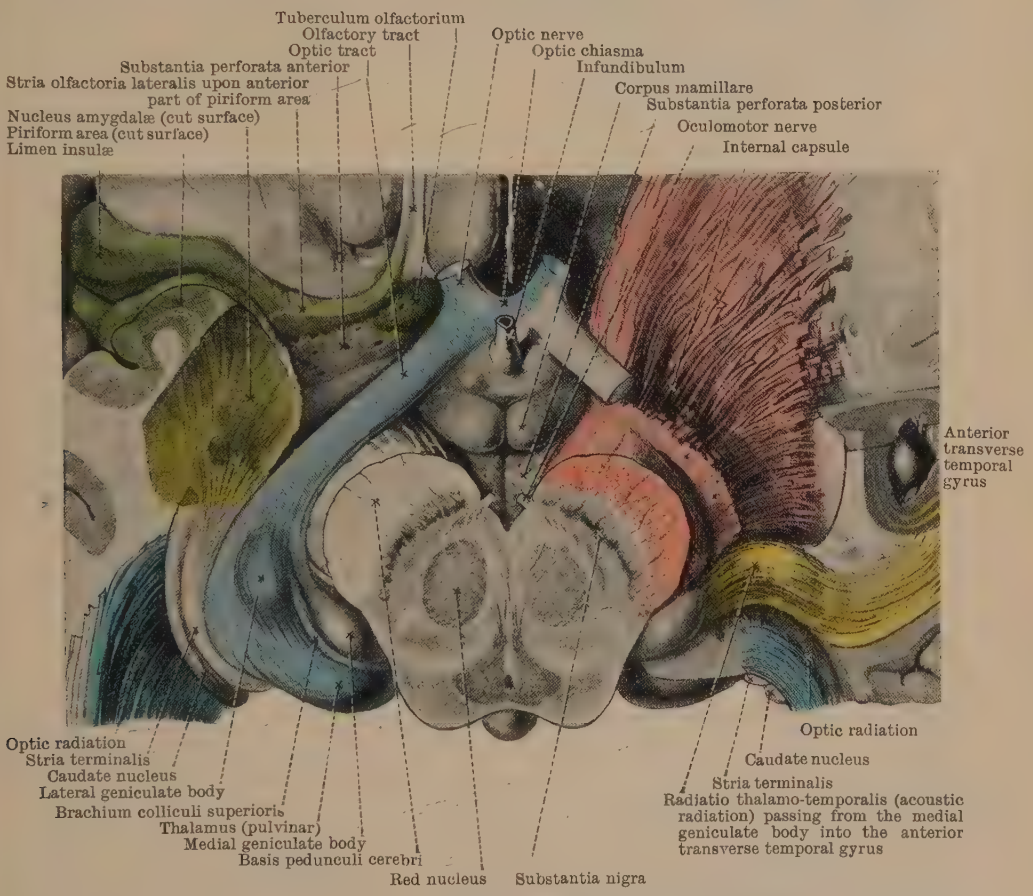

FIG. 514.—THE VENTRAL ASPECT OF PART OF THE PROSENCEPHALON, SHOWING THE RIGHT OPTIC TRACT. The mesencephalon has been cut across. Olfactory area, dull yellow; optic fibres, blue; motor fibres, red; acoustic fibres, bright yellow.

corpus geniculatum laterale receives the largest contribution of fibres from the optic tract. These partly sink into its interior and partly spread out over its surface. The former enter into the construction of the curved lamellæ of white matter which traverse this nuclear mass, and to a large extent end in the gray matter which intervenes between these lamellæ. The deep fibres which are not exhausted in this way proceed onwards through the lateral geniculate body and enter the pulvinar. Of the superficial fibres which spread over the surface of the lateral geniculate body some dip into its substance and end there, but the majority are carried over it and enter the stratum zonale of the pulvinar. Most of the fibres of the optic tract, which end in the **pulvinar**, therefore reach their destination by passing either over or through the lateral geniculate body.

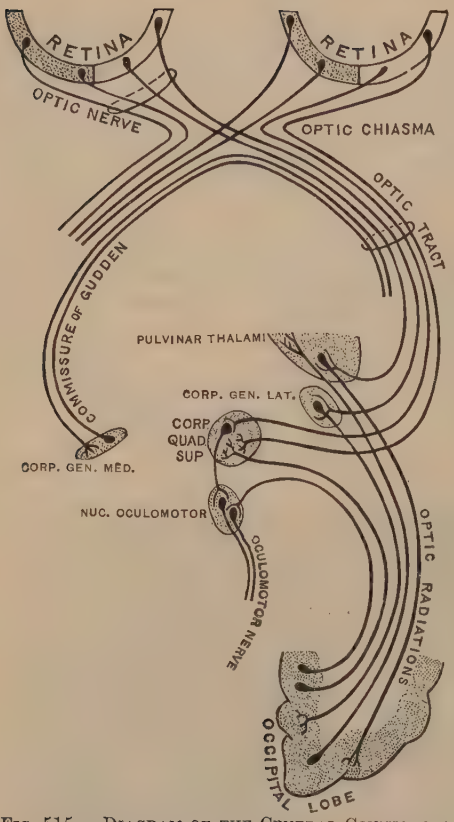

FIG. 515.—DIAGRAM OF THE CENTRAL CONNEXIONS OF THE OPTIC NERVE AND OPTIC TRACT.

Cortical Connexions of the Optic Path.—The superior colliculus, the lateral geniculate body, and the pulvinar constitute the lower visual centres or terminal nuclei of the optic tract. The higher visual centre is placed in the cortex of the occipital region of the cerebral hemisphere, and the connexions between this and the lower centres are established by a large strand of fibres which runs in the central white matter of the posterior part of the cerebral hemisphere, and which constitutes the **optic radiation.** The optic radiation is composed both of corticipetal and corticifugal fibres. The former arise as the axons of the cells in the lateral geniculate body and the pulvinar, around which the retinal fibres end, and they terminate in the cortex of the occipital lobe. The corticifugal fibres take origin in the cortex of the occipital lobe and end in the pulvinar and superior quadrigeminal body (Ferrier and Turner). Thus constituted, the optic radiation forms a conspicuous strand (Figs. 514, p. 617; 520, p. 622; 534, p. 635), which, reaching the retrolenticular part of the internal capsule, sweeps backwards into the occipital lobe of the cerebral hemisphere on the lateral side of the posterior horn of the lateral ventricle. Its connexions will be studied more fully at a later stage.

THE PARTS DERIVED FROM THE TELENCEPHALON.

CEREBRAL HEMISPHERES.

The cerebral hemispheres form the largest part of the fully developed brain. When viewed from above they form an ovoid mass, the broadest end of which is directed backwards, and the longest transverse diameter of which will be found in the vicinity of the parts which lie subjacent to the parietal tuberosities of the cranium. The massive rounded character of the anterior or frontal end of each cerebral hemisphere constitutes a leading human characteristic; but the posterior or occipital end is narrow and pointed, and is directed somewhat downwards. The two cerebral hemispheres are separated from each other by a deep median cleft, termed the longitudinal fissure.

The cerebral hemisphere is formed from a small area of the extreme anterior end of the alar lamina, in the angle between the foremost part of the roof and the upper end of the lamina terminalis (Fig. 516, L), which becomes continuous with the roof (at the point marked X).

The rapid expansion of this area leads to the development of a lateral bulging containing a diverticulum of the third ventricle, which is known as the **ventriculus lateralis.** This at first communicates with the third ventricle by means of a wide opening (F.M.), the **foramen inter-ventriculare [Monro],** corresponding in size to the extent of the area of the side wall that was bulged outwards to form the hemisphere vesicle. The thin epithelial roof of the telencephalon takes no share in the formation of the two cerebral hemispheres, but serves with the lamina terminalis (L) as a bond of union between them. At a somewhat later stage in development two folds become invaginated from this epithelial roof in the

whole extent of the prosencephalon, both its telencephalic and diencephalic parts. In the greater part of their length these folds project into the third ventricle, and form its **chorioid plexus** (Fig. 517); but the anterior parts of the two chorioidal folds, namely, those parts formed from the roof of the interventricular foramina (F.M.), become greatly enlarged and project each into the corresponding lateral ventricle. The furrow corresponding to this invagination of the roof is called the **fissura chorioidea**. When the hemisphere vesicle first begins to expand, the thinner part of the hemisphere wall, which is called the **pallium**, is freely continuous around the vertical caudal margin of the foramen interventriculare (Fig. 516, Y) with the thalamus (TH).

But as development proceeds the wall of the prosencephalon becomes attenuated along the line of this pallio-thalamic junction, and eventually the edge of the pallium fringing this attachment to the thalamus becomes reduced to a thin layer of epithelium which is continuous at its superior end with the lamina chorioidea of the roof.

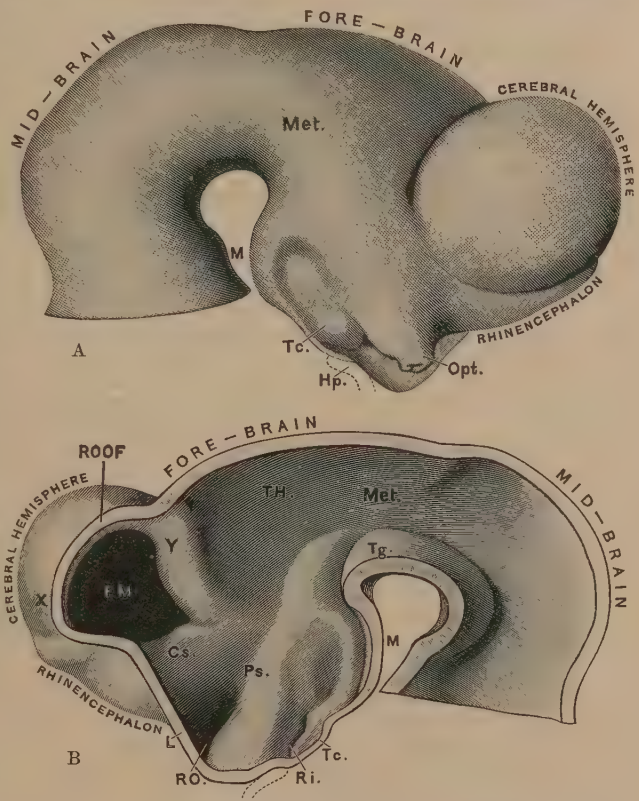

FIG. 516.—TWO DRAWINGS OF THE EMBRYONIC BRAIN. (After His.)

Into this secondarily formed caudal extension of the chorioid lamina the invagination that commenced in the roof of the foramen interventriculare extends until it reaches the inferior extremity of the deep cleft separating the cerebral hemisphere from the thalamus (Fig. 516, A). Below this point the thalamus remains in uninterrupted continuity with the floor of the cerebral hemisphere (Cs), which is becoming thickened to form the **corpus striatum**.

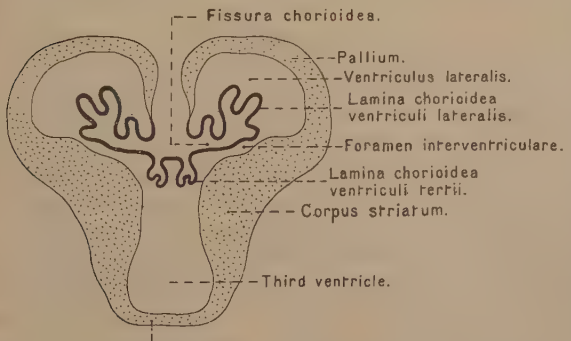

FIG. 517.—DIAGRAM OF A TRANSVERSE SECTION THROUGH A FŒTAL BRAIN TO SHOW THE INVAGINATION OF THE ROOF THROUGH EACH INTERVENTRICULAR FORAMEN.

At a very early stage in the development of the embryo, long before there is any sign of the hemisphere vesicles, the ectoderm upon each side of the anterior neuropore (see p. 502) becomes thickened

to form the **area olfactoria** (see Fig. 417, D, p. 503). Certain of the epithelial cells in this area become converted into bipolar sensory cells, which become specially adapted to be affected by certain kinds of air-borne chemical stimuli that awaken a consciousness of smell. These cells always remain *in situ* in the olfactory epithelium, just as the most primitive sensory cells do in Hydra (Fig. 414, p. 499). But other nerve-cells seem to be derived from the area olfactoria which do not remain in the parent epithelium, but become attached to the adjoining part of the neural tube. These cells form the **olfactory ganglion**, which acts as the receptive organ for the impressions brought into it by the processes of the sensory cells in the olfactory epithelium; and the area of the neural tube to which it becomes attached is destined to become part of the cerebral hemisphere. At the end of the first month this portion of the hemisphere becomes drawn out as a hollow protrusion, the distal end of which is coated with a layer of olfactory ganglion and is known as the **bulbus olfactorius**; the rest forms a peduncle. In the course of its subsequent development in the human brain (though not in those of most mammals) the cavity in the bulb and peduncle becomes completely obliterated. The peduncle becomes so greatly elongated and attenuated that,

to the unaided eye, it appears to be wholly formed of white nerve-fibres passing to and fro between the olfactory bulb and the hemisphere; hence it is called the **tractus olfactorius.**

The cerebral hemisphere first appears in the form of a slight bulging upon each side of the fore-brain, but it soon assumes large dimensions. At first it grows forwards and upwards (Fig. 518), and a distinct cleft, the floor of which is the roof-plate and lamina terminalis, appears between the two hemispheres: this is known as the **fissura longitudinalis cerebri.** The separation of the two cerebral vesicles by the longitudinal fissure begins at the end of the first month. This fissure becomes occupied by mesodermic tissue, which later on forms the falx cerebri. The cerebral hemisphere, in its further growth, is carried progressively backwards over the posterior parts of the developing brain. At the end of the third month it has covered the thalamus. A month later it reaches the corpora quadrigemina, and by the seventh month it has not only covered these, but also the entire upper surface of the cerebellum.

In the earlier stages of its development the cerebral hemisphere is a thin-walled vesicle with a relatively large cavity, which represents the primitive condition of the lateral ventricle. At first the vesicle is bean-shaped and the cavity is curved. As development proceeds the posterior portion of the hemisphere grows backwards over the cerebellum in the shape of a hollow protrusion, and a distinct occipital

lobe enclosing the posterior horn of the lateral ventricle is the result. This developmental stage begins about the fourth month.

The Connexions of the Olfactory Nerves.

The olfactory nerves are the axons of the spindle-shaped bipolar cells situated in the olfactory mucous membrane (Fig. 519). These axons collect in the submucous layer to form small bundles, which enter the cranial cavity through the foramina in the lamina cribrosa of the ethmoid bone. They at once enter the inferior surface of the bulbus olfactorius, and each fibre breaks up into a tuft of terminal filaments. Towards these tufts dendrites proceed from large **mitral cells** placed in a deeper plane within the bulb, and each dendrite also breaks up into numerous terminal branches intertwined with those of the olfactory nerves. In this way are formed a large number of globular bodies, each consisting of the arborescent terminations of a mitral dendrite and of certain olfactory nerve-fibres. These are the **olfactory glomeruli** of the bulb. Each mitral cell gives off several dendrites and one axon. Only one dendrite enters into the formation of a glomerulus, but several nerve-fibres may be connected with such a body. It thus happens that, through its dendrite, a mitral cell may stand in connexion with several olfactory nerve-fibres. The axon of the mitral cell passes upwards to the white matter of the bulb, enters this, and, bending backwards, is conducted through the tract towards the cerebral cortex.

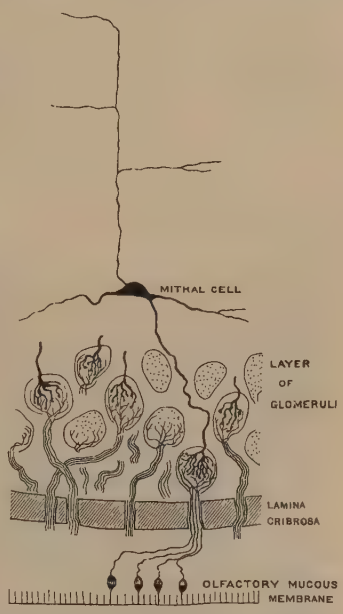

Fig. 519.—Diagram of the Minute Structure of the Olfactory Bulb.

The **olfactory bulb** is a small, flattened, elliptical mass of gray substance placed upon the upper surface of the lamina cribrosa of the ethmoid. Its posterior extremity is attached to the rest of the cerebral hemisphere by the long **tractus olfactorius** (Fig. 450), a prismatic band of white substance placed in a furrow (**sulcus olfactorius**) on the under surface of the frontal region of the cerebral hemisphere. A short distance in front of the optic chiasma each olfactory tract becomes inserted into the hemisphere (Fig. 520). The swollen pyramidal-shaped attached end of the peduncle is called the **trigonum olfactorium**. Immediately behind the trigone a small obliquely placed ovoid area of gray matter, the **tuberculum olfactorium**, can sometimes be detected in the human brain; but in the brains of most mammals with a greater development of the organs of smell this swollen area is much more prominent and constant. In most human brains, however, it is difficult to distinguish it from a much more extensive area, which is situated behind it and to its lateral side, and is named the **substantia perforata anterior** (Fig. 520). Along the anterior margin of this perforated substance there can sometimes be detected a small, rounded, rope-like strand of gray matter, the medial end of which passes into the trigonum olfactorium. This is the anterior part of the **area piriformis**—the stalk of the pear-shaped lobe—and upon its surface is placed a very well-defined narrow band of nerve-fibres, the **stria olfactoria lateralis**, which is composed of axons of mitral cells (in the olfactory bulb) proceeding to the piriform area. Even when the anterior part of the piriform area is not distinguishable, the stria lateralis is always a prominent feature.

The piriform area extends transversely laterally in the deep valley between the orbital and temporal regions of the hemisphere (**fossa cerebri lateralis**); becoming slightly broader, and reaching what is known as the **insula** (of which it forms the **limen insulæ**), it becomes sharply bent upon itself (Figs. 520, and 521, C). It then passes medially and backwards, and emerges from the fossa as a broad area upon the under surface of the temporal region (Fig. 521, C). This greatly

expanded caudal extremity of the pear is the **area piriformis** in the strict sense of the term.

If the brain of almost any other mammal is examined (take the rabbit's as an example), the area piriformis will be found to constitute relatively an enormously larger proportion of the cerebral hemisphere than it does in the human brain; and it is separated from the part of the hemisphere (**neopallium**) that lies above it by a longitudinal furrow called the **fissura rhinalis**. The enormous expansion of the neopallium in the human brain accentuates the flexure of the piriform area at the point x (Fig. 521), and at the point y the exuberant growth of neopallium relegates the swollen posterior part of the piriform area on to the

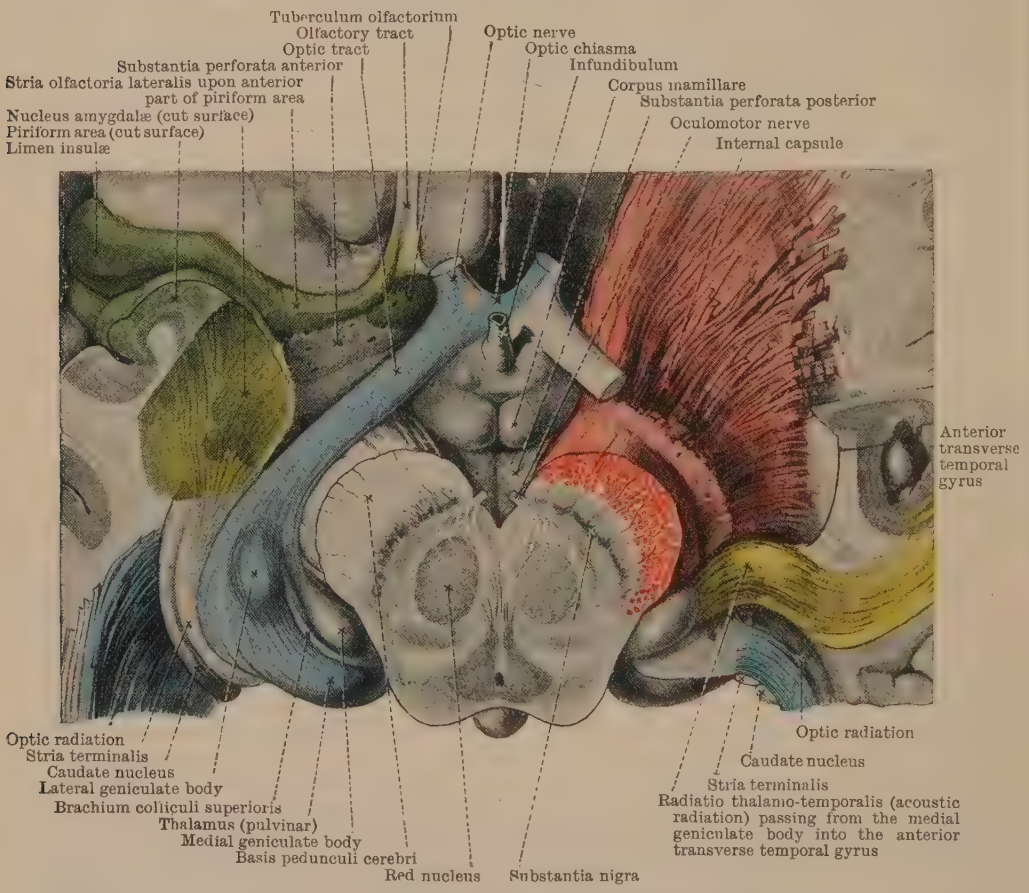

FIG. 520.—PART OF THE VENTRAL SURFACE OF THE PROSENCEPHALON, SHOWING THE ATTACHMENT OF THE OLFACTORY TRACT.

Olfactory area, dull yellow; optic, blue; motor fibres, red; acoustic fibres, bright yellow.

medial surface (Fig. 522), where the posterior part of the rhinal fissure persists to separate it from the neopallium.

The surface of the piriform area often presents numerous small wart-like excrescences; and it is whitened by a thin layer of fibres (**substantia reticularis alba**) prolonged backwards from the stria olfactoria lateralis. By these fibres olfactory impulses are poured directly from the mitral cells of the bulb into the piriform area. If we call the olfactory nerves the **primary olfactory neurones**, the fibres which pass from the bulb to the piriform area would then be **secondary olfactory neurones.**

Formatio Hippocampalis.—From all parts of the area piriformis, as well as the trigonum and tuberculum olfactorium, fibres arise (**tertiary olfactory neurones**), and proceed on to the medial aspect of the hemisphere, where they terminate in the edge of the pallium, alongside the lamina chorioidea. In the human brain the

vast majority of these tertiary neurones proceed from the posterior extremity of the piriform area, but a certain number arise in the neighbourhood of the substantia perforata anterior and proceed at once on to the medial surface of the hemisphere. The large number of small nerve-cells that collect in the medial edge of the pallium become specially modified in structure to form a receptive organ for impressions of smell, known as the **fascia dentata**; and the axons of these cells pass into the part of the pallium which immediately surrounds the peripheral edge of the fascia dentata and is known as the **hippocampus** (Fig. 524). In the hippocampus impressions of smell are brought into relation with those of other senses (probably taste); and from the hippocampal cells fibres are emitted to form a system known as the **fornix**, which establishes connexions with the hippocampus of the other hemisphere and with the hypothalamus, thalamus, and more distant parts of the brain.

The rudiment of the hippocampal formation (coloured orange in Fig. 522) that

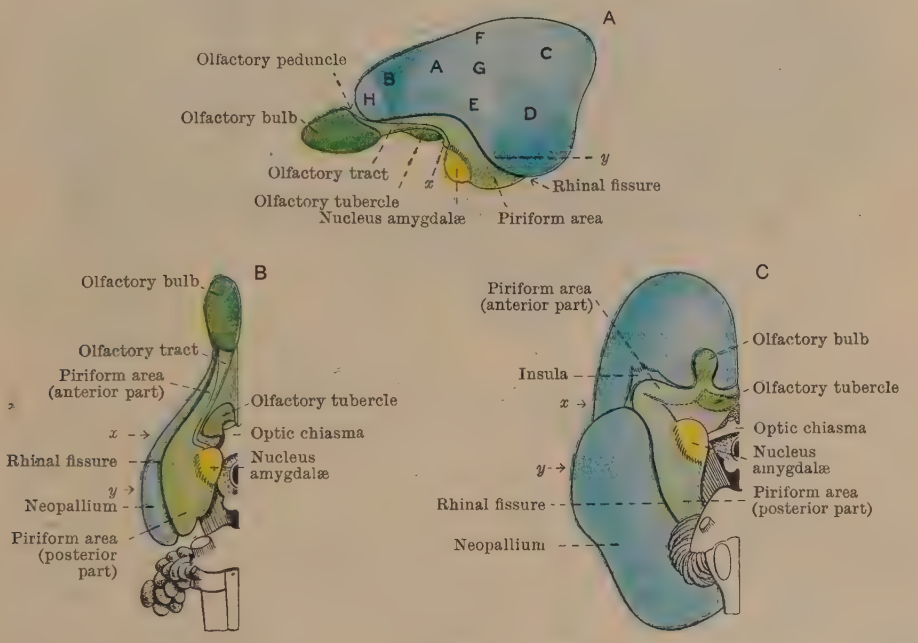

Fig. 521.

Olfactory areas, green; neopallium, blue.

develops on the medial surface begins in front, alongside the place where the stalk of the olfactory peduncle (which becomes the trigonum olfactorium) is inserted; it passes upwards to the superior end of the lamina terminalis, from the rest of which it is separated by a triangular mass of gray matter called the **corpus paraterminale** (shown in blue in Fig. 522); and then it proceeds upward to the rostrum of the corpus callosum and passes forward around the genu to reach the upper surface of the corpus callosum. Extending backward it passes around the splenium to join the fully developed part of the hippocampal formation. The anterior part of this great hippocampal fringe of the pallium does not attain its full development in the human brain and remains as a more or less vestigial aborted structure; but the posterior part undergoes a peculiar transformation. The tertiary olfactory neurones, coming mainly from the posterior part of the area piriformis (green in the figure), enter the margin of the hippocampal formation, and the small cells which receive these incoming fibres multiply rapidly during the third month, and arrange themselves in a densely packed row of granules, which represent the distinctive feature of the **fascia dentata** (Fig. 524). At first this cell-column is continuous at

its peripheral margin with a much more loosely packed column of larger and less numerous cells, which represent the **hippocampus**; and these in turn give place to the more diffusely arranged and laminated cells of the typical **cortex cerebri**, which

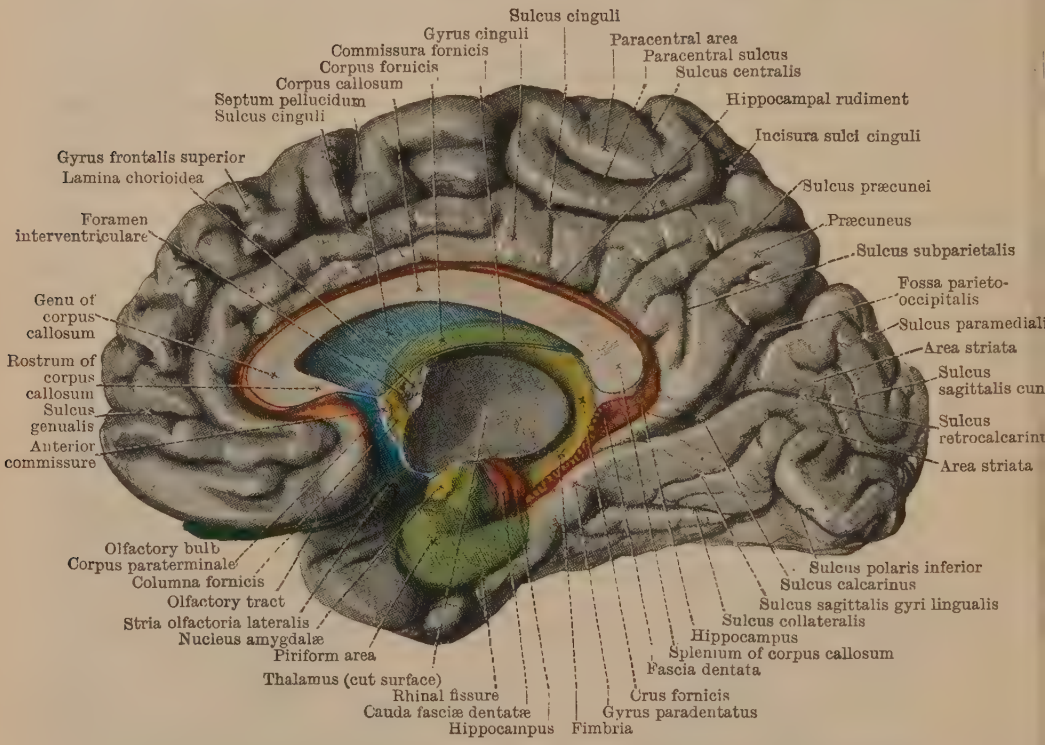

FIG. 522.—MEDIAL ASPECT OF THE RIGHT CEREBRAL HEMISPHERE, WITH THE OLFACTORY PARTS COLOURED.

we call the **neopallium**. As development proceeds both the dentate and hippocampal columns of cells rapidly increase in length, and both appear to push their way towards the ventricle (Fig. 524, B) into the substance of the wall, which becomes correspondingly thickened. The ventricular swelling thus formed is the hippocampus; and it is important to recognise that this swelling is not produced by any invagination of the surface, such as is usually described under the name of the **fissura hippocampi**. *There is no fissura hippocampi in the human brain.* What is usually described under this name is an artificial cleft made by pushing the handle of a scalpel into the hippocampal formation at the edge of the exposed part of the fascia dentata (Fig. 524, B and C, at *x*) and separating the morphological surface of the hippocampus from that of the buried part of the fascia dentata. Cleavage readily occurs along this line because there are numerous nerve-fibres, hippocampal and dentate respectively, upon each side of it.

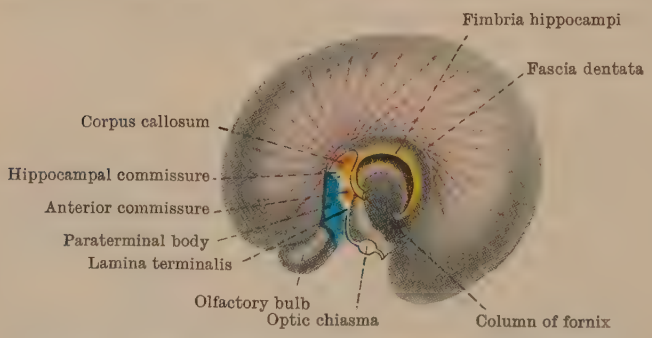

FIG. 523.—MEDIAL ASPECT OF THE RIGHT CEREBRAL HEMISPHERE OF A HUMAN FŒTUS OF THE FOURTH MONTH.

The broken red lines indicate the paths taken by callosal fibres in the neopallium to reach the upper end of the lamina terminalis.

As development proceeds a break occurs in the cell-column at the junction

of its hippocampal and dentate parts, and the two columns (Fig. 524, C) become partially interlocked.

THE FORNIX.

The Fornix is the efferent tract from the hippocampus to (*a*) the hippocampus in the other hemisphere, and (*b*) to the brain-stem.

The axons of the hippocampal cells collect upon the ventricular surface to form the *alveus* (Fig. 524), the fibres of which converge towards the margin of the fascia dentata, where they bend into the longitudinal direction (*i.e.* parallel to the edge of the pallium and the lamina chorioidea) to form a prominent white marginal fringe, the **fimbria** (Fig. 524).

The fibres of the fimbria pass upwards and forwards (Fig. 523), and ultimately reach the upper end of the lamina terminalis, which provides a bridge to conduct a certain number of them across the median plane into the fornix or fimbria of the other hemisphere, so as to link together in functional association the two hippocampi. These crossing fibres are known as the **commissura hippocampi**.

Most of the fibres that go up in the fimbria from the hippocampus do not pass into the hippocampal commissure, but bend downwards in the anterior lip of the foramen interventriculare to enter the thalamic region. They are

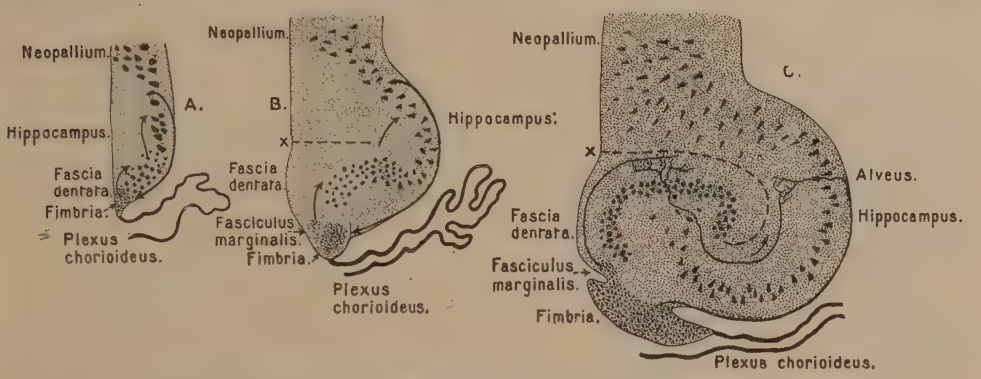

FIG. 524.—DIAGRAMS REPRESENTING THREE STAGES IN THE DEVELOPMENT OF THE HIPPOCAMPAL FORMATION.

collected into a vertical rounded column, which is called the **columna fornicis**; when it reaches the hypothalamus it bends backward to end in the corpus mamillare, and from the latter fibres arise which descend in the tegmentum and establish connexions with the lower parts of the brain.

The olfactory bulb and tract, the area piriformis, tuberculum olfactorium, corpus paraterminale, and the formatio hippocampalis together form a part of the hemisphere, which is concerned mainly with the function of smell. Hence they may be grouped together as the **rhinencephalon**; but this term has been used in so many different ways that it is of doubtful utility.

In the lowest vertebrates the whole hemisphere is practically rhinencephalon. Nevertheless, fibres coming from other parts of the nervous system and conveying impressions from other sense organs than those of smell make their way into the cerebral hemisphere and influence the state of its activities. In other words, the hemisphere is primarily an olfactory receptive nucleus, but is also the place where impressions of smell are brought under the modifying influences of other sensory impressions before they make their effects manifest in behaviour.

But it is only in the most highly organised types of brain, more especially those of mammals and birds, that the non-olfactory senses acquire a representation in the hemisphere which is relatively independent of, or at any rate not wholly subservient to, the influence of the sense of smell. In the mammalian brain a definite area of pallium is set apart to receive impressions of the tactile, visual, acoustic, and other senses. This area is the **neopallium**. In the human brain it

has grown to such an extent that it forms almost the whole of the hemispheres—a mass far greater than the whole of the rest of the central nervous system.

THE CEREBRAL COMMISSURES AND THE SEPTUM PELLUCIDUM.

We have seen that certain fibres from the hippocampi cross from one hemisphere to the other, using the upper part of the lamina terminalis as a bridge across the median plane. But at an earlier stage of development other fibres can be detected at a slightly lower level in the lamina terminalis forming a bundle, of oval outline in sagittal section, called the **commissura anterior.** Its fibres come from the olfactory bulb, area piriformis, tuberculum olfactorium, and a small temporal area of neopallium. If the composition of the hippocampal commissure is analysed in a fœtus of the third month, it will be found that there are intermingled with the truly hippocampal fibres some which come from the neopallium. During the fourth month the bulk of the neopallial element in this dorsal commissure outgrows the hippocampal element. The latter fibres become crowded into the postero-inferior corner of the commissure and the neopallial fibres come to form a flattened transverse bridge—the **corpus callosum**—above them. These fibres are enclosed in a neuroglial matrix derived from the lamina terminalis and the adjoining paraterminal bodies. Some nerve-cells also may make their way into this matrix. As it elongates, the corpus callosum pushes its way forwards in the upper part of the paraterminal body of each hemisphere, and as development proceeds a small area of this body becomes almost completely circumscribed by the corpus callosum and commissura hippocampi. As these commissural bands increase in size this small circumscribed patch of paraterminal body becomes greatly stretched and expanded to form a thin translucent leaf. The two leaves thus formed in the medial walls of the two hemispheres are known as the **septum pellucidum**; and the narrow cleft that separates them the one from the other in the median plane is called the **cavum septi pellucidi.**

There is still an element of uncertainty concerning the precise manner in which these changes are brought about, and especially as to the precise mode of closure of the cavum septi. As the cerebral hemisphere expands, some parts of it grow forwards, others upwards, and others again backwards. Such growth in each part will naturally tend to exert traction upon its commissural fibres that pass through the corpus callosum. Hence the anterior part of this great commissure becomes drawn forwards, its posterior part backwards, and the greater intermediate part upwards, so that it comes to assume the form shown in Fig. 525, C. As the posterior part of the corpus callosum pushes its way backwards, it exerts traction upon the fibres of the hippocampal commissure and their matrix, which becomes enormously stretched so as to form a thin lamella (the floor of the cavum septi) stretching from a point just above the anterior commissure to the under surface of the swollen posterior end of the corpus callosum, which is called the **splenium** (Fig. 522). The hippocampal commissural fibres are scattered throughout this lamella. The backward growth of the splenium also thrusts back the upper end of the hippocampal formation so that it becomes removed far from the lamina terminalis. The fibres of the fimbria which are prolonged forwards under the corpus callosum and septum pellucidum to bridge this great gap form the **crus fornicis** on each side. As a rule in the human adult brain the crura fornicis of the two hemispheres become crowded together at the median plane so as to obscure the connecting lamella which serves as a matrix for the commissura hippocampi (Fig. 525, C); but the true arrangement can be seen in the brains of fœtuses of the sixth, seventh, and eighth months, and is at once revealed in the adult if the corpus callosum is raised up by an accumulation of fluid in the lateral ventricles (hydrocephalus), so as to put a strain upon the septum pellucidum. The mass formed by the crura fornicis and their commissure is called the **corpus fornicis.**

The fascia dentata appears as a notched band behind and below the fimbria; its upper end passes on to the under surface of the splenium of the corpus

callosum, where it tapers and ends (**fasciola cinerea**); but as it dwindles the upper end of the hippocampus emerges upon the surface below and behind it and passes into a thin film of gray matter—**indusium griseum**—which is prolonged on to the upper surface of the corpus callosum. It proceeds forwards, becoming as a rule still more attenuated, and after surrounding the anterior end (**genu**) of the corpus callosum it passes downwards towards the trigonum olfactorium along the line that separates the corpus paraterminale from the neopallium. The indusium represents the atrophied remains of the anterior part of the hippocampal arc of the fœtal brain (Fig. 523), from which the fascia dentata has entirely disappeared. It is accompanied by longitudinal fibres homologous to the fornix system: in other words, the fornix fibres of the atrophied supracallosal hippocampus; they form the **striæ longitudinales** of the corpus callosum (Fig. 522; Fig. 531, p. 633; Fig. 526, p. 628).

The inferior (or anterior) extremity of the fascia dentata dips into a deep furrow, around which the area piriformis is bent in a hook-like manner (**uncus**); in this it becomes considerably reduced in diameter and then emerges (at right angles to its previous direction) to form Giacomini's "**banderella**," which we may call the **cauda fasciæ dentatæ**. Behind this the inferior end of the hippocampus

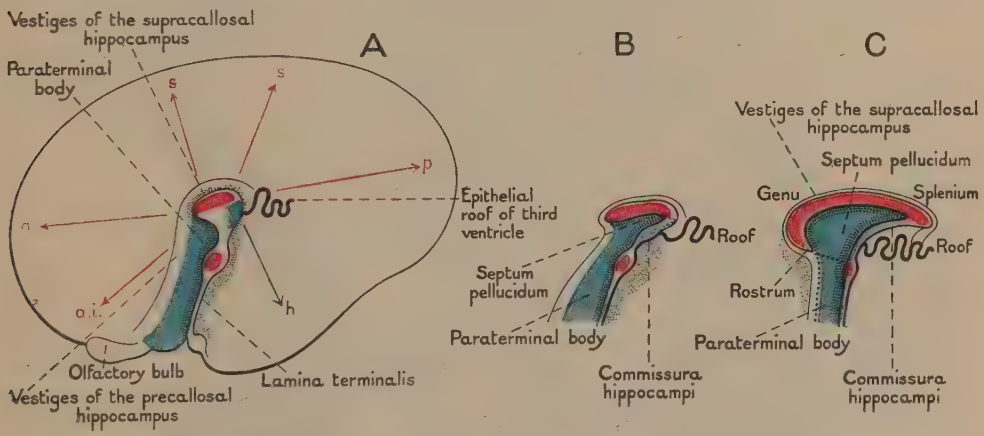

FIG. 525.—THREE STAGES IN THE DEVELOPMENT OF THE CORPUS CALLOSUM.

comes to the surface, but is turned inside out, *hippocampus inversus*. Just in front of the upper ending of the **cauda fasciæ dentatæ** a little knob of solid gray matter appears upon the surface, surrounded by the area piriformis. It is the **nucleus amygdalæ** (Fig. 522).

Corpus Callosum.—The corpus callosum is the great transverse commissure which passes between the two cerebral hemispheres. It is placed nearer the anterior than the posterior aspect of the brain, and it unites the medial surfaces of the hemispheres throughout very nearly a half of their antero-posterior length. The corpus callosum is highly arched from before backwards, and presents a convex superior surface and a concave inferior surface when viewed from the side (Fig. 522).

The *superior surface* of the corpus callosum forms the bottom of the longitudinal fissure, and on each side of this it is covered by the gyrus cinguli. Only in its posterior part is it approached by the falx cerebri; in front, this process of dura mater falls considerably short of it. The superior surface of the corpus callosum is covered by a thin layer of indusium continuous at the bottom of the sulcus corporis callosi with the gray cortex on the surface of the hemisphere. In this there are embedded, on each side of the median plane, two delicate longitudinal bands of fibres, called respectively the stria longitudinalis medialis and lateralis. The **stria longitudinalis medialis** is the more strongly marked of the two, and it is separated from its fellow of the opposite side by a faint median furrow. The **stria longitudinalis lateralis** is placed farther out, under cover of the gyrus

cinguli. The thin coating of gray matter, with the two striæ, represents the aborted remains of the hippocampus (see p. 624). So thin is this gray coating that the transverse direction pursued by the callosal fibres proper can be easily perceived through it.

The two extremities of the corpus callosum are much thickened, whilst the intermediate part or **body** is considerably thinner. The massive *posterior end*, which is full and rounded, lies over the mesencephalon and extends backwards as far as the highest point of the cerebellum. It is called the **splenium**, and it consists of a superior and inferior part. The latter is bent forwards under the upper part, to the inferior surface of which it is closely applied. The *anterior end* of the corpus

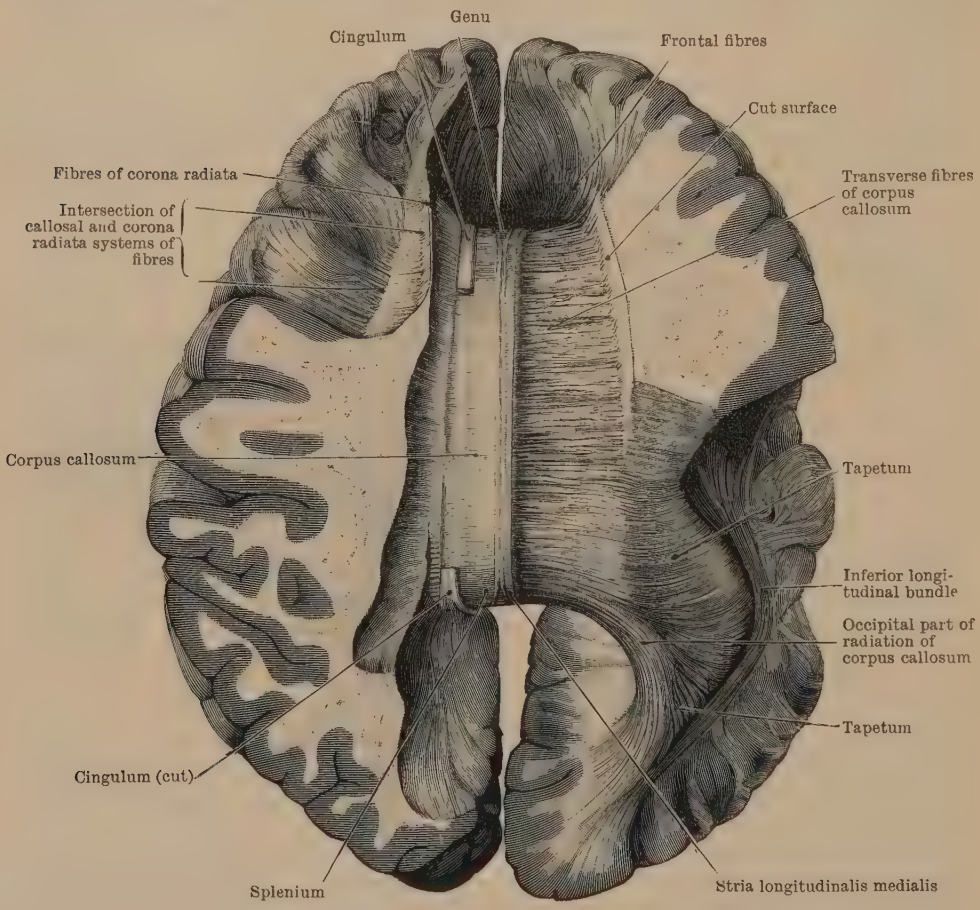

FIG. 526.—THE CORPUS CALLOSUM, exposed from above and the right half dissected, to show the course taken by its fibres.

The lateral longitudinal stria (which lies near the cingulum) is not shown.

callosum is not quite so massive, and it is folded downwards and backwards on itself. It is termed the **genu**. The recurved inferior part of the genu is separated from the part of the corpus callosum which lies above, by an interval. It rapidly thins as it passes backwards and receives the name of the **rostrum**. The fine terminal edge of the rostrum becomes connected by means of a band of neuroglial tissue with the lamina terminalis on the antero-superior aspect of the anterior commissure (Fig. 522).

The *inferior surface* of the corpus callosum, on each side of the median plane, is coated with ependyma (Fig. 531, p. 633), and forms the roof of the anterior horn and the central part of the lateral ventricle. In the median plane, however, it is attached to subjacent parts, viz., to the septum pellucidum in front and directly or indirectly (Fig. 522) to the body of the fornix behind (Fig. 522, p. 624).

The transverse fibres of the corpus callosum, as they enter the white medullary centre of the cerebral hemisphere, separate from each other so as to reach most parts of the cerebral cortex. These diverging fibres are termed the **radiatio corporis callosi**, and they intersect those which form the corona radiata or, in other words, the fibres which extend between the internal capsule and the cerebral cortex (Figs. 535, p. 636, and 536, p. 637). The more anterior of the fibres which compose the genu of the corpus callosum sweep forwards in a series of curves into the anterior frontal region of the hemisphere. A large part of the splenium, forming a solid bundle termed the **occipital part of the radiation of the corpus callosum** (O.T. **forceps major**), bends suddenly and abruptly backwards into the occipital lobe (Fig. 526). Fibres from the body and superior part of the splenium, curving round the lateral ventricle, form a very definite stratum, called the

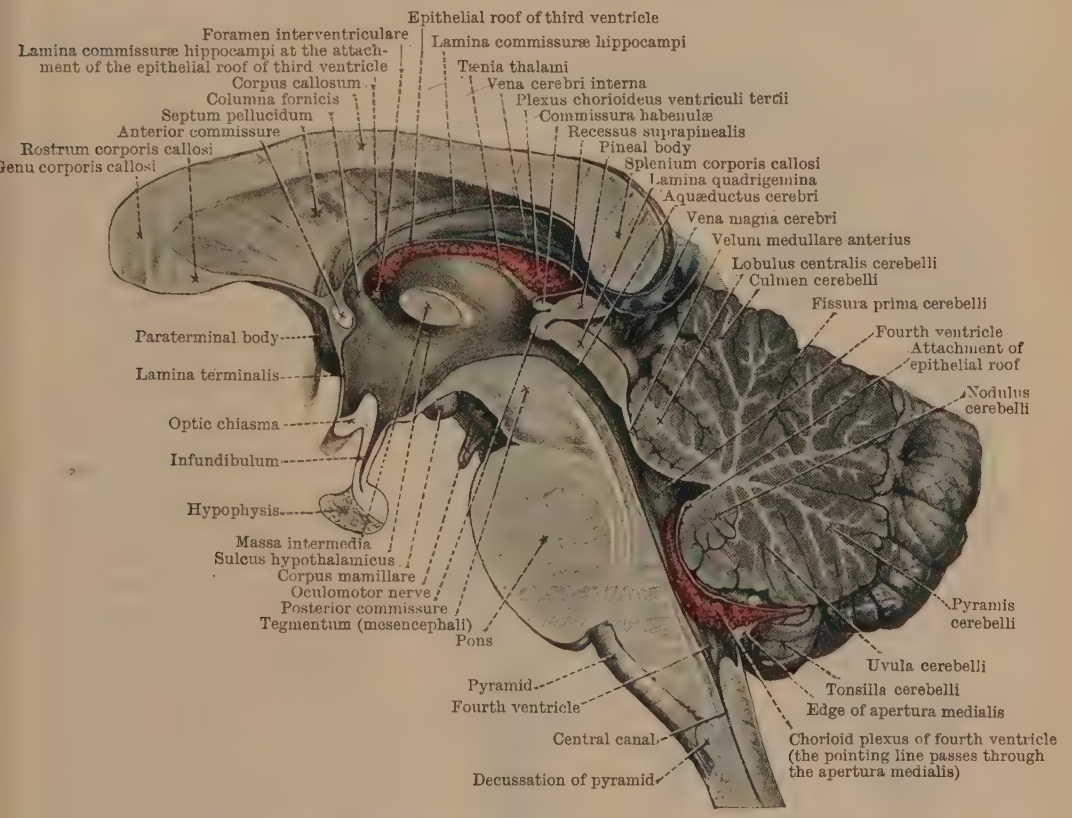

FIG. 527.—THE PARTS OF THE BRAIN CUT THROUGH IN A MEDIAN SAGITTAL SECTION.
The side walls of the ventricular cavities are also shown.

tapetum. This is a thin layer in the medullary centre of the hemisphere, which constitutes the immediate roof and lateral wall of the posterior horn and the lateral wall of the posterior part of the inferior horn of the lateral ventricle. In frontal sections through the occipital and posterior temporal regions the tapetum stands out very distinctly (Fig. 526, p. 628; see also Figs. 532, p. 633, and 534, p. 635).

Septum Pellucidum.—The septum pellucidum is a thin vertical partition which intervenes between the two lateral ventricles. It is triangular in shape, and posteriorly it is prolonged backwards for a variable distance between the body of the corpus callosum and the fornix, to both of which it is attached. In front it occupies the gap behind the genu of the corpus callosum, whilst below, in the narrow interval between the posterior edge of the rostrum of the corpus callosum and the fornix, it is prolonged downwards in the paraterminal body towards the base of the brain. The septum pellucidum is composed of two

thin laminæ in apposition with each other in the median plane (Fig. 529; Fig. 531, p. 633).

Cavum Septi Pellucidi.—This name is applied to the median cleft between the two laminæ of the septum pellucidum. It varies greatly in size in different brains.

Ventriculus Lateralis.

The cavity in the interior of the cerebral hemisphere is called the **lateral ventricle**. It is lined throughout by ependyma continuous with the ependymal lining of the third ventricle. In some places the walls of the cavity are in apposition, whilst in other localities spaces of varying capacity, and containing cerebro-spinal fluid, are left between the bounding walls.

The **lateral ventricle** communicates with the third ventricle of the brain by means of a small foramen, just large enough to admit a crow-quill, which is termed the **foramen interventriculare.** This aperture is placed in front of the anterior end of the thalamus and behind the column of the fornix.

The highly-irregular shape of the lateral ventricle can be best understood by the study of a cast of its interior (Figs. 528 and 513, p. 616). It is usual to describe it as being composed of a body and three horns, viz. an anterior, a posterior, and an inferior horn. The **cornu anterius** is that part of the cavity which lies in front of the interventricular foramen. The **body** or **pars centralis** is the portion of the ventricle which extends from the interventricular foramen to the splenium of the corpus callosum. At this point the posterior and inferior horns diverge from the posterior part of the body. The **cornu posterius** curves backwards and medially into the occipital lobe. It is very variable in its length and capacity: the chief reason for this variability is that adhesions between the walls of this part of the ventricle are of common occurrence. The **cornu inferius** proceeds with a bold sweep round the posterior end of the thalamus, and then tunnels in a forward and medial direction through the temporal lobe towards the temporal pole.

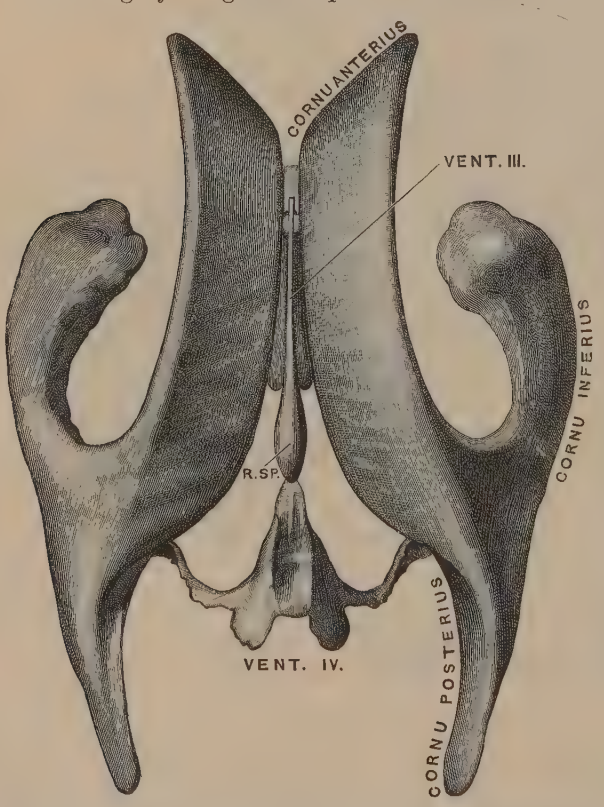

Fig. 528.—Drawing taken from a Cast of the Ventricular System of the Brain, as seen from above. (After Retzius.)

Vent. III. Third ventricle. Vent. IV. Fourth ventricle.
R.SP. Recessus suprapinealis.

The early fœtal lateral ventricle is very capacious and presents an arched or semilunar form. It is composed of parts which correspond to the anterior horn, the central part and the inferior horn, and there is little or no demarcation between them. The posterior horn is a later production. It comes into existence as a diverticulum or elongated pouch, which grows backwards from the superior and posterior part (*i.e.* the convexity) of the primitive cavity.

Cornu Anterius.—The anterior horn forms the foremost part of the cavity, and extends in a forward and lateral direction in the frontal lobe. When seen in

frontal section (Fig. 528) it presents a triangular outline, the floor sloping upwards and laterally to meet the roof at an acute angle. It is bounded *in front* by the posterior surface of the genu of the corpus callosum; the *roof* also is formed by the corpus callosum. The *medial wall*, which is vertical, is formed by the septum pellucidum; whilst the sloping *floor* presents a marked elevation or bulging, viz., the smooth, rounded, and prominent extremity of the pear-shaped caudate nucleus.

Pars Centralis.—The central part or body of the cavity is likewise *roofed* by the corpus callosum. On the *medial side* it is bounded by the posterior part of the septum pellucidum which attaches the fornix to the inferior surface of the corpus callosum. On the *lateral side* it is closed, as in the case of the anterior horn, by the meeting of the floor and the roof of the cavity. On the *floor* a number of important objects may be recognised. From the lateral to the medial side these are met in the following order: (1) the caudate nucleus; (2) a groove which extends obliquely from before backwards and laterally between the caudate nucleus and the thalamus, in which are placed the vena terminalis and a white band called the stria terminalis; (3) a portion of the superior surface of the thalamus; (4) the chorioid plexus; (5) the thin, sharp edge of the fornix (Fig. 531).

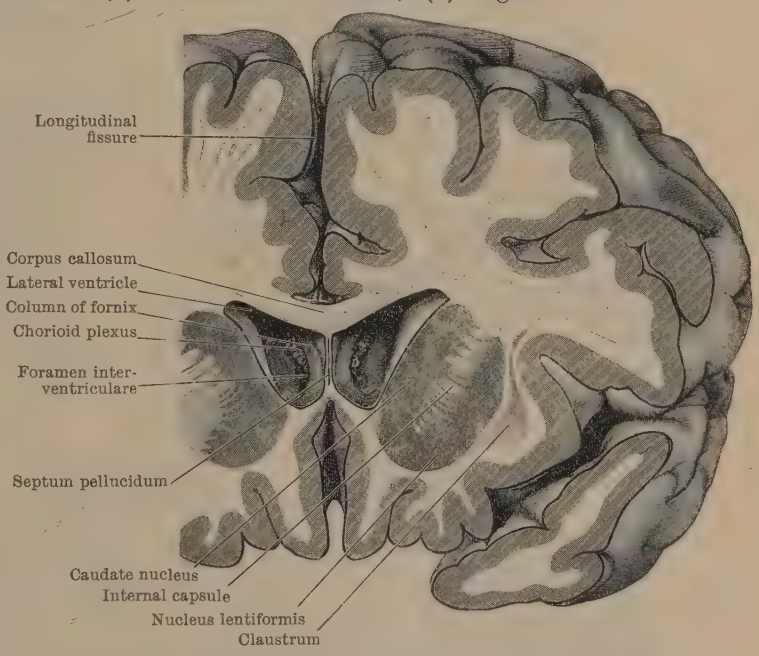

FIG. 529.—FRONTAL SECTION THROUGH THE CEREBRAL HEMISPHERES so as to cut through the anterior horns of the lateral ventricles, through which the central part of the ventricles, the columns of the fornix, and the interventricular foramina can be seen.

The **caudate nucleus** narrows rapidly as it proceeds backwards on the lateral part of the floor of the lateral ventricle. The **vena terminalis** (O.T. **vein of the corpus striatum**) is covered over by ependyma. It joins the **vena cerebri interna** close to the foramen interventriculare. The connexions of the **stria terminalis** will be dealt with later. The portion of the superior surface of the **thalamus** which appears in the floor of the ventricle is in great part hidden by the chorioid plexus, which lies upon it. The **lamina chorioidea** is an epithelial fringe which is attached to the sharp edge of the fornix superiorly, and after surrounding a rich vascular fold of pia mater becomes fixed to the superior surface of the thalamus. The vascular fold is the chorioid plexus. In front it is continuous, in the interventricular foramen, with the corresponding chorioid plexus of the third ventricle (Fig. 522), whilst behind, it is carried into the inferior horn of the ventricle. Although the chorioid plexus has all the appearance of lying free within the ventricle, it must be borne in mind that it is invested by the epithelial chorioidal lamina which represents a portion of the hemisphere wall and excludes it from the cavity.

Cornu Posterius.—The posterior horn is an elongated diverticulum carried backwards into the occipital lobe from the posterior end of the ventricle. It tapers to a point and describes a gentle curve, the convexity of which is directed laterally. The *roof* and *lateral wall* of this portion of the ventricular cavity are

formed by the tapetum of the corpus callosum. In frontal sections through the occipital lobe this is seen as a thin but distinct layer of white fibres, which lies immediately lateral to the ependyma and to the medial side of a much larger strand of fibres in the medullary substance of the occipital lobe, viz., the optic radiation.

On the *medial wall* two elongated curved elevations may be observed. The uppermost of these is termed the **bulb of the cornu (bulbus cornu posterioris)**, and is

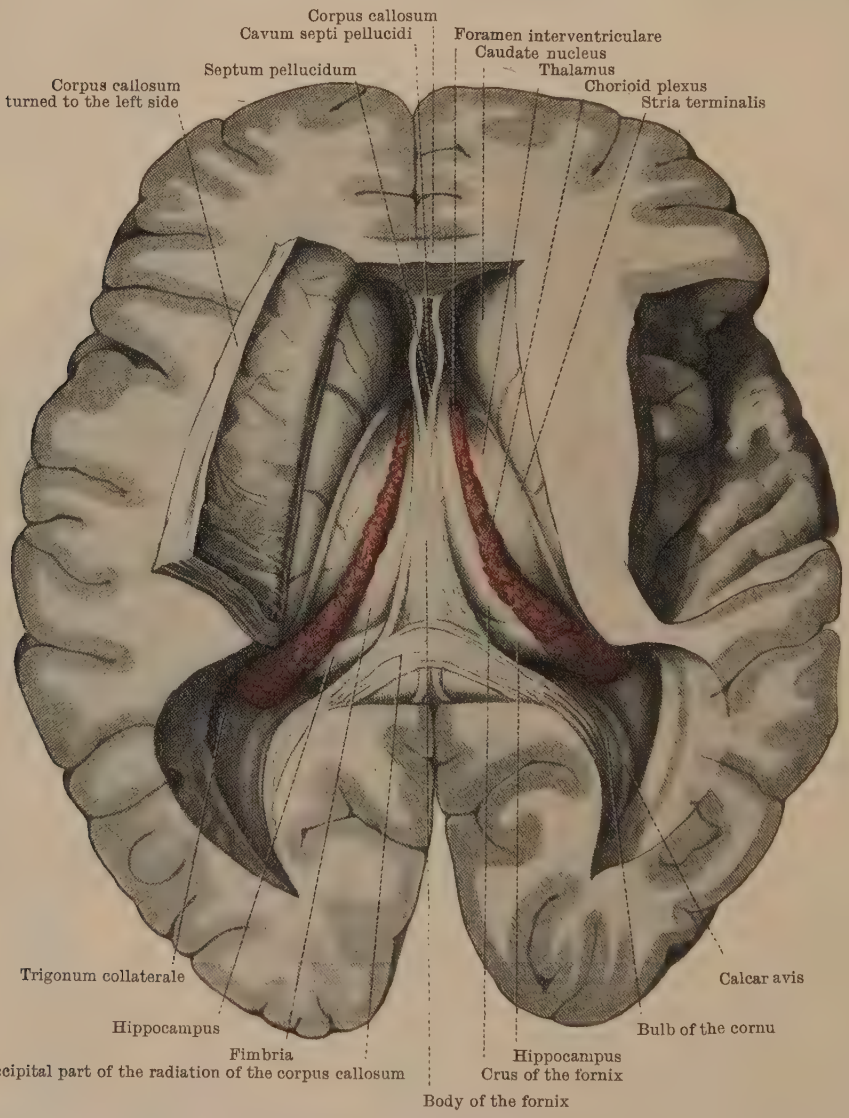

FIG. 530.—DISSECTION, to show the fornix and lateral ventricles ; the body of the corpus callosum has been turned over to the left.

produced by the fibres of the radiation of the corpus callosum as they curve abruptly backwards from the lower part of the splenium of the corpus callosum into the occipital lobe. Below this is the elevation known as the **calcar**. It varies greatly in size in different brains, and is caused by an infolding of the ventricular wall in correspondence with the anterior part of the calcarine sulcus on the exterior of the hemisphere. It may come into contact with and adhere to the lateral wall of the ventricle in a part or even the whole of its extent.

Cornu Inferius.—The **inferior horn** is the continuation of the cavity into the temporal region. At first directed backwards and laterally, the inferior horn

suddenly sinks downwards behind the thalamus into the temporal region, in the centre of which it takes a curved course forwards and medially to a point about an inch behind the extremity of the temporal pole.

In the angle between the diverging posterior and descending horns the cavity of the ventricle presents an expansion of a somewhat triangular shape. To this the name of **trigonum collaterale** is sometimes given.

The *roof* of the inferior horn is formed for the most part by the tapetum of

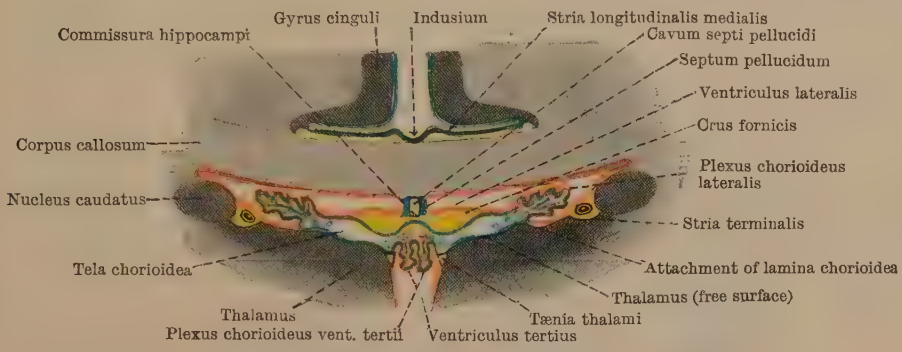

FIG. 531.—DIAGRAM OF TRANSVERSE SECTION ACROSS THE CENTRAL PARTS OF THE LATERAL VENTRICLES.

the corpus callosum. At the extremity of the horn the roof presents a bulging into the cavity. This is produced by a collection of gray matter termed the amygdaloid nucleus. The **stria terminalis** and the attenuated **tail of the caudate nucleus** are both prolonged into the inferior horn and are carried forwards, in its roof, to the amygdaloid nucleus.

On *the floor* of the inferior horn the following structures are seen: (1)

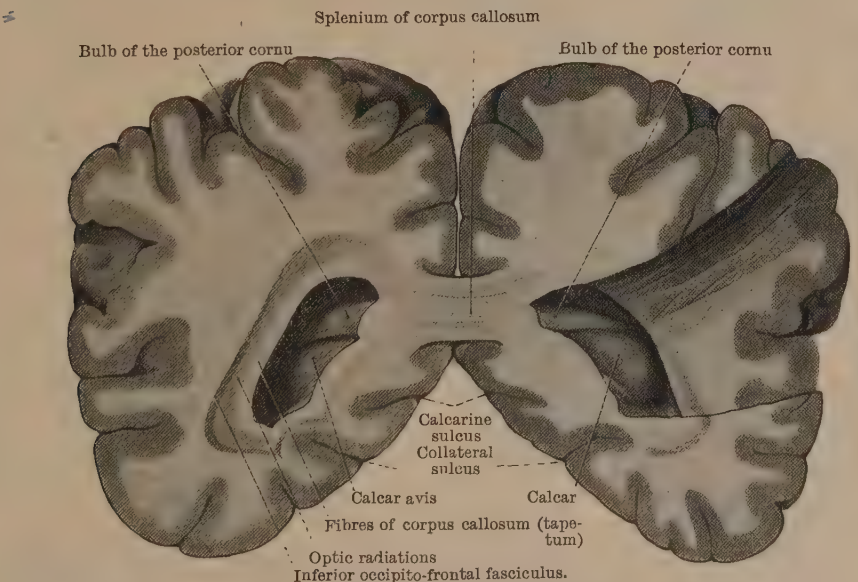

FIG. 532.—FRONTAL SECTION THROUGH THE POSTERIOR HORNS OF THE LATERAL VENTRICLES, VIEWED FROM THE FRONT.

hippocampus; (2) the chorioid plexus; (3) the fimbria; and (4) the eminentia collateralis.

The **hippocampus** is for the most part covered by the chorioid plexus of the lateral ventricle. If this is detached a fissure appears between the fimbria and the roof of the ventricular horn. This is the **chorioid fissure.** It appears at a very early date in the development of the cerebral hemisphere, and takes an arcuate

course round the posterior end of the thalamus. In the region of the pars centralis of the lateral ventricle it extends as far forwards as the foramen interventriculare and is formed by the involution of an epithelial part of the wall of the ventricle over the chorioid plexus (p. 619). In the region of the inferior horn, when the chorioid plexus, with the involuted epithelial layer which covers it, is withdrawn, the chorioid fissure is converted into an artificial gap which leads directly into this part of the ventricular cavity.

The **chorioid plexus** is a convoluted system of blood-vessels in connexion with a fold of pia mater, which is prolonged into the inferior horn of the lateral ventricle. It lies on the surface of the hippocampus and is continuous, behind the posterior part of the thalamus, with the chorioid plexus in the pars centralis of the lateral ventricle. But it must not be supposed that the chorioid plexus lies free in the ventricular cavity. It is clothed in the most intimate manner by an epithelial layer, which represents the medial wall of the inferior horn involuted into the cavity over the chorioid plexus. The ventricle, therefore, opens on the surface only through the chorioid fissure when this thin epithelial layer is torn away by the withdrawal of the chorioid plexus. From the above, it will be understood that the arcuate chorioid fissure, throughout its whole length (viz., from the interventricular foramen to the extremity of the inferior horn of the lateral ventricle), is formed by the involution of the roof and a portion of the wall of the hemisphere which remains epithelial. In the central part of the ventricle this layer is attached, on the one hand, to the sharp margin of the fornix, and on the other to the superior surface of the thalamus; in the inferior horn it is attached, in like manner, to the edge of the fimbria hippocampi or crus of the fornix, whilst, above, it joins the roof of this portion of the ventricle along the line of the stria terminalis (Fig. 531).

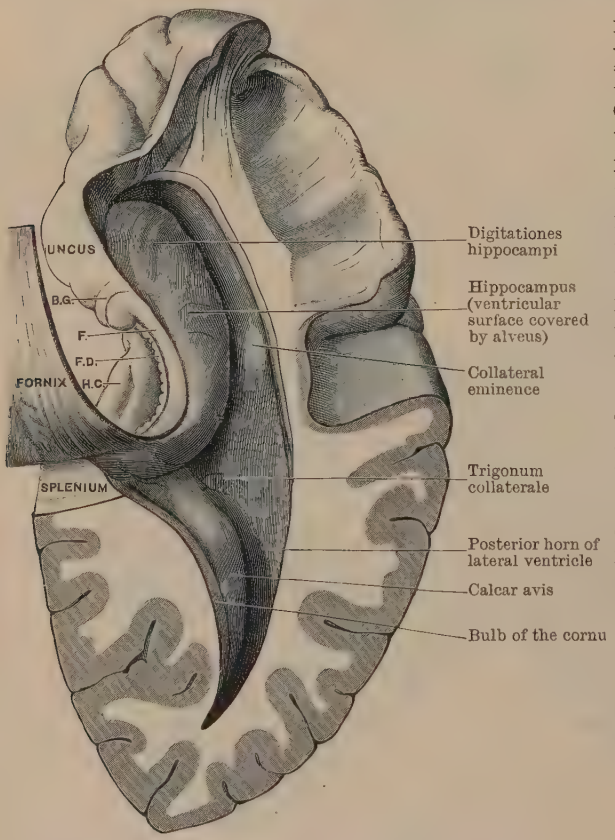

FIG. 533.—DISSECTION from above, to show the posterior and inferior cornua of the lateral ventricle.

B.G. Cauda fasciæ dentatæ. F.D. Fascia dentata hippocampi.
F. Fimbria hippocampi. H.C. Gyrus hippocampi.

The **eminentia collateralis** shows very great differences in its degree of development.

The **trigonum collaterale** is a smooth elevation in the floor of the ventricle, in the interval which is left between the calcar avis and the hippocampus as they diverge one from the other.

BASAL GANGLIA OF THE CEREBRAL HEMISPHERE.

Under this heading are included certain masses of gray matter more or less completely embedded in the white medullary substance of the hemisphere, and which are developed in its wall. They compose the caudate and lentiform nuclei, which together form the corpus striatum, and the amygdaloid nucleus.

The **nucleus caudatus** bulges into the lateral ventricle. It is a piriform, highly arched mass of gray matter, which presents a thick, swollen head, or anterior

extremity, and a long, attenuated tail. The head projects into the anterior horn of the lateral ventricle, whilst its narrower part is prolonged laterally and posteriorly in the floor of the ventricle, where it is separated from the thalamus by the stria terminalis. Finally, its tail curves downwards with a bold sweep and enters the inferior horn of the lateral ventricle. In the roof of this horn it is prolonged forwards to the amygdaloid nucleus, the lower part of which it joins. The caudate nucleus thus presents a free ventricular surface, covered with ependyma, and a deep surface embedded in the white substance of the cerebral hemisphere, and for the most part related to the internal capsule.

Owing to its arched form it follows that, in horizontal sections through the cerebral hemisphere below a particular level, it is cut at two points, and both the head and the tail appear on the field of the section (Fig. 534). In frontal sections behind the amygdaloid nucleus, it is also divided at two places.

The anterior extremity of the head of the caudate nucleus coincides very nearly with that of the anterior horn of the lateral ventricle. In the region of the substantia perforata anterior, the head of the caudate nucleus gains the surface and its gray matter becomes continuous with that of the cerebral cortex.

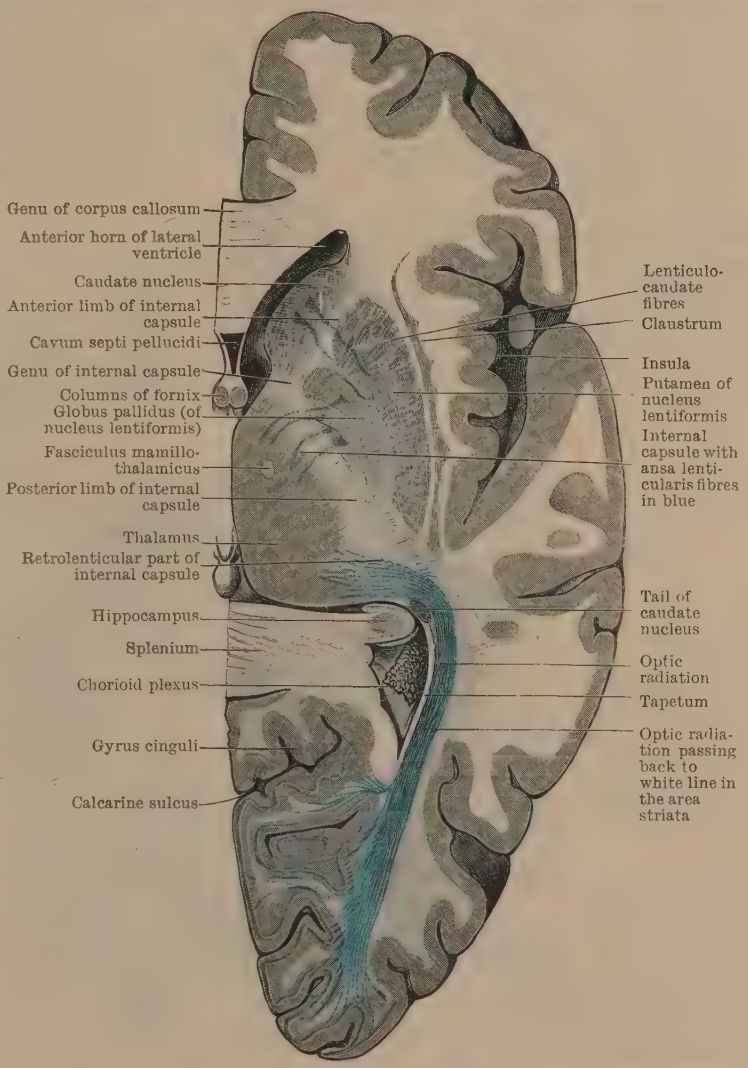

FIG. 534.—HORIZONTAL SECTION THROUGH THE RIGHT CEREBRAL HEMISPHERE AT THE LEVEL OF THE WIDEST PART OF THE LENTIFORM NUCLEUS.

The **nucleus lentiformis** lies on the lateral side of the caudate nucleus and thalamus, and is for the most part embedded within the white medullary substance of the cerebral hemisphere. It does not extend either so far forwards or so far backwards as the caudate nucleus. Indeed, it presents a very close correspondence in point of extent with the insula on the surface. When seen in horizontal section, it presents a shape similar to that of a biconvex lens. Its medial surface bulges more than the lateral surface, and its point of highest convexity is placed opposite the stria terminalis and the interval between the caudate nucleus and the thalamus. In frontal section the appearance presented by the lentiform nucleus differs very much in different planes of section. Fig. 535 represents a section through its anterior

portion. Here it is semilunar or crescentic in outline and is directly continuous below with the head of the caudate nucleus; above, also, it is intimately connected with the caudate nucleus by bands of gray matter, which pass between the two nuclei and break up the white matter of the anterior part of the intervening internal capsule. It is due to the ribbed or barred appearance, which is presented by such a section as this, that the term **corpus striatum** is applied to the two nuclei. In the region of the substantia perforata anterior both nuclei reach the surface and become continuous with the cortex.

When a section is made in a plane further back (*e.g.* immediately posterior to the anterior commissure, as in Fig. 536) the divided lentiform nucleus assumes an altogether different shape, and is seen to be completely cut off from the caudate nucleus by the internal capsule. It is now triangular or wedge-shaped. Its *base* is turned towards the insula and is in direct relation to a thin lamina of white matter, termed the external capsule. Its *medial surface* is oblique and is applied to the internal capsule, whilst its *inferior surface* is horizontal and is directed downwards towards the base of the brain. But, further, two white laminæ, the **external** and **internal medullary laminæ**, are now evident, which traverse its substance in a vertical direction and divide it into three masses. The lateral, basal, and larger mass is termed the **putamen**; the two medial portions together constitute the **globus pallidus**.

The **putamen** forms much the largest part of the lentiform nucleus. It is darker in colour than the globus pallidus, and in this respect resembles the caudate nucleus. It is traversed by fine radiating bundles of fibres, which enter it from the external medullary lamina. Both in point of structure and in mode of development it is closely associated with the caudate nucleus, and it is the only part of the lentiform nucleus which is connected by intervening bands of gray matter with the caudate nucleus. The anteroposterior length, as well as the vertical depth of the putamen, is much greater than in the case of the globus pallidus; consequently, in both frontal and horizontal sections through the cerebrum it is encountered before the plane of the globus pallidus is reached.

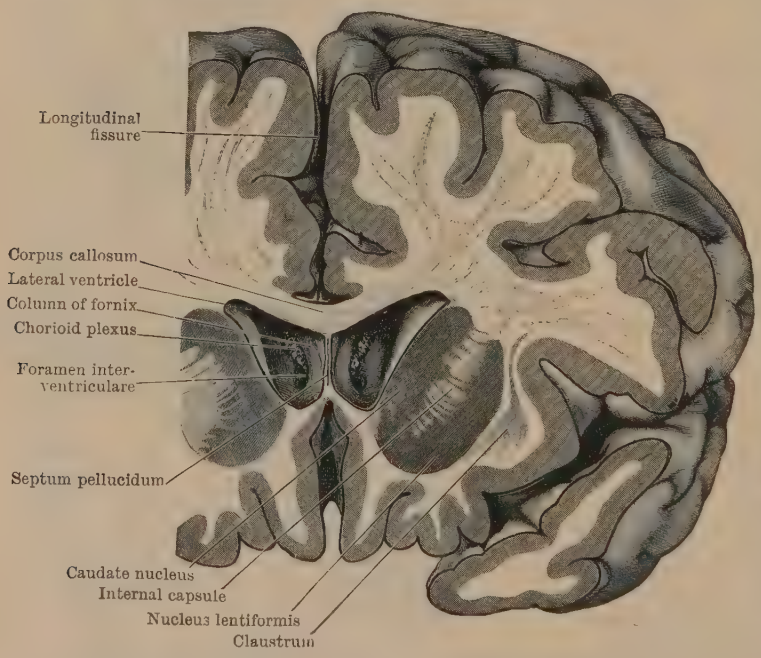

FIG. 535.—FRONTAL SECTION THROUGH THE CEREBRAL HEMISPHERES so as to cut through the anterior part (putamen) of the lentiform nucleus in front of the globus pallidus. Viewed from in front; looking through the anterior horn into the central part of the ventricle.

The external capsule is loosely connected with the lateral surface of the putamen, and it can be readily stripped off. This accounts for the tendency, exhibited in hæmorrhages in this locality, for the effused blood to spread out in the interval between these structures.

The **globus pallidus** is composed of the two smaller and medial masses of the lentiform nucleus. They present a faint yellowish tint, and are paler and more

abundantly traversed by fibres than the putamen. The mass next the putamen (*i.e.* the intermediate part) is much larger than the medial subdivision. It extends forwards to a point a little in front of the plane of the anterior commissure. When the lentiform nucleus is cut in a frontal direction, and in its widest part, the medial mass shows an indication of a separation into two parts, so that here the globus pallidus appears to consist of three subdivisions.

Connexions of the Corpus Striatum.—Recent clinical investigation has demonstrated the importance of the functions of the corpus striatum, which seems to exercise a "steadying influence" (Kinnier Wilson) upon the muscles which perform voluntary movements that call for delicate co-ordination. Hence it is desirable to study the connexions of these large masses of gray matter. Fibres of the internal capsule coming from the motor cortex (as well as from all other cortical areas) end in the corpus striatum (Fig. 537), so that when a voluntary movement is initiated this structure is called into activity. Fibres coming from the nucleus caudatus break through the anterior limb of

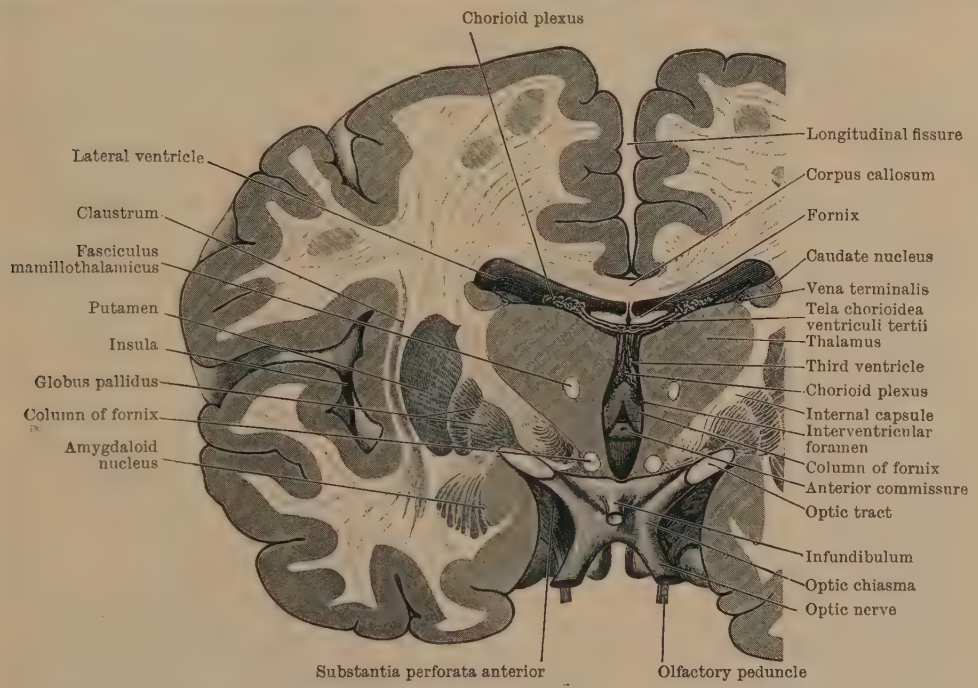

FIG. 536.—FRONTAL SECTION THROUGH THE CEREBRUM so as to cut through the three divisions of the lentiform nucleus ; posterior surface of the section shown here.

the internal capsule (Fig. 538), some of them to reach the putamen, others to pass through the external medullary lamina to the globus pallidus. Other tracts pass from the lentiform nucleus into the caudate nucleus (**fibræ lenticulocaudatæ**). From the globus pallidus fibres arise which proceed into the internal capsule in the region of the genu and the neighbouring part of the posterior limb (Fig. 538). Many of these fibres become collected on the inferior aspect of the lentiform nucleus, where they form a transversely directed bundle (Fig. 538), known as the **ansa lenticularis**, which is distributed to the thalamus (Fig. 538, **fasciculus striothalamicus**) and hypothalamus, the red nucleus (**fasciculus striorubricus**) and substantia niger (**fasciculus strionigricus**). These connexions afford some explanation of the difficulties of articulation and swallowing and in the performance of delicate voluntary movements that result from damage to the corpus striatum or to this system of fibres.

This system of fibres is phylo-genetically very old, being the most primitive efferent tract from the cerebral hemisphere.

Claustrum.—This is a thin plate of gray substance embedded in the white matter which intervenes between the lentiform nucleus and the gray cortex of the insula. Followed in an upward direction, it becomes gradually thinner and ultimately disappears. As it is traced downwards, however, it thickens consider-

ably, and at the base of the brain it comes to the surface at the anterior perforated substance and becomes continuous with the gray matter of the cortex. Its extent corresponds very closely with the area occupied by the insula, and its surface towards this portion of the cerebral cortex shows ridges and depressions corresponding to the insular gyri and sulci.

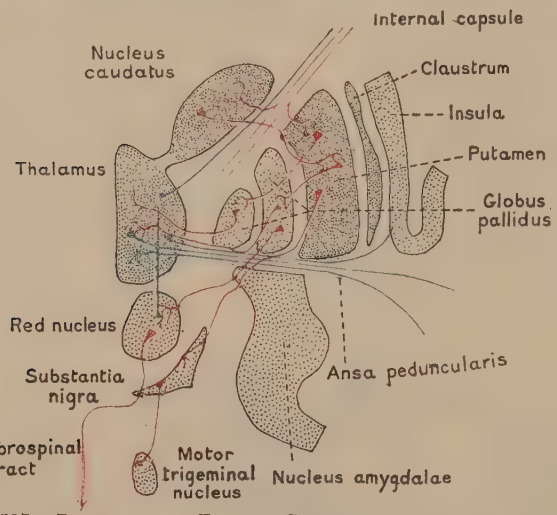

FIG. 537.—DIAGRAM OF A FRONTAL SECTION TO ILLUSTRATE THE FIBRE CONNEXIONS OF THE CORPUS STRIATUM.

Nucleus Amygdalæ.—In the anterior part of the temporal region, above the piriform area a fusiform mass of gray matter appears upon the surface (Fig. 522, p. 624), at the lateral extremity of the substantia perforata anterior (Fig. 520, p. 622). It is part of a large rounded mass, called the **amygdaloid nucleus**, which occupies a position in front of, and to some extent above the extremity of the inferior horn of the lateral ventricle. The tail of the caudate nucleus joins its inferior part (Fig. 539, p. 640), whilst above it is carried up into the putamen. Inferiorly it is continuous with the gray cortex of the piriform area, to which it is functionally related, probably in the same way that the major part of the corpus striatum is associated with the neopallium.

Stria Terminalis.—This is a band o fibres which, for the most part, arise in the amygdaloid nucleus. From this it runs backwards in the roof of the inferior horn of the lateral ventricle (Fig. 520, p. 622, and Fig. 539, p. 640), and then arches upwards and forwards, so as to gain the floor of the pars centralis of the lateral ventricle. In both situations it lies close to the medial side of the nucleus caudatus, and finally, at the interventricular foramen, it bends downwards towards the anterior commissure. Some of its fibres pass in front and others behind the commissure, and ultimately they end in the neighbourhood of the substantia perforata anterior (Kölliker).

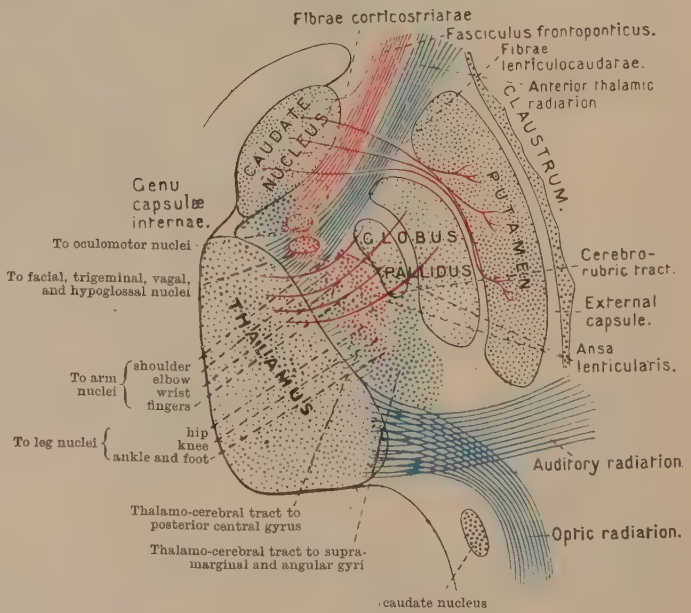

FIG. 538.—DIAGRAMMATIC REPRESENTATION OF THE INTERNAL CAPSULE (AS SEEN IN HORIZONTAL SECTION).

Internal Capsule.—This term is applied to the broad band of white matter which intervenes between the lentiform nucleus, on the lateral side, and the thalamus and caudate nucleus on the medial side. It presents many different appearances, according to the plane in which the brain is cut. A frontal section through the

brain which passes through the cerebral peduncles shows that, in great part, the internal capsule is directly continuous with the basal part of the cerebral peduncle (Fig. 546, p. 649). Viewed from the lateral aspect after removing all else of the cerebral hemisphere excepting the corpus striatum (Fig. 539), the cut ends of the fasciculi of the internal capsule form three-fourths of an ellipse, the other fourth of which is occupied by the bridge of union between the lentiform and caudate nuclei, the substantia perforata anterior, the amygdaloid nucleus and the anterior commissure. It may be divided into an **anterior (lenticulo-caudate) part**, a **superior (lenticulo-thalamic) part**, a **retrolenticular part** (not labelled in the figure), and a **postero-inferior (sublenticular) part.** The last three parts are usually grouped together as the posterior limb. In horizontal section the internal capsule is observed to be bent upon itself opposite the stria terminalis, or the interval between the caudate nucleus and the thalamus. This bend, which points medially, is called the **genu.** About one-third of the internal capsule lies in front of the genu, and is termed the anterior limb; the remaining two-thirds, which lie behind the genu, constitute the posterior limb (Fig. 538).

The **anterior limb of the internal capsule** intervenes between the lentiform nucleus and the caudate nucleus. In its inferior and anterior part it is much broken up by the connecting bands of gray matter which pass between the anterior part of the putamen and the caudate nucleus.

The anterior limb of the internal capsule is composed largely of corticipetal fibres belonging to the anterior thalamic radiation. It contains corticifugal fibres also. The *corticipetal fibres* arise in the median and anterior part of the lateral nucleus of the thalamus, and go through the anterior limb of the internal capsule to reach the cortex of the frontal lobe.

The *corticifugal fibres* are represented by the fronto-pontine tract.

The **fronto-pontine tract** arises in the cortex of the frontal region, traverses the anterior limb of the internal capsule, forms the medial fifth of the basis of the cerebral peduncle, and finally ends in the nuclei pontis.

The **posterior limb of the internal capsule** is placed between the thalamus and the lentiform nucleus, and it extends backwards for a short distance beyond the posterior end of the putamen on the lateral side of the posterior part of the thalamus and of the tail of the caudate nucleus. The posterior limb, therefore, is spoken of as consisting of a lenticular, a retrolenticular, and a sublenticular part.

The **lenticular** or more properly **lenticulo-thalamic part** of the posterior limb is composed of both corticipetal and corticifugal fibres. The *corticipetal fibres* enter the internal capsule from the lateral aspect of the thalamus, and are composed of fibres which arise within the thalamus from the ventral (ventro-lateral) nucleus, and proceed upwards to the cerebral cortex.

The *corticifugal fibres* consist of the cerebro-spinal tract and the cortico-thalamic fibres.

The great **motor** or **cerebro-spinal tract,** descending from the cerebral cortex, occupies the anterior half of the lenticular part of the internal capsule. The fibres, that go to the nuclei of the oculomotor, trigeminal, and facial nerves, lie close to the genu, and behind these are the fibres which go to the hypoglossal nucleus; still further back are cerebro-spinal fibres which enter the spinal medulla and end around the motor cells of the anterior column of gray matter. This cerebro-spinal tract has been observed occupying the middle part of the pedunculus cerebri, into which it passes directly from the internal capsule.

According to Monakow the posterior limb contains also an important tract of fibres passing from the motor cortex to the red nucleus **(fasciculus cerebrorubricus).**

The **retrolenticular part** of the posterior limb contains: (1) the fibres of the optic radiation as they pass from the lateral geniculate body to establish their connexions with the occipital cerebral cortex; (2) the fibres of the acoustic radiation, or those which connect the medial geniculate body with the acoustic cortical field in the temporal lobe (Fig. 538, p. 638, and Fig. 544, p. 647); (3) the temporo-pontine tract, which is composed of fibres which take origin in the middle and inferior gyri of the temporal lobe and pass through the sublenticular section of the internal capsule to reach the lateral part of the pedunculus cerebri. Through this they reach the basilar part of the pons, in the gray matter of which they end. This tract is accompanied by the **fasciculus**

temporothalamicus, which has a widespread origin from the temporal and occipital regions and passes through the sublenticular part of the internal capsule.

If the fibres of the internal capsule are traced upwards they are found to spread out widely from each other in a radiating or fan-shaped manner, as they are followed to the various gyri of the cerebral hemisphere. This arrangement is termed the **corona radiata**. The callosal system of fibres, as they proceed into the hemisphere, also radiate, and they intersect the fibres of the corona radiata (Fig. 542, p. 645).

External Capsule.—The thin lamina of white matter between the lateral aspect

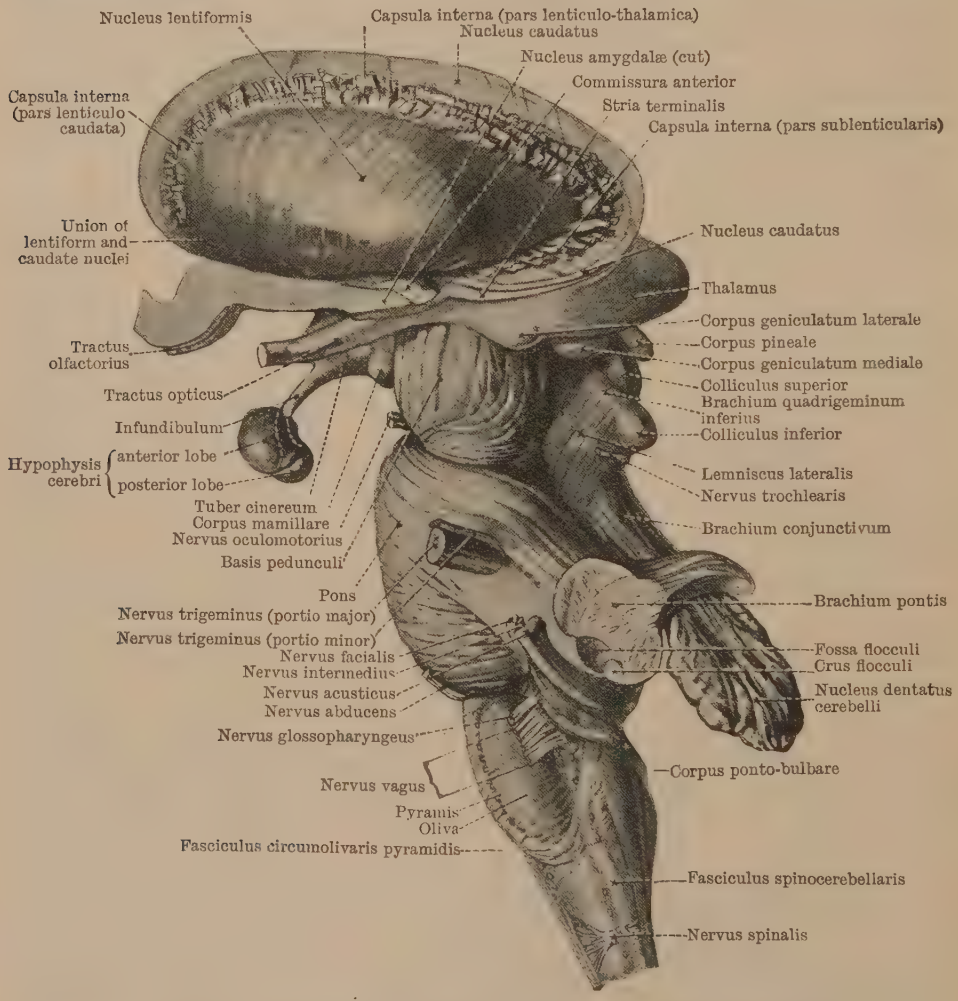

FIG. 539.—DISSECTION EXPOSING THE LATERAL ASPECT OF THE LENTIFORM NUCLEUS OF THE LEFT HEMISPHERE.

of the putamen and the claustrum is called the external capsule. This joins with the internal capsule in front of and behind the putamen, and in this manner the nucleus lentiformis is encapsuled by white matter.

INTIMATE STRUCTURE OF THE CEREBRAL HEMISPHERE.

The cerebral hemisphere is composed of an external coating of gray matter, termed the **cortex**, spread over an internal mass of white matter, which is called the **medullary centre**. The cortex is of peculiar interest, seeing that there is good reason for believing that in it the higher functions of the brain, or those which may be classed under the general designation of the intellectual functions, take place. It

is within the same layer of gray matter that the influence of those external impressions, which gain access to the cerebro-spinal axis through the senses, finally take shape as consciousness; and in it are placed also the centres which carry on the psycho-motor functions. The white medullary centre is composed of nerve-fibres which constitute the paths along which the influence of impressions is carried to and from the cortex, and from one part of the cortex to another.

THE CEREBRAL CORTEX.

The gray cortex is spread over the entire surface of the cerebral hemisphere, but it does not form a layer of equal thickness in all localities. At the summit of a

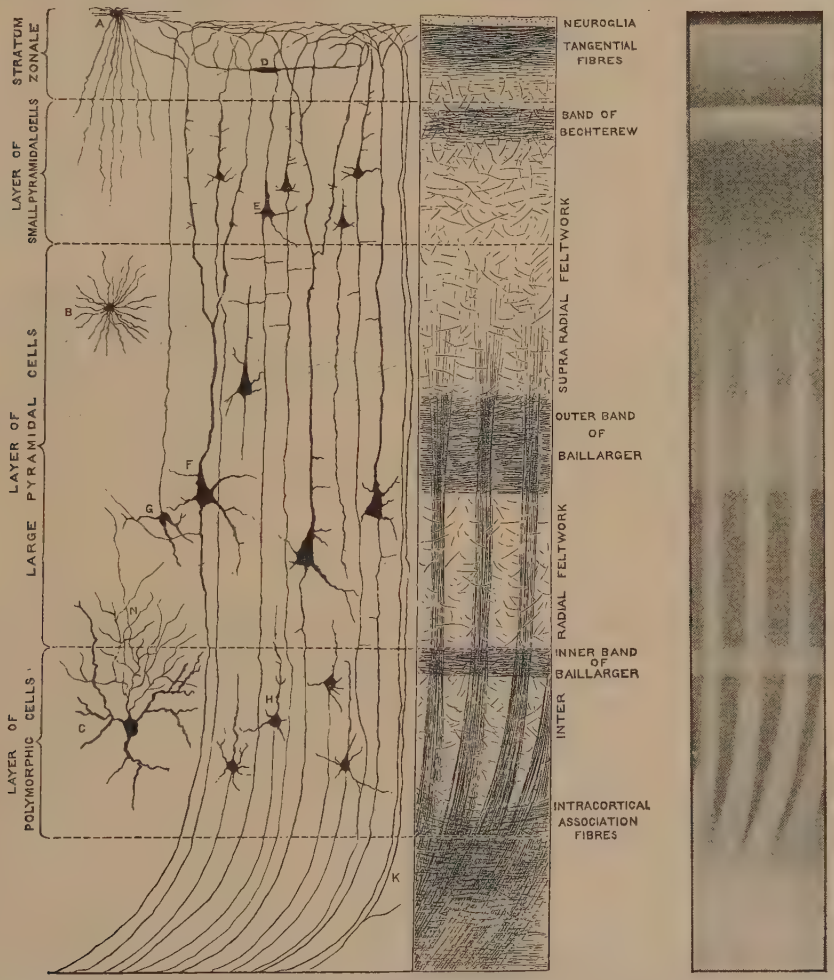

FIG. 540.—DIAGRAM TO ILLUSTRATE THE MINUTE STRUCTURE OF THE CEREBRAL CORTEX AND EXPLAIN HOW IT INFLUENCES THE MACROSCOPIC APPEARANCE.

K. Corticipetal fibres.

ygrus it is apt to be thicker than at the bottom of a furrow. The maximum thickness of cortex (about 4 mm.) is attained in the superior parts of the motor area, whilst the minimum (about 1·25 mm.) may be observed in the region of the occipital pole. The amount of gray cortex differs considerably in different individuals, and appreciably diminishes in old age. It is also stated, but upon

imperfect evidence, that it is relatively more abundant in the male than in the female.

In structure, likewise, marked differences may be noted in the gray cortex of different regions, and much has been recently done in the direction of pointing out the connexion of these structural peculiarities with the functional characteristics of particular areas and applying them to the determination of the significance of the furrows that subdivide the cerebral cortex into a series of ridges or gyri. This structural difference is quite apparent to the naked eye when sections are made through the cortex in a fresh brain, and sharp transitions in structure occur at the place where one area joins another. It is only to those general structural features which more or less characterise the entire cortical layer that we shall be able to refer.

When sections are made through the fresh brain, and the cut surface is closely inspected, it will usually be apparent that the cortex is distinctly stratified. On the outside there is a thin, whitish layer, and beneath this the gray matter presents two strata of very nearly equal thickness, viz., a middle, gray-coloured stratum and an inner, yellowish-red stratum. Between the two latter layers a narrow white band is, in many places, visible. This is termed the **outer band of Baillarger.** When the layers indicated above are present, four strata, superimposed one upon the other, are recognised; but in certain regions a second white streak traverses the deep or inner gray layer and divides it into further stratifications. This is termed the **inner white band of Baillarger**, and, when it is present, the gray cortex becomes divided obscurely into six alternating white and gray layers.

The outer band of Baillarger is strongly marked in the region behind the calcarine sulcus and gives a characteristic appearance to this portion of the cortex. In this locality it receives the name of the **stria of Gennari** (Fig. 530, p. 632).

White Medullary Centre of the Cerebral Hemisphere.—The white matter of the hemisphere which lies subjacent to the gray cortex is composed of medullated nerve-fibres, arranged in a very intricate manner. But the arrangement of these fibres cannot be properly understood until the configuration of the surface of the hemisphere has been considered.

THE NEOPALLIUM.

Fibre-tracts proceed into different districts of the neopallium from the various nuclei of the thalamus to serve as the channels through which tactile, visual, acoustic, and other kinds of sensory impressions are poured into it. These districts may be regarded as the receptive sensory areas, tactile, visual, acoustic, etc.; but around each sensory area there is differentiated a series of more or less concentric bands of neopallium, which are related to an incoming sensory path only through the intermediation of the sensory area which it fringes. Finally, there are interposed between the sensory area and its fringing bands of one sense and those of another, certain **association areas**, which cannot be regarded as the territory of any one sense, but as the place of meeting (and the physical counterpart of the blending in consciousness) of the impressions of different senses. In the human brain the neopallium becomes mapped out into a large series (more than forty) of areas, which differ one from the other in structure and in their connexions, and presumably therefore in their functions; and many of these areas may be further subdivided into a series of less obtrusively differentiated territories (Figs. 486 and 580).

The gray matter of the neopallium is spread over the surface of the white matter as a thin film (**cortex cerebri**), which is nowhere more than 4 millimetres, and may be only 1·25 millimetres thick. In different regions it presents every gradation of thickness between these two extremes. As the cortex increases in volume it does so not by any addition to its depth, but solely by an expansion of its superficial area. Thus it happens that in all larger mammalian brains, as the cerebral hemisphere expands and there is an increasing disproportion between the bulk of the hemisphere and the area of its surface, the cortex must become folded to accommodate itself to the limited area of surface upon which it has to be packed.

But this process of folding does not take place in any haphazard or purely mechanical way. The situations of the furrows or **sulci** which make their appearance are determined, for the most part, by the arrangement and the relative rates of expansion of the various areas into which the neopallium becomes differentiated.

The great majority of the furrows belong to a group, which we may call (1) **sulci terminales**, *i.e.* they make their appearance along the boundary lines between areas of different structure. The fissura rhinalis and sulcus centralis are examples of this group. Another group, which may be called (2) **sulci axiales**, develop by the folding of areas of uniform structure, *i.e.* along the axis of certain territories. The retro-calcarine sulcus and the sulcus occipitalis lateralis belong to this group. There is a third group of (3) **sulci operculati**, where the edge of one area becomes pushed over an adjoining territory, so that a trough is formed (Fig. 541, C), which is neither a limiting nor an axial sulcus. The sulcus lunatus is an example. And finally there is a fourth group, in which some more definitely mechanical factor comes into play to complicate the operation of these other factors, or even to determine the development of a furrow. The sulcus parieto-occipitalis and the fissura lateralis are examples of the fourth group.

[It is the custom to call certain furrows *sulci* and others *fissures*, and to call some of them *complete*, because they indent the whole thickness of the wall of the ventricle, and to call the rest *incomplete*. There is no justification whatever for any such distinctions.

It is usual also to subdivide the surface of the hemisphere in a purely arbitrary manner into "*lobes*" and to speak of *interlobar fissures*, but this is an artificial and misleading terminology which we shall avoid as far as possible.]

Fissura Longitudinalis Cerebri.—The longitudinal fissure is not a fissure of the cortex but is the great cleft between the two cerebral hemispheres. In front and behind it separates the cerebral hemispheres completely the one from the other. In its middle part, however, the fissure is interrupted and floored by the corpus callosum, a white commissural band, which passes between the hemispheres and connects them together. The superior surface of the corpus callosum is displayed when the contiguous medial surfaces of the cerebral hemispheres are drawn asunder. The longitudinal fissure is occupied by a median fold of dura mater, termed the falx cerebri, which partially subdivides the part of the cranial cavity allotted to the cerebrum into a right and left chamber.

External Configuration of each Cerebral Hemisphere.—Each cerebral hemisphere presents a lateral, a medial, and an inferior surface. The *lateral surface* is convex and is adapted accurately to the internal surface of the cranial vault. The *medial surface* is flat and perpendicular, and bounds the longitudinal fissure. In great part it is separated from the corresponding surface of the opposite hemisphere by the falx cerebri. The *inferior surface* is irregular and is adapted to the anterior and middle cranial fossæ of the cranial floor and, behind these, to the superior surface of the tentorium cerebelli. Traversing this surface in a transverse direction, nearer the anterior end of the hemisphere than the posterior end, is the stem of the lateral fissure. This deep cleft divides the inferior surface into an anterior or *orbital area*, which rests on the orbital part of the frontal bone and is consequently concave from side to side, and a more extensive posterior or *tentorial area*, which lies on the floor of the lateral part of the middle cranial fossa and upon the superior surface of the tentorium cerebelli. This surface is arched from before backwards, and looks medially as well as downwards. In its posterior two-thirds it lies above the cerebellum, from which it is separated by the tentorium cerebelli.

The borders which intervene between these surfaces are the supero-medial, the superciliary, the infero-lateral, the medial occipital and medial orbital. The *supero-medial border*, convex from before backwards, intervenes between the convex lateral surface and the flat medial surface of the hemisphere. The *superciliary border* is highly arched and separates the orbital surface from the lateral surface. The *infero-lateral border* marks off the tentorial surface from the lateral surface. The *medial occipital border* can be seen only in cases where the brain has been hardened *in situ* and faithfully retains the natural form. It extends from the posterior end

of the hemisphere towards the posterior extremity of the corpus callosum, and intervenes between the medial and tentorial surfaces. It is the border which lies along the straight blood sinus, and it therefore occupies the angle which is formed by the attachment of the posterior part of the falx cerebri to the superior surface of the tentorium cerebelli. The *medial orbital* border separates the medial surface from the orbital surface.

The most projecting part of the anterior end of the cerebral hemisphere is called the **frontal pole**, whilst the most projecting part of the posterior end is termed the

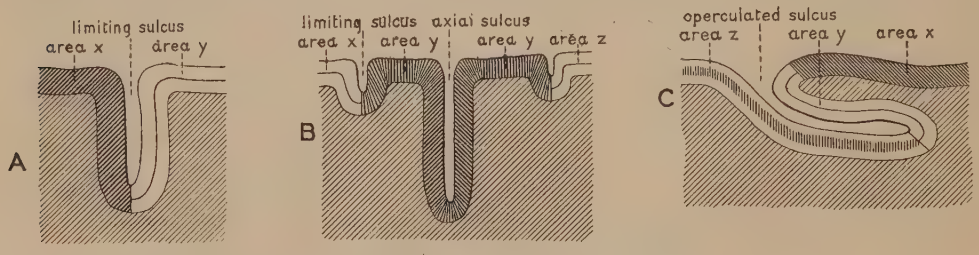

Fig. 541.—Diagrams to explain Three Types of Cerebral Furrows.

occipital pole. On the inferior surface of the hemisphere the prominent point of cerebral substance which extends forwards below the lateral fissure receives the name of the **temporal pole**. In a well-hardened brain a broad groove is usually present on the medial and inferior aspect of the occipital pole of the right hemisphere. This corresponds to the commencement of the right transverse venous sinus. A less distinct groove on the occipital pole of the left hemisphere frequently indicates the commencement of the left transverse sinus. On the tentorial surface, a short distance behind the temporal pole, a well-marked depression, **impressio petrosa**, is always visible. This corresponds to the elevation on the anterior surface of the petrous portion of the temporal bone over the superior semicircular canal.

The White Matter of the Cerebral Hemispheres.

According to the connexions which they establish the fibres forming the white medullary matter of the hemispheres may be classified into three distinct groups, viz., (1) commissural fibres; (2) association fibres; and (3) projection fibres.

Commissural Fibres.—These are fibres which link together portions of the gray cortex of opposite cerebral hemispheres. They are arranged in three groups forming three definite structures, viz., the corpus callosum, the anterior commissure, and the hippocampal commissure.

The **corpus callosum** has in a great measure been already studied (p. 626). As it enters each hemisphere, its fibres spread out in an extensive radiation (the radiation of the corpus callosum). It thus comes about that every part of the cerebral cortex, with the exception of the bulbi olfactorii, the olfactory parts of the hemisphere, and the inferior and anterior part of the temporal lobe, is reached by the callosal fibres. But it should be clearly understood that all the regions of the cortex do not receive an equal proportion of fibres; in other words, some cortical areas would appear to be more plentifully supplied than others. Another point of some importance consists in the fact that the callosal fibres do not, as a rule, connect together symmetrical portions of the gray cortex. As the fibres cross the median plane they become greatly scattered, so that dissimilar parts of the cortex of opposite hemispheres come to be associated with each other.

The **commissura anterior** is a structure supplemental to the corpus callosum, although originally it was the principal cerebral commissure long before the corpus callosum was evolved. It connects together the two olfactory bulbs, and also portions of the opposite temporal lobes. It presents a cord-like appearance and in median section appears as a small oval bundle in the lamina terminalis (Fig. 512, p. 615). The middle free portion is placed immediately in front of the

columns of the fornix as they curve downwards, and also in intimate relation to the anterior end of the third ventricle. Posteriorly, the small portion of the anterior commissure which appears in the ventricle between the two columns of the fornix is clothed with the ventricular ependyma; anteriorly, the commissure is connected with the lamina terminalis as it stretches from the optic chiasma upwards towards the inferior (anterior) end of the hippocampal commissure.

The lateral part of the anterior commissure penetrates the cerebral hemisphere, and, gaining the inferior part of the anterior end of the internal capsule, divides into two portions, viz., a small inferior olfactory part and a much larger temporal part.

The **olfactory portion** of the anterior commissure is an exceedingly small fasciculus. It passes downwards and forwards, and finally enters the olfactory tract. It is composed (1) of true commissural fibres, which bind one olfactory bulb to the other; and (2) of other fibres, which connect the olfactory bulb of one side with the piriform area of the other side.

The **temporal portion** is formed of almost the whole of the fibres of the

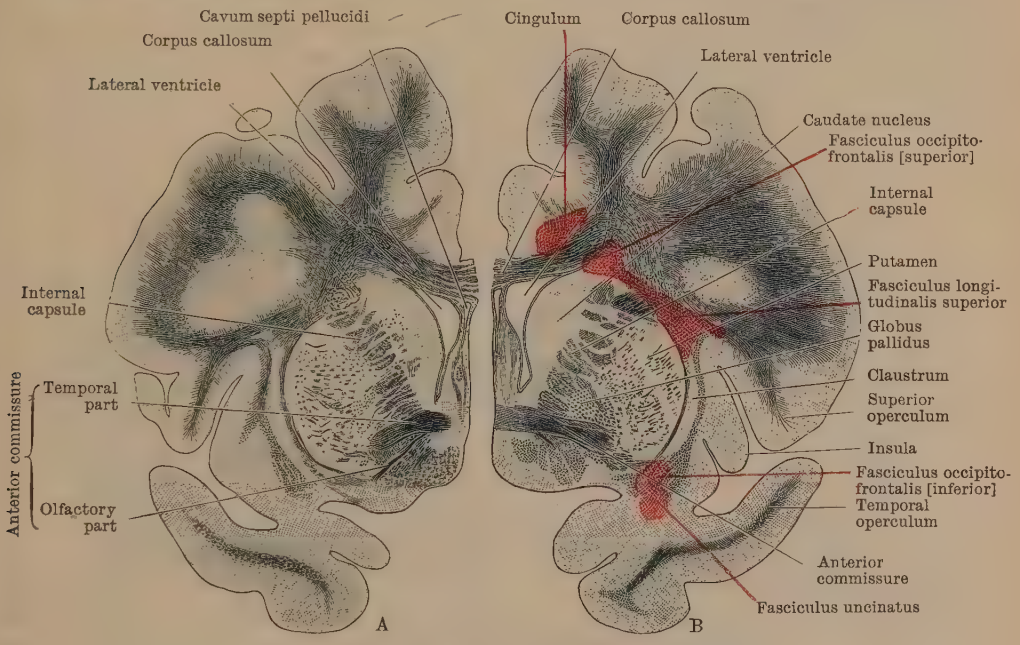

FIG. 542.—TWO FRONTAL SECTIONS THROUGH THE CEREBRAL HEMISPHERES OF AN ORANG, IN THE PLANE OF THE ANTERIOR COMMISSURE.

A, Section through the left hemisphere in a plane a short distance behind B, which is a section through the right hemisphere. The positions of the great longitudinal association tracts are indicated in red.

commissure. It is carried laterally under the lentiform nucleus, until it gains the interval between the globus pallidus and the putamen. At this point it changes its direction and sweeps backwards. In frontal sections through the brain, posterior to this bend, the temporal portion of the anterior commissure appears as an oval bundle of fibres cut transversely and placed in close contact with the inferior surface of the lentiform nucleus (Fig. 542). Finally, it turns sharply downwards on the lateral aspect of the amygdaloid nucleus, and its fibres are lost in the white medullary centre of the temporal lobe. When the lateral part of the anterior commissure is displayed by dissection, it is seen to be twisted like a rope.

The **hippocampal commissure** is composed of fibres which connect the hippocampus of one side with the corresponding structure of the opposite side. It is described on p. 626.

Association Fibres.—The association fibres bind together different portions of the cortex of the same hemisphere. They are grouped into long and short association bundles.

The greater number of the **short association fibres** pass between adjacent gyri. They curve round the bottoms of the sulci in U-shaped loops. Some of these occupy the deepest part of the gray cortex itself, and are termed *intracortical association fibres* (Figs. 543 and 544); others lie immediately subjacent to the gray matter—between it and the general mass of the white matter—and receive the name of *subcortical fibres.* Many groups of short association fibres, instead of linking together contiguous gyri, pass between gyri more or less remote. It is only after birth, when intellectual effort and education have stimulated different portions of the cortex to act in harmony and in conjunction with each other, that these association fibres assume their sheaths of myelin and become functional.

The **long association fibres** are arranged in bundles which run for considerable distances within the white medullary centre of the cerebral hemisphere, and unite districts of gray cortex which may be far removed from each other. The better known of these fasciculi are the following: (1) the uncinate bundle; (2) the cingulum; (3) the superior longitudinal bundle; (4) the inferior longitudinal; and (5) the occipito-frontal.

The **fasciculus uncinatus** is composed of fibres which arch over the stem of the lateral cerebral fissure and connect the frontal pole, and the orbital gyri of the frontal lobe, with the anterior portion of the temporal lobe.

The **cingulum** is a very well-marked and distinct band, which is closely associated

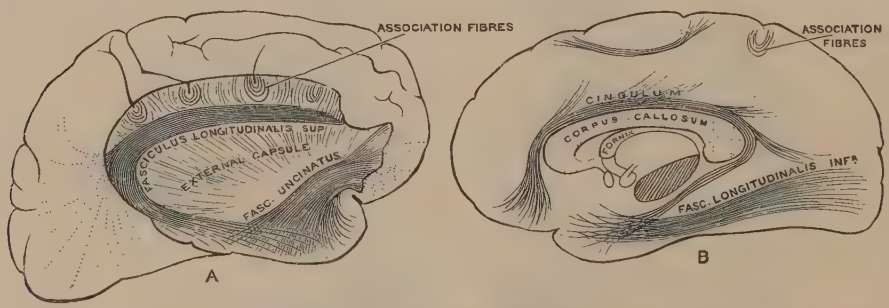

FIG. 543.—DIAGRAMS OF THE LEADING ASSOCIATION BUNDLES OF THE CEREBRAL HEMISPHERE. (Founded on the drawings of Déjerine.)

A, Lateral aspect of hemisphere. B, Medial aspect of hemisphere.

with the medial edge of the neopallium. Beginning in front, in the region of the anterior perforated substance, it arches round the genu of the corpus callosum and is carried backwards on the superior surface of this structure at the place where its fibres pass into the callosal radiation. The cingulum, therefore, lies under cover of the gyrus cinguli and stands in intimate relation to the white centre of this gyrus (Fig. 526, p. 628). At the posterior end of the corpus callosum the cingulum turns round the splenium and is carried forwards, in relation to the hippocampal gyrus, to the uncus and the temporal pole. The cingulum is composed of several systems of fibres which run only for short distances within it.

The **fasciculus longitudinalis superior** is an arcuate bundle which is placed on the lateral aspect of the foot or basal part of the corona radiata and connects the frontal, occipital, and temporal regions of the hemisphere. It lies in the base of the superior operculum and sweeps backwards over the insular region to the posterior end of the lateral cerebral fissure. Here it bends downwards round the posterior end of the putamen and proceeds forwards in the temporal lobe, to reach its anterior extremity. As it turns downwards to reach the temporal lobe numerous fibres radiate from it into the occipital lobe.

The **fasciculus longitudinalis inferior** is a very conspicuous bundle which extends along the whole length of the occipital and temporal regions (Fig. 543, B). Curran has recently demonstrated that the fasciculus uncinatus and the inferior longitudinal bundle are merely the shorter inferior fibres of a much bigger and longer tract (Fig. 544), to which he has applied the name **occipito-frontalis inferior.** The arrangement of these longitudinal tracts may be put concisely by saying that fibre

connexions of differing lengths link together the various cortical areas in the longitudinal direction, the deeper fibres (*i.e.* those furthest removed from the cortex, medial, lateral, superior or inferior) being progressively longer than the superficial. The deepest fibres extend the whole length of the hemisphere and are pushed aside by the insula (Fig. 544) and collected into two great bundles, a superior longitudinal and an inferior occipito-frontal bundle. In the occipital lobe the inferior occipito-frontal bundle is placed on the lateral aspect of the optic radiation, which takes a similar direction and from which it is distinguished by the greater coarseness of its fibres (Figs. 542, p. 645; 544; 526, p. 628). It is not present in the macaque monkey (Ferrier and Turner), but is well developed in the orang and the chimpanzee.

The **fasciculus occipito-frontalis superior** is a bundle of fibres which runs in a sagittal direction in intimate relation to the lateral ventricle (Fig. 542, p. 645). It may be regarded as the medial edge of the superior longitudinal bundle. It has been pointed

out (Forel, Onufrowicz, and others) that, in cases where the corpus callosum fails to develop, the tapetum remains apparently unaffected, and Déjerine has endeavoured to prove that the fibres of this layer really belong to the fasciculus occipito-frontalis. The fasciculus occipito-frontalis lies on the medial aspect of the corona radiata in intimate relation to the caudate nucleus, and posteriorly it spreads out over the superior and lateral aspect of the lateral ventricle, immediately outside the ependyma, where, according to Déjerine, it constitutes the tapetum (see p. 629).

Projection Fibres.—We have already seen that every part of the cerebral cortex is linked to other cortical areas, not only in its own neighbourhood (short association fibres) (Fig. 544), but also in the most distant parts of the hemisphere (long association fibres), as well as to the cortex of the other hemisphere (commissural fibres). In addition there are two large series of fibres: (i.) an ascending group which conveys to the cerebral cortex impulses coming from the thalamus and metathalamus, the corpora quadrigemina and the red nucleus, and the various

other sensory nuclei scattered throughout the brain stem and spinal medulla; and (ii.) a descending group connecting the cerebral hemisphere with the corpus striatum, various parts of the diencephalon, mesencephalon and cerebellum, as well as with all the motor nuclei scattered throughout the central nervous system. These two groups of tracts, respectively passing to and from the cerebral cortex, are known collectively as its **projection fibres.**

While examining the general arrangement of these projection fibres of the cerebral hemisphere it is convenient to refer incidentally to certain other fibre-tracts which do not fall strictly within this group.

The Sensory Tracts.—A certain proportion of the fibres that enter the spinal medulla by its posterior root, which are supposed to be the sensory nerves of muscles, tendons, and joints, pass upwards without interruption in the posterior funiculi throughout the whole length of the spinal medulla until they reach the medulla oblongata, where they end in the nucleus gracilis and nucleus cuneatus. From these nuclei, arcuate fibres (**fasciculus bulbothalamicus**) arise, and, after crossing the median plane, proceed upwards in the medial lemniscus of the other side to end in the ventro-lateral nucleus of the thalamus, from which a third group of neurones arises and proceeds upwards through the internal capsule to the cerebral cortex, where the impulses conveyed by it excite a consciousness of position and movement. But other sensory fibres end in the spinal medulla near their place of entry into it, and from the cells related to the endings of these fibres a new tract (**fasciculus spino-thalamicus**) arises, crosses the median plane to reach the antero-lateral funiculus of the opposite side, in which it proceeds upwards throughout the whole length of the spinal medulla (that lies above its origin), the rhomb-encephalon and mesencephalon to the thalamus, where it ends alongside the bulbo-thalamic tract in relationship with cells of the ventro-lateral nucleus. The fibres arising from this nucleus proceed to the gyrus centralis posterior, and convey impulses to it, which may excite a consciousness of touch, pressure, pain, heat, or cold. Some of these spino-thalamic fibres enter the medial lemniscus in the medulla oblongata, but others remain separate from it (Fig. 546) until they reach the level of the pons, where they become added to the lateral margin of the bulbo-thalamic tract.

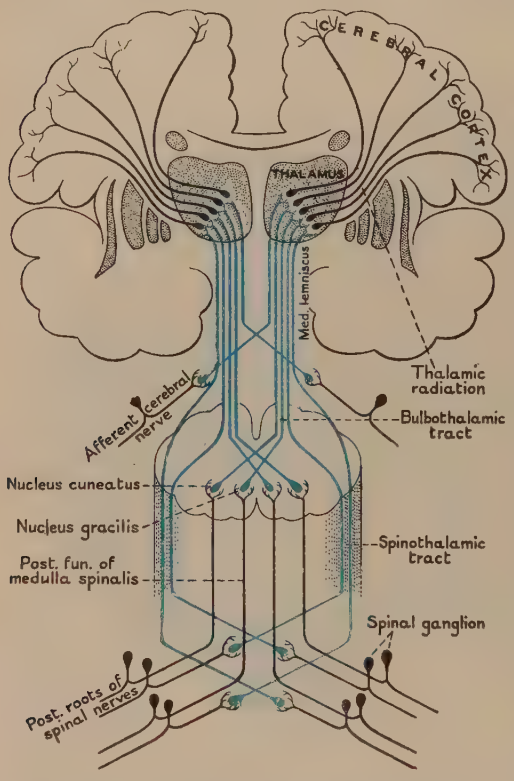

FIG. 545.—DIAGRAM OF THE SENSORY TRACTS FROM THE SPINAL MEDULLA TO THE CEREBRAL CORTEX.

[In Fig. 546 the line from the label "lemniscus medialis" points to the place of junction of the spino- and bulbo-thalamic tracts.]

Other groups of fibres, serially homologous to both the spino-thalamic and the bulbo-thalamic tracts, come from the various sensory cerebral nerves—trigeminal, facial, glossopharyngeal, and vagus—and become added to the great strands that are proceeding upwards to the thalamus (Figs. 545 and 465, p. 561).

Of the other great ascending tracts in the spinal medulla, such as the two pairs of fasciculi spinocerebellares, nothing further need be said; nor is it necessary to do more than remind the reader that from the nucleus dentatus of the cerebellum a great tract (brachium conjunctivum) ascends to the opposite red nucleus and

thalamus, and through them establishes an indirect connexion with the cerebral cortex in the precentral and frontal regions.

The other sensory pathways to the cerebrum, auditory, vestibular, visual, gustatory, and olfactory, are described elsewhere.

The Corticifugal Projection Strands.—The **fasciculus cerebrospinalis**, the great motor or pyramidal tract, is composed of fibres which arise from giant pyramidal cells of Betz in the posterior part of the precentral cortex (p. 661) in the district immediately in front of the sulcus centralis. The fibres descend through the corona radiata into the posterior limb of the internal capsule. From this point the further course of the pyramidal tract has been traced, viz., through the central part

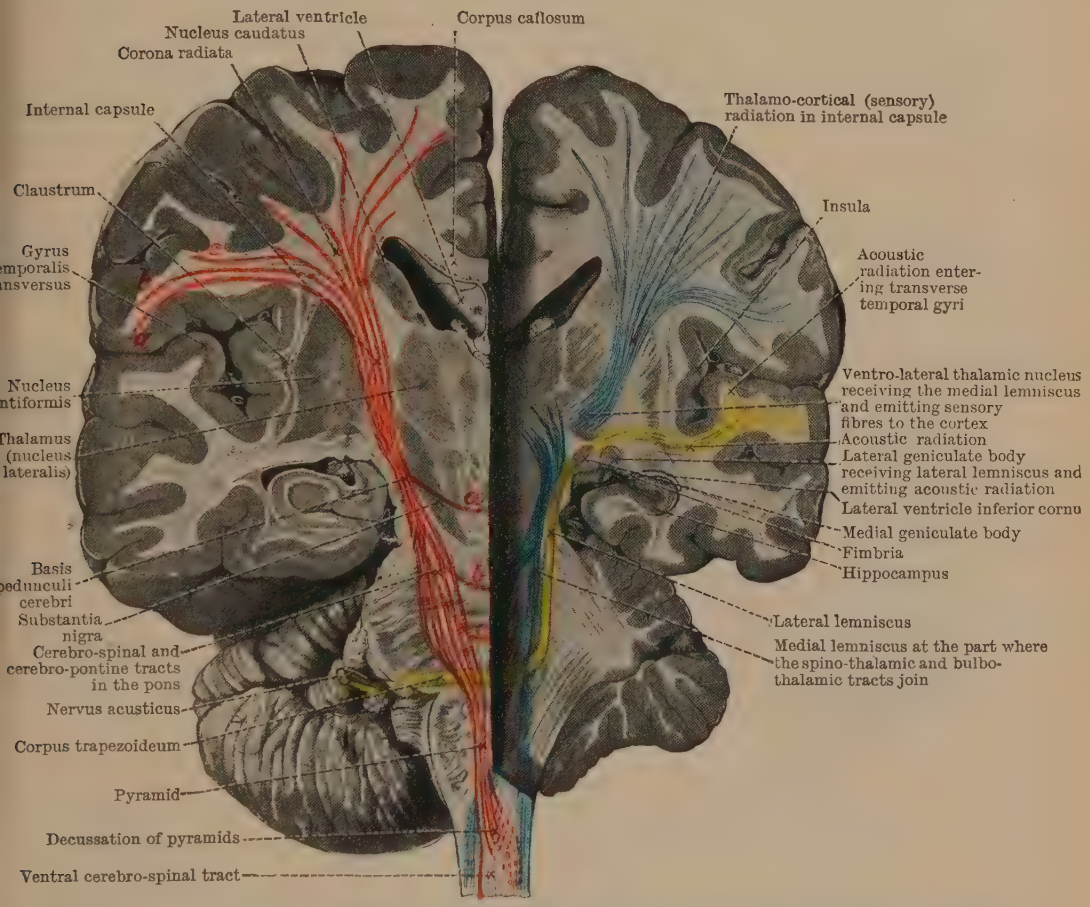

FIG. 546.—FRONTAL SECTION OF BRAIN, PASSING IN THE LINE OF THE CEREBRO-SPINAL TRACT (*marked in red*) IN THE RIGHT HEMISPHERE (left side of Fig.), and on a more posterior plane in the left hemisphere, where the sensory paths (tactile in blue, and acoustic in yellow) have been represented.

of the basal region of the cerebral peduncle and pons, and the pyramid of the medulla oblongata. At the level of the foramen magnum it decussates in the manner already described, and enters the spinal medulla as the lateral cerebro-spinal and anterior cerebro-spinal tracts. The fibres composing these end in connexion with the ventral or motor column of cells, from which the fibres of the anterior roots of the spinal nerves arise.

Similar fibres arise from the inferior part of the precentral area and proceed through the internal capsule and cerebral peduncle to all the motor nuclei upon the opposite side of the brain stem (**fasciculi cerebronucleares**). Hence the cerebral cortex of one hemisphere can control all the muscles of the opposite side of the body.

The **fronto-pontine strand** is composed of fibres which arise as the axons of the cells in the cortex which covers the frontal region that lies in front of the

precentral furrows. It descends in the anterior limb of the internal capsule, enters the medial part of the base of the cerebral peduncle, through which it gains the basilar part of the pons. In this its fibres end amongst the cells of the nuclei pontis, from which axons arise and establish relations with the cortex of the opposite cerebellar hemisphere.

The **temporo-pontine tract** consists of fibres which spring from the cells of that part of the cortex which covers the middle portions of the lower two temporal gyri. The temporo-pontine tract passes medially under the nucleus lentiformis, enters the retrolenticular part of the posterior limb of the internal capsule, and thus gains the lateral part of the cerebral peduncle. From this it descends into the basilar part of the pons, in which it ends in the nuclei pontis.

Cortico-striate and other Descending Fibres.—From the fibres of the internal capsule numerous collateral branches are given off to the nucleus caudatus and nucleus lentiformis, and from these basal ganglia fibres arise which enter the cerebral peduncle as constituent elements of the great cerebro-spinal tract.

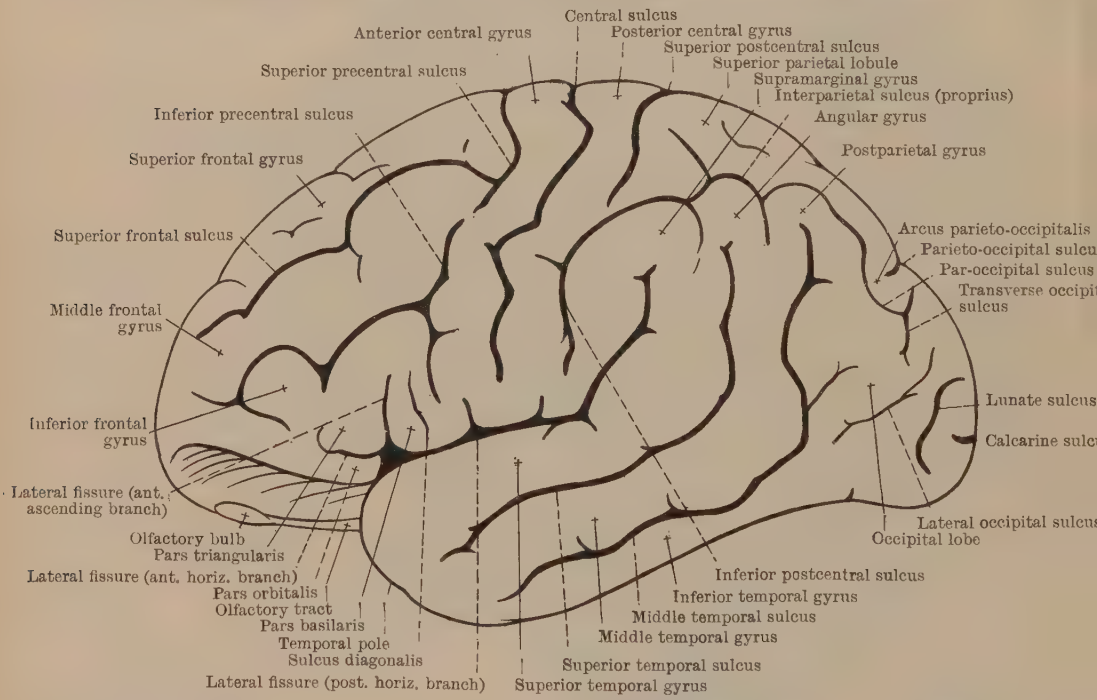

FIG. 547.—DIAGRAM OF THE SULCI AND GYRI ON THE SUPERO-LATERAL SURFACE OF THE HEMISPHERE. The middle frontal sulcus, which sometimes lies between the superior and inferior frontal sulci, is not shown.

Some of the fibres from the corpus striatum, especially the nucleus lentiformis, as well as others descending from the frontal cortex, pass into the red nucleus (Fig. 537), which also receives afferent tracts from the tectum mesencephali and from the cerebellum: it emits an important efferent tract **(fasciculus rubrospinalis)**, which crosses the median plane and descends in the brain stem and spinal medulla to the various motor nuclei (see Fig. 429).

THE SULCI AND GYRI OF THE CEREBRAL HEMISPHERES.

Fissura Cerebri Lateralis (O.T. **Fissure of Sylvius**).—This is the most conspicuous furrow on the surface of the cerebral hemisphere. In reality it is formed, not as a furrow upon the surface of the hemisphere, but as a great fossa, the margins of which develop into large lip-like folds that bulge over the fossa and meet to form the superficial pattern of the lateral fissure. It is composed of a short main stem, from the lateral extremity of which two or three branches or

limbs radiate. The **stem** of the lateral fissure is placed on the inferior surface of the hemisphere. It begins at the substantia perforata anterior and passes laterally, forming a deep cleft between the temporal pole and the orbital surface of the frontal region. Appearing on the lateral surface of the hemisphere, the fissure immediately divides into two or three radiating rami. These are: (1) the ramus posterior; (2) the ramus anterior horizontalis; (3) the ramus anterior ascendens, of which the last is inconstant.

The **posterior ramus** is the longest and most constant of the three limbs. It extends backwards, with a slight inclination upwards, on the lateral surface of the hemisphere for a distance which may vary from about two to three inches. It intervenes between the frontal and parietal regions, which lie above it, and the

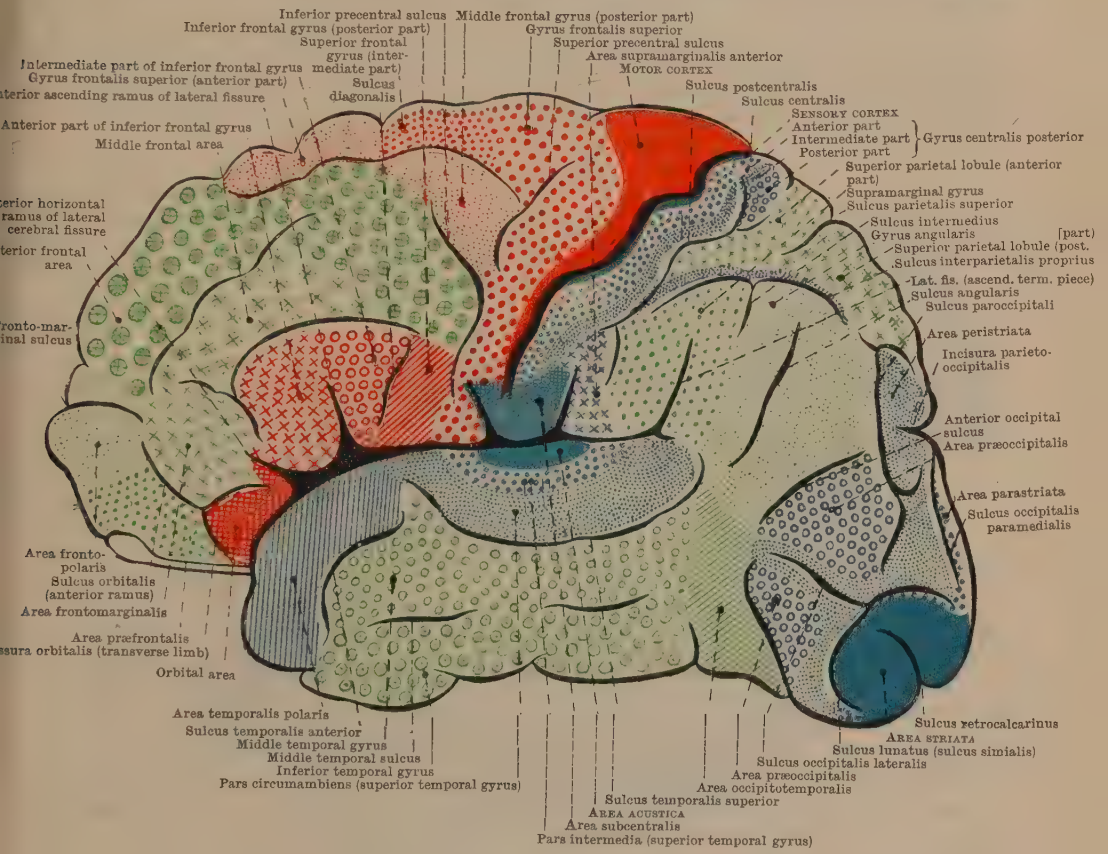

Fig. 548.—A Diagram of the Lateral Aspect of the Left Cerebral Hemisphere.

The *inferior frontal sulcus* (the superior boundary of the inferior frontal gyrus), the *middle frontal sulcus* (separating the anterior and middle frontal areas), and the *superior frontal sulcus* (bounding the superior frontal gyrus) are not labelled.

temporal region which lies below it; and it finally ends in the region subjacent to the parietal tuberosity of the cranial wall by turning upwards into the parietal region in the form of an *ascending terminal piece.*

The **anterior horizontal ramus** extends horizontally forwards in the frontal region for a distance of not more, as a rule, than three-quarters of an inch, immediately above and parallel to the posterior part of the superciliary margin of the hemisphere.

The **anterior ascending ramus** proceeds upwards and slightly forwards, into the inferior part of the lateral surface of the frontal region for a variable distance (an inch or less). In many cases the two anterior limbs spring from a common stem of greater or less length, and not infrequently there is only a single anterior limb.

Sulcus Circularis.—If the lips of the posterior ramus of the lateral fissure are pulled widely asunder from each other, the **insula** (island of Reil) will be seen at the

bottom. The insular district of the cortex is completely hidden from view, when the lateral fissure is closed, by overlapping portions of the cerebral hemisphere, and, when brought into view in the manner indicated, it is observed to present a triangular outline and to be surrounded by a limiting sulcus, of which three parts may be recognised, viz., a *superior part*, bounding it above and separating it from the parietal and frontal regions; an *inferior part*, marking it off below from the temporal region; and an *anterior part*, separating it in front from the frontal region.

The insula consists of three areas of different structure. At the antero-inferior corner (where the sulcus circularis is deficient) the knee-like bend of the area piriformis (see Figs. 550 and 520) appears at the **limen insulæ**. The rest is subdivided by an oblique furrow (**sulcus centralis insulæ**) into a posterior part divided into **gyri longi** and an anterior part divided into **gyri breves**.

Opercula Insulæ.—The overlapping portions of the cerebral substance which cover over the insula are termed the insular opercula, and they form, by the apposition of their margins, the three rami of the lateral fissure. The rami of the fissure extend from the exposed surface of the hemisphere to the submerged surface of the insula, and, in this manner, separate the opercula from each other.

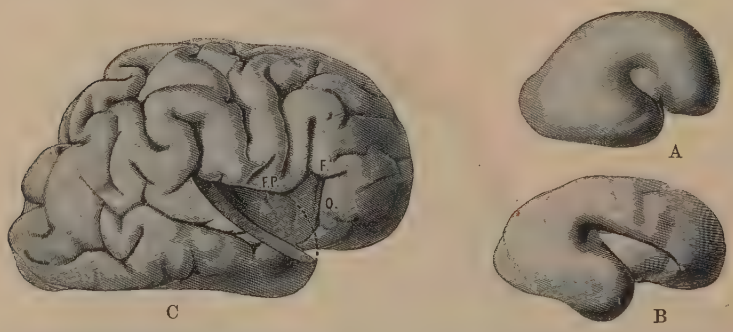

Fig. 549.—Right Hemispheres of Human Fœtuses showing Three Stages in the Development of the Insula and the Insular Opercula.

A, Right cerebral hemisphere from a fœtus in the latter part of the fourth month of development; B, Right cerebral hemisphere from a fœtus in the fifth month of development; C, Right cerebral hemisphere from a fœtus in the latter part of the eighth month of development.

In C the temporal operculum has been removed, and thus a large part of the insula is exposed. The outline of the temporal operculum is indicated by a dotted line.

F.P, Superior operculum. F, Frontal operculum. O, Orbital operculum.

The **temporal operculum (pars temporalis)** extends upwards over the insula from the temporal region, and its superior margin forms the inferior lip of the posterior ramus of the lateral fissure.

The **superior operculum** is carried downwards from the parietal (**pars parietalis**) and frontal (**pars frontalis**) regions over the insula, and its inferior margin, meeting the temporal operculum, forms the superior lip of the posterior ramus of the lateral fissure.

The small triangular piece of cerebral substance which sometimes intervenes between the ascending and horizontal anterior rami of the lateral fissure is formed by the bending downwards of the front part of the upper operculum. It covers over a small part of the anterior portion of the insula, and is sometimes termed the **pars triangularis**.

The **orbital operculum** is, for the most part, on the inferior surface of the hemisphere. It lies below and to the medial side of the horizontal anterior ramus of the lateral fissure, and proceeds backwards from the orbital aspect of the frontal lobe over the anterior part of the insula.

Development of the Lateral Fissure and of the Insular District of the Cerebral Hemisphere.—It is only during the latter half of the intra-uterine period of development that the opercula take shape and grow over the insula, so as to shut it out from the surface. In its early condition the insula presents the form of a depressed area on the side of the cerebral hemisphere, surrounded by a distinct boundary wall formed by the surrounding more elevated surface of the hemisphere (Fig. 549, A). After a time this depressed area, which is called the fossa lateralis, assumes a triangular outline, and then the bounding wall is observed to be composed of three distinct parts, viz., a superior or fronto-parietal, an inferior or temporal, and an anterior or orbital part (Fig. 549, B). The angle formed by the meeting of the superior and anterior portions of the boundary may become flattened, and a short oblique part of the limiting wall develop into a small triangular frontal operculum (Fig. 549, F). Each of these portions of the bounding wall of the fossa becomes a line of growth, from which an operculum

takes origin, and by the approximation of these opercula, as they grow over the surface of the fossa, the insula becomes closed in and the rami of the lateral fissure are formed (Fig. 549, C).

The lateral fissure is an example of the fourth category of furrows enumerated above. It is largely the result of the operation of the mechanical factors incidental to the bending downwards of the pallium in front of and behind the place where the hemisphere-wall is supported and held in position by the corpus striatum. The cortical area roughly corresponding to the surface of the corpus striatum is the insula; the temporal region extends downwards behind it, and to a less extent the frontal region in front of it (Fig. 549, A). Then towards the end of the fifth month of fœtal life the exuberant growth of the free fronto-parietal pallium above the insula (Fig. 549, B) and the temporal pallium below and behind it leads to the development of lip-like folds of neopallium—the opercula—which gradually approach one another (Fig. 549, C) and eventually cover up the insula. Other factors come into play in determining the form and topographical relations of the fissura lateralis. For example, the posterior part of the fissure is the morphological boundary between the acoustic and tactile territories of the neopallium.

THE ACOUSTIC AREA AND FIBRE-TRACTS.

In the embryo of the fifth month (Fig. 549, B), as well as in every later stage, even up to the adult condition (Fig. 550), an area upon the superior surface of

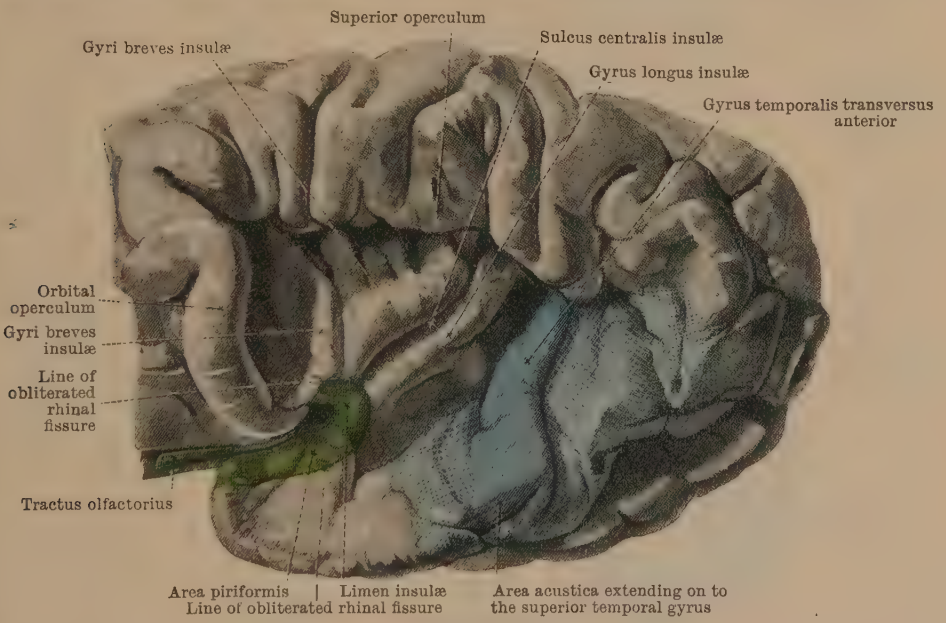

FIG. 550.—PART OF A LEFT CEREBRAL HEMISPHERE WITH THE OPERCULA OF THE INSULA WIDELY SEPARATED TO EXPOSE THE INSULA AND THE SUPERIOR SURFACE OF THE TEMPORAL OPERCULUM.

The *area acustica* is coloured a uniform blue, the *area intermedia* with large blue spots and the *area circumambiens* with fine blue dots.

the temporal operculum can be seen to slope medially towards the upper limb of the sulcus circularis, behind the insula. This area constitutes the receptive centre for acoustic impressions—the **gyrus temporalis transversus** or **Heschl's convolution**—although the extent of this acoustico-sensory area does not coincide exactly with that of the transverse temporal gyrus. The area formed by the upper surface of the temporal operculum immediately behind this prominent transverse gyrus is also called by the same name, so that there are anterior and posterior transverse temporal gyri (Fig. 550; the posterior transverse temporal gyrus is not labelled in the figure).

In studying the brain-stem we have seen that a tract of fibres originating in the cochlear terminal nuclei (in the medulla oblongata) crosses the median plane (corpus trapezoideum) and bends upwards in the lateral lemniscus of the other side (Fig. 546) to end in the medial geniculate body of the metathalamus. From the medial geniculate body a new tract arises (composed of tertiary acoustic neurones), which passes laterally (Figs. 546 and 520) to end in the transverse temporal gyri. This tract may be called the **radiatio thalamotemporalis.**

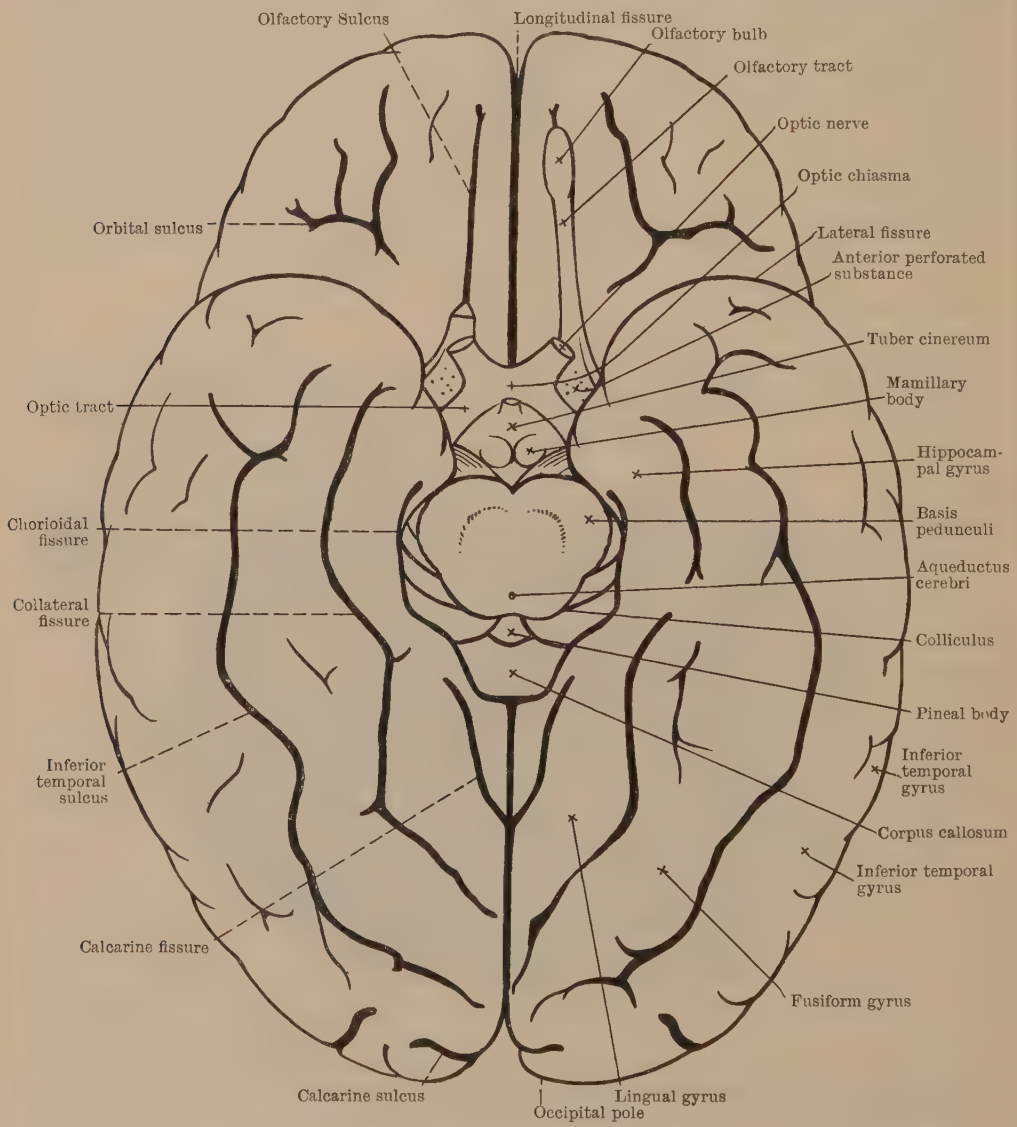

FIG. 551.—DIAGRAM OF THE GYRI AND SULCI OF THE INFERIOR SURFACES OF THE HEMISPHERES.

The area into which this acoustic radiation is inserted occupies not only the region of the anterior transverse temporal gyrus (Fig. 550) hidden within the lateral fissure, but also extends over its inferior lip, on to the exposed surface of the superior temporal gyrus (Fig. 548). Surrounding this area there are two concentric bands, which are also concerned with acoustic functions, but are related to the acoustic radiation only through the intermediation of the **area acustica** of the transverse gyrus (Figs. 548 and 550).

These areas may be distinguished as the **pars intermedia** and **pars circumambiens**, respectively, of the **gyrus temporalis superior**. During the sixth month of fœtal life a

furrow makes its appearance along the line of the inferior boundary of the superior temporal area (Fig. 558). It is called the **sulcus temporalis superior.**

At a much later stage of development another furrow (**sulcus temporalis anterior**) makes its appearance further forwards in the temporal region, as the posterior boundary of the **area temporalis polaris**; it often becomes confluent with the real sulcus temporalis superior, and is usually described as part of it. But it is genetically quite distinct from it (Fig. 548).

If the area acustica is cut across in a perfectly fresh brain it will be found to be composed of a thin layer (1·75 mm.) of cortical gray matter, in which two very dense and fairly broad bands of white matter are visible (Fig. 520). These bands are composed largely of fibres of the acoustic radiation, which have entered the cortex to terminate in it. The superior temporal area is composed of somewhat thicker cortex with two bands which are not so densely white as those of the area acustica. The cortex of the temporal polar area is composed of moderately thick, clear, gray matter in which there is a single, narrow, sharply defined white line.

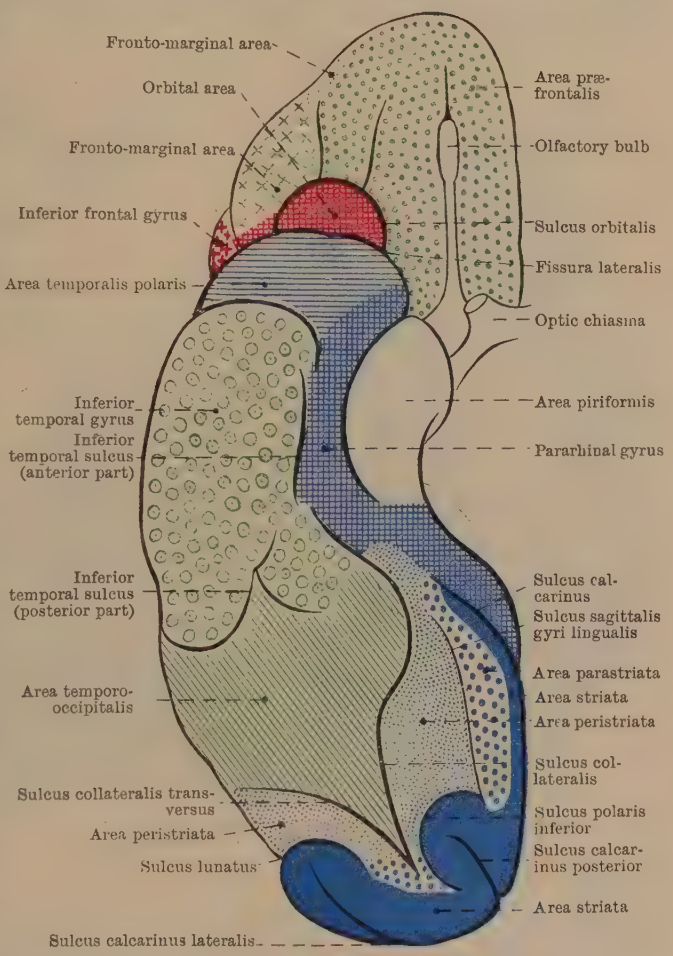

FIG. 552.—CORTICAL AREAS on the tentorial and orbital aspects of the cerebral hemispheres.

The remainder of the true temporal region is composed of an extensive district below the superior temporal sulcus. It is composed of thicker cortex than the superior temporal area, ranging from 3 mm. just below the superior temporal sulcus to 2·5 mm. at the inferior border of the hemisphere. It is composed of three bands of different texture, the **middle temporal gyrus**, the **inferior temporal gyrus**, and the **pararhinal gyrus**, which fringes the area piriformis on the tentorial surface. Upon the lateral aspect of the temporal region a series of irregular furrows are situated along the line of demarcation between the **gyrus temporalis medius** and the **gyrus temporalis inferior**; they are considered to represent a **sulcus temporalis medius**, but they are subject to much irregularity, especially in highly developed brains. The **sulcus temporalis inferior**, which forms the line of demarcation between the gyrus temporalis inferior and the gyrus fusiformis, is placed upon the inferior aspect of the temporal region.

The great extent of the middle and inferior temporal gyri constitutes one of the outstanding features distinctive of the human brain. Flechsig has shown that the fibres passing to and from these two gyri are the last to become medullated, later even than the important parietal and frontal areas.

THE VISUAL AREAS AND FIBRE-TRACTS.

We have already seen (Fig. 520) that each optic tract ends in the lateral geniculate body, the pulvinar of the thalamus, and the superior colliculus. From the lateral geniculate body (and according to most writers the thalamus also, though this is not admitted by all) a tract arises which conveys visual impulses back to the occipital pole of the hemisphere. This **radiatio thalamo-occipitalis (Gratiolet's optic radiation)** is seen from various points of view in the figures mentioned, but it is possible (see Fig. 553) to expose it in a section which will display it in its relationship to the rest of the visual path (Fig. 554).

From this it will be seen that the fibres of the optic radiation, after emerging

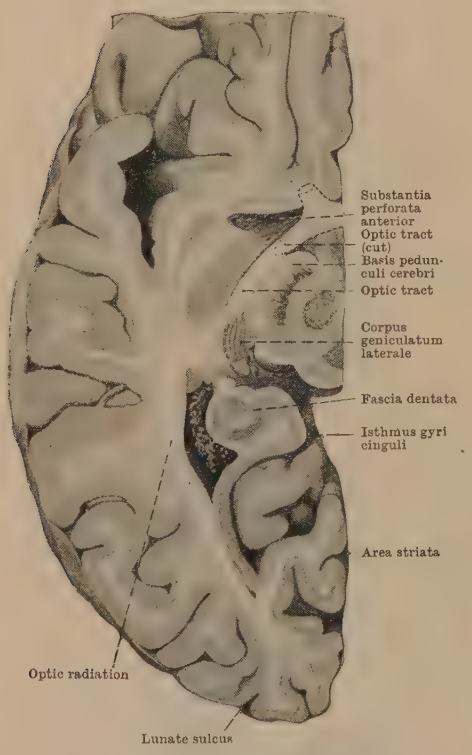

FIG. 553.—A SLIGHTLY OBLIQUE (ALMOST HORIZONTAL) SECTION THROUGH A CEREBRAL HEMISPHERE IN THE PLANE OF THE OPTIC TRACT AND RADIATION. The area striata contains the white line of Gennari.

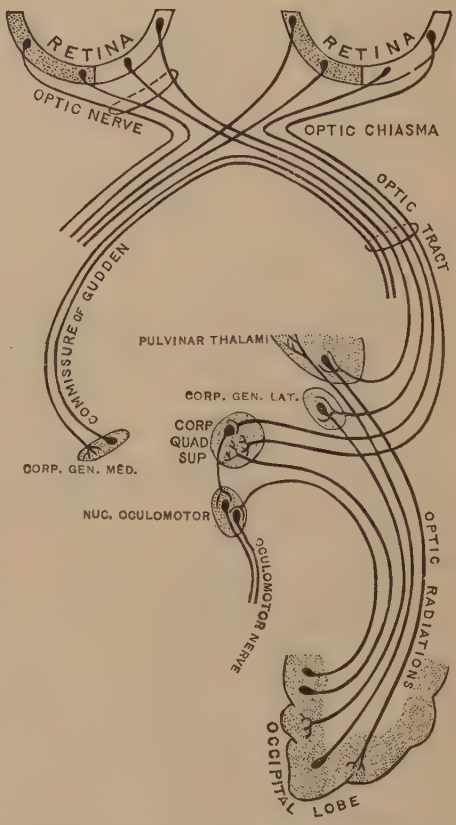

FIG. 554.—DIAGRAM OF THE CENTRAL CONNEXIONS OF THE OPTIC NERVE AND OPTIC TRACT.

from the lateral geniculate body, bend backwards in the lateral wall of the ventricle and proceed to an extensive district of thin cortex (1·5 mm. or less in thickness), occupying an area of about 3000 sq. mm. of the medial surface and pole of the occipital area. The cortex in this area is distinguished by the presence of a very distinct white line or stria, which was first noticed by Gennari in the year 1776.

If this visual receptive **area striata** of the occipital cortex is excised and spread out in one plane, it will be found to present an elongated ovoid form and a superficial extent of about 3000 sq. mm. (varying in different brains from about 2700 to 4000). The narrow extremity of the oval is placed a short distance behind and below the splenium of the corpus callosum; and from this point the area extends horizontally backwards to the occipital pole, or even beyond it on to the lateral aspect of the hemisphere. In the course of development this area

striata becomes folded along its axis during the sixth month, and the furrow thus formed is usually called the **sulcus calcarinus**. This name was applied to the furrow by Huxley because its deep anterior part indents the whole thickness of the medial wall of the hemisphere, and the swelling so produced in the posterior cornu of the lateral ventricle was supposed by the older anatomists to resemble a cock's spur and was hence called **calcar avis** (see Fig. 533, p. 634).

The anterior part of this furrow is much deeper, more constant in form and position, more precocious in development, and phylogenetically much older than the posterior part. As it is the part of the sulcus which gives rise to the calcar avis, it is the true calcarine; while the newer, shallower posterior part is wholly on the caudal side of the calcar avis, and is called **sulcus calcarinus posterior**. If the area striata is prolonged on to the lateral surface, it also may become folded in the line of its axis, and so give rise to a **sulcus calcarinus lateralis**.

There is a fundamental distinction between the calcarine sulcus and the posterior calcarine in their relations to the area striata. For the stria of Gennari is found only in the inferior wall of the sulcus calcarinus, which is therefore a sulcus

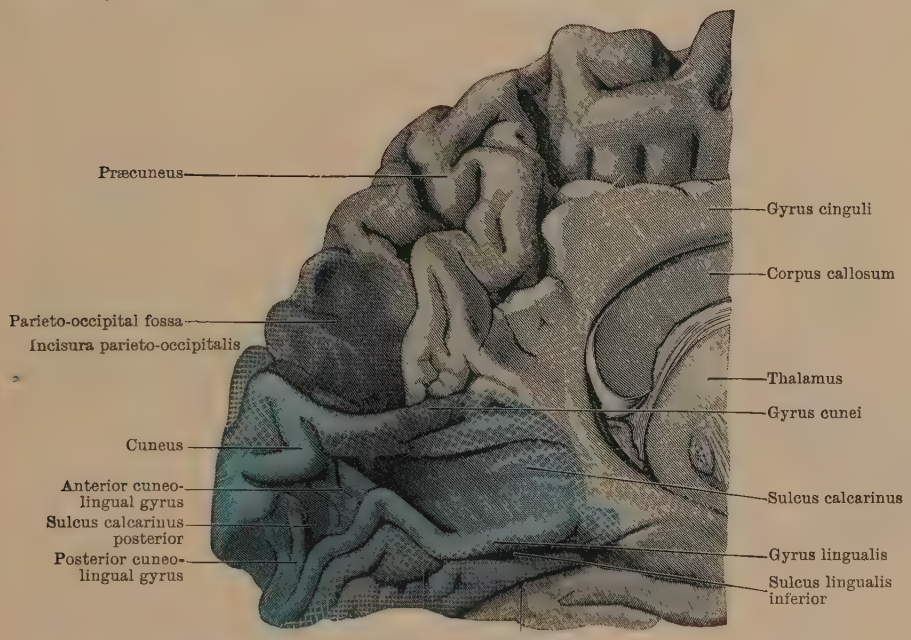

FIG. 555.—THE PARIETO-OCCIPITAL AND THE CALCARINE SULCI FULLY OPENED UP, so as to show the deep transitional gyri marking off the several elements of the ≺-shaped system.

limitans; whereas the stria extends throughout both walls of the posterior calcarine sulcus, and in most cases beyond its lips on to the surface of the **cuneus** and the **gyrus lingualis** (Figs. 555 and 557), *i.e.* the exposed cortical areas placed upon the superior and inferior aspects respectively of the sulcus calcarinus posterior.

Along the superior and inferior boundary lines of this area shallow limiting sulci usually develop (Fig. 557), and these furrows often pass backwards into little arched *sulci polares*, which are furrows of the operculated variety (see p. 642), called into existence by the broadening out of the area striata (not an actual broadening, but an unfolding) as it passes round the edge of the hemisphere.

At the point of transition from the deep sulcus calcarinus into the shallower sulcus calcarinus posterior (Fig. 555) a submerged ridge is usually found—the **gyrus cuneolingualis anterior**; and other similar ridges, which may be exposed on the surface or may be submerged, are often found interrupting the posterior and lateral calcarine sulci themselves (Fig. 555).

The posterior and lateral calcarine sulci are subject to a very wide range of variation in form, but they are always axial foldings of the area striata.

When the area striata crosses on to the lateral surface of the hemisphere a small semilunar furrow develops a short distance in front of its anterior edge. This is the **sulcus lunatus.** The larger the lateral extension the closer does the edge of the area striata approximate to the caudal lip of the sulcus, which under such circumstances assumes a definitely operculated form. Such cases occur most often in the left hemisphere and in the brains of primitive people; and they represent a perfect realisation of a furrow once supposed not to occur in the human brain, but to be distinctive of the ape. Hence it used to be called the "**Affenspalte**" or **sulcus simialis.**

The area striata is surrounded by two peripheral concentric bands—an inner, which may be called **area parastriata,** and an outer, the **area peristriata.** Sulci develop along the boundary lines of each of these areas; and those which indicate the superior and inferior limits of the peripheral band (*i.e.* peristriate area)

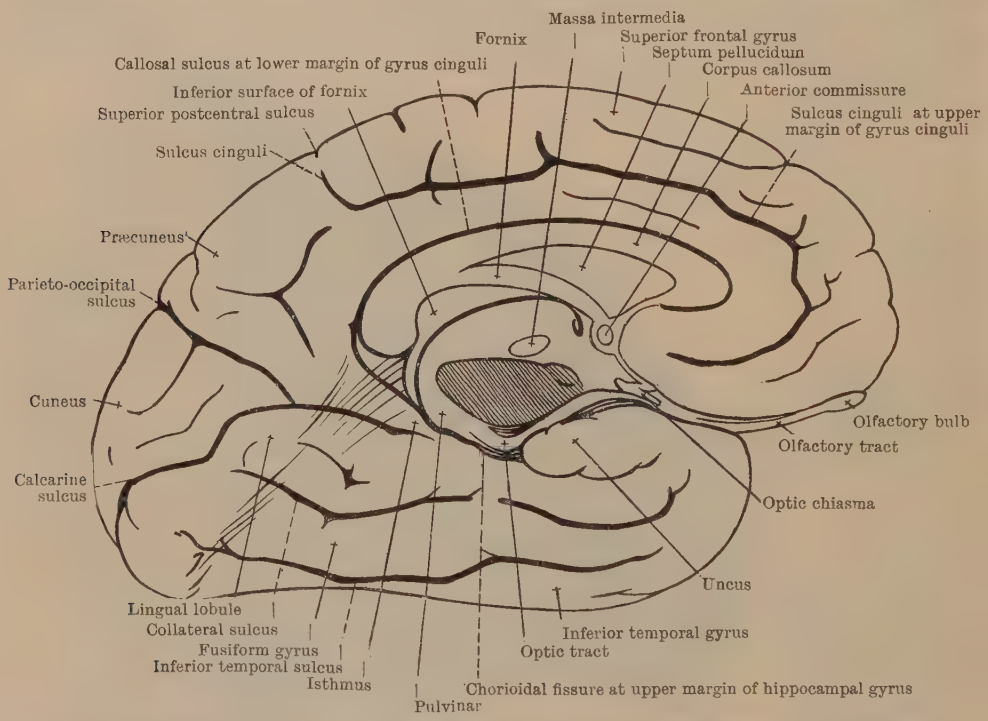

FIG. 556.—DIAGRAM OF SULCI AND GYRI OF MEDIAL AND INFERIOR SURFACES OF HEMISPHERE.

make their appearance relatively early in development and become very deep furrows.

The inferior of these is placed upon the tentorial surface, and is known as the **sulcus collateralis**; the superior limiting furrow of the visual territory (its peristriate part) is upon the superior surface of the hemisphere, and is usually regarded as the **ramus occipitalis** of the **sulcus interparietalis.** But it is genetically independent of the latter furrow, and may be distinguished as the **sulcus paroccipitalis.**

Near the supero-medial margin of the hemisphere there is a furrow, which indicates the line of demarcation between the para- and the peristriate areas—the **sulcus occipitalis paramedialis.** It may be situated upon either the medial or the superior surface of the hemisphere. In some cases it belongs to the category of limiting sulci, in others to the group of operculated sulci (see p. 643).

Passing horizontally forwards upon the lateral surface of the hemisphere there is a constant furrow formed by the axial folding of part of the peristriate area, approximately in line with the axial folding of the striate area (sulcus calcarinus lateralis); it is the **sulcus occipitalis lateralis.** When there is a fully developed sulcus lunatus the lateral occipital sulcus joins it near its midpoint (Fig. 548, p. 651).

The **sulcus (or fossa) parieto occipitalis** (Fig. 522) is usually a deep furrow upon the medial aspect of the hemisphere which passes vertically downwards from the supero-medial border and appears to join the calcarine sulcus near its union with the posterior calcarine, forming upon the surface a Y-shaped pattern, the stem of which is calcarine, the limbs posterior calcarine and parieto-occipital respectively, and the wedge-shaped area between the limbs the **cuneus** (Fig. 555; compare with the pattern shown in Fig. 557, where the parieto-occipital sulcus is not labelled).

If, however, the lips of these three furrows are divaricated (Fig. 555), the parieto-occipital depression will be found to be separated from the calcarine by a prominent submerged cortical ridge, the **gyrus cunei**; and the parieto-occipital will be found to be something more than a mere sulcus. It is, in fact, a great fossa in which are submerged the anterior parts of the area parastriata and area peristriata, and the

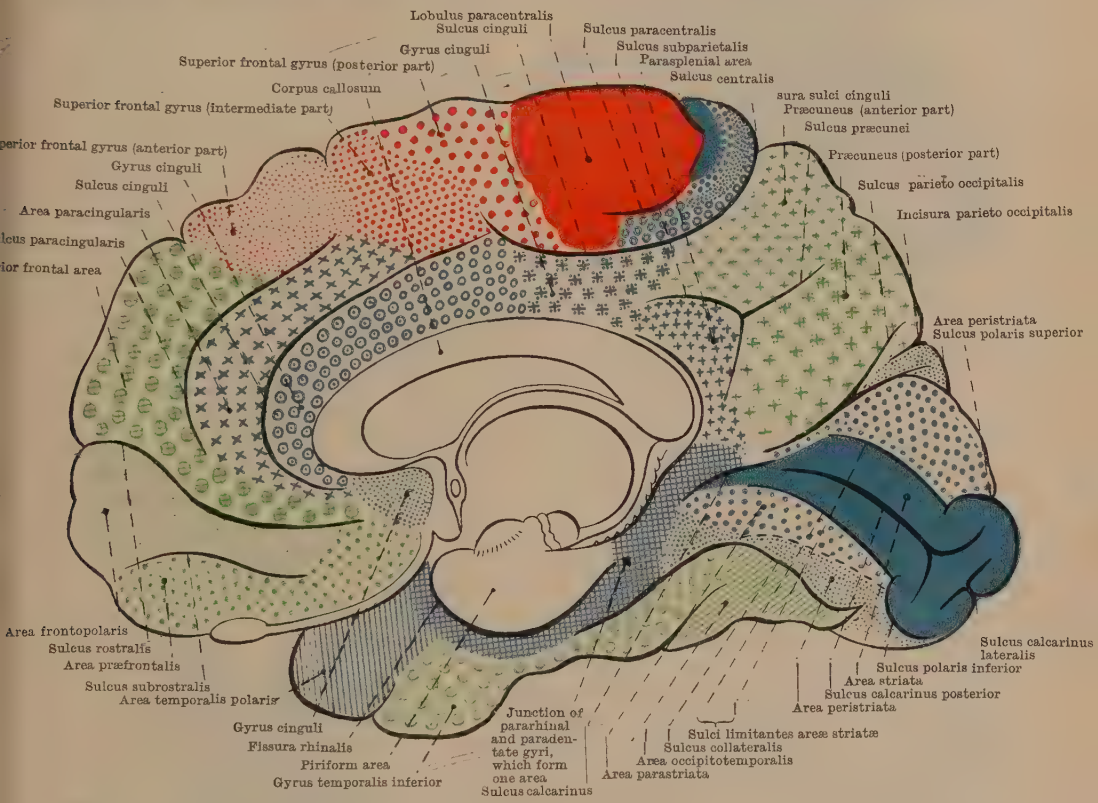

FIG. 557.—THE CORTICAL AREAS ON THE MEDIAL ASPECT OF THE CEREBRAL HEMISPHERE.

posterior part of the parietal area known as the **præcuneus**, as well as the sulci which separate these territories one from the other. It is a great trough formed by the splenium of the corpus callosum as in the course of its development it thrusts itself backwards and crumples up the cortex. When the corpus callosum fails to develop, no parieto-occipital fossa makes its appearance. The part of the sulcus that notches the supero-medial border (Fig. 557) forms a distinct element, which Retzius has called the *incisura parieto-occipitalis*.

Sulcus Collateralis.—The collateral sulcus is a strongly marked furrow on the tentorial face of the cerebral hemisphere. It begins near the occipital pole and extends forwards towards the posterior end of the rhinal fissure, with which it sometimes becomes confluent. In its posterior part it is placed below, and parallel to, the calcarine fissure, from which it is separated by the lingual gyrus. From the posterior extremity a sulcus proceeds forwards and then laterally across the inferior surface of the occipital region, forming a V-shaped pattern with the collateral sulcus (Fig. 552). As it is serially homologous with the latter, being, like

it, an inferior boundary of the area peristriata, it may be called the **sulcus collateralis transversus.** The lingual gyrus is sometimes subdivided by a furrow (*sulcus sagittalis gyri lingualis*) midway between the collateral sulcus and the inferior margin of the area striata. It is the line of demarcation between the parastriate and peristriate areas, and when deep is often mistaken for the collateral sulcus.

THE PARIETAL REGION.

We have seen that the acoustic pathway leads into the temporal region and the visual pathway into the occipital region. The facts of clinical medicine show that large areas in these two regions beyond the limits of the cortex in which the acoustic and optic radiations end are concerned with the functions of hearing and vision. A large part of the parietal area is interposed between these temporal and occipital territories, and its integrity and normal functioning are necessary conditions for the proper performance of many acts, such as reading written or printed documents, in the appreciation of which both hearing and vision have played some part. But the parietal region also includes the cortical area in which a part, at least, of the chief thalamo-cerebral tract ends—the bundle of fibres that represents the third stage of the great sensory pathway, the first stage of which is formed by the spinal and cerebral sensory nerves and their central prolongations, and the second stage by the spino-thalamic, bulbo-thalamic, and ponto-thalamic fasciculi, which pass upwards in the medial lemniscus and end in the ventral nucleus of the thalamus (Figs. 545, 546).

The sensory area in question forms part of the **gyrus centralis posterior**, which intervenes between two oblique furrows, the **sulcus centralis** and the **sulcus post-centralis**, which extend across the whole breadth of the hemisphere above the sulcus lateralis (Fig. 548).

Sulcus Centralis.—During the sixth and seventh months of fœtal life the expanding posterior central area becomes raised up into a prominent ridge, and a similar ridge is formed immediately in front of it (Fig. 590) from the area which emits the great efferent or motor tract to control all the motor nuclei upon the other side of the brain and spinal medulla. As these ridges become raised up a depression is left between them: this is the **sulcus centralis.** At first it consists of two parts, a superior and an inferior (Fig. 590, r^2 and r^1); but as a rule these become confluent later.

The sulcus centralis in the adult takes an oblique course across the lateral convex surface of the cerebral hemisphere, and intervening between the frontal and parietal regions it forms the immediate posterior boundary of the motor area of the cortex. Its upper end cuts the supero-medial border of the hemisphere a short distance behind the mid-point between the frontal and occipital poles, whilst its inferior end terminates above the middle of the posterior ramus of the lateral fissure. Its superior extremity, as a rule, turns round the supero-medial border of the hemisphere, and is then continued backwards for a short distance on the medial surface. Although, in its general direction, the sulcus is oblique, it is very far from being straight. It takes a sinuous course across the hemisphere. This is largely due

to the varying breadth of the motor areas representing the lower limb, trunk, upper limb, and head, respectively, which are placed immediately in front of it.

When the sulcus centralis is widely opened up, so that its bottom and its opposed sides may be fully inspected, it will be seen that the two bounding gyri are dovetailed into each other by a number of interlocking gyri, which do not appear on the surface (Fig. 559). Further, two of these, placed on opposite sides of the fissure, are frequently joined across the bottom of the sulcus in the form of a sunken bridge of connexion, which constitutes what is termed a *deep transitional gyrus*. The continuity of the sulcus is thus, to some extent, interrupted. This condition is rendered interesting when considered in connexion with the development of the sulcus. The deep interlocking gyri indicate a great exuberance of cortical growth in this situation in the early stages of the development of the sulcus; and the presence of the deep transitional gyrus is explained by the fact that the sulcus generally develops in two pieces, which run into each other to form the continuous sulcus of the adult, viz., a part corresponding to the inferior two-thirds, and a superior part, which represents the superior third and which appears at a slightly later date. In certain very rare cases the sulcus centralis is found to remain double throughout life, through a failure of its two pieces to unite. In such cases the deep transitional gyrus, which is frequently seen at the bottom of the furrow, remains on the surface. Heschl, who examined 2174 cerebral hemispheres, found this anomaly only six times; Eberstaller met with it twice in 200 brains.

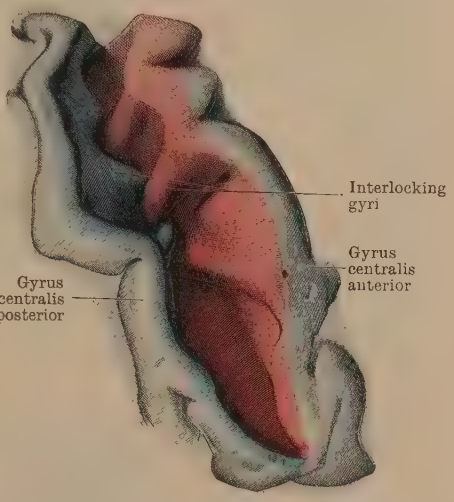

FIG. 559.—RIGHT SULCUS CENTRALIS FULLY OPENED UP, so as to exhibit the interlocking gyri and deep transitional gyrus within it.

Motor cortex coloured *red*, sensory cortex *blue*.

If a section is made at right angles to this sulcus in a fresh brain (Fig. 560), it will be seen that its anterior (gyrus centralis anterior) and posterior (gyrus centralis posterior) walls present a marked contrast the one to the other, and that the transition from the one type of cortex to the other takes place precisely at, or near to, the bottom of the sulcus. The anterior wall is composed of thick (3·5 to 4 mm.) motor cortex thickly laden with medullary matter arranged in the form of three or four pale bands with blurred edges and multitudes of fine pencils of fibres passing to and fro between it and the white matter of the hemisphere. The posterior wall is composed of thin (1·5 mm.) cortex containing two narrow and sharply defined white lines.

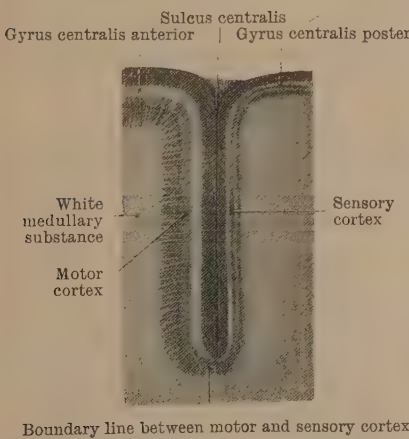

FIG. 560.—SECTION ACROSS THE SUPERIOR PART OF THE SULCUS CENTRALIS IN A FRESH BRAIN.

This sensory area forms little more than the posterior wall of the sulcus centralis, and barely emerges upon the surface to form the posterior lip of the sulcus (Fig. 548). Here it becomes continuous with a slightly thicker cortex with doubled lines which are less dense than those of the sensory cortex; this area forms the crest of the gyrus centralis posterior, and then gives place to another slightly modified type of cortex which forms the anterior wall of the sulcus postcentralis. Thus the sensory cortex has two fringing bands analogous to those already noticed alongside the visual and acoustic areas.

The motor and sensory areas cross on to the medial aspect of the hemisphere, into a region known as the **lobulus paracentralis**. In this region a furrow (**sulcus paracentralis**) is sometimes found along the line of demarcation of the medial parts of the motor and sensory areas (Fig. 557).

That portion of the parietal region which intervenes between the gyrus

centralis posterior and the occipital region is usually subdivided into two distinct parts (**lobulus parietalis superior** and **lobulus parietalis inferior**) by a horizontal furrow, called the **sulcus interparietalis proprius.** The term **sulcus interparietalis** is usually applied in a purely arbitrary and artificial manner to a complex of four genetically distinct and independent furrows (Fig. 561, p^1, p^2, p^3, and p^4), the **sulcus postcentralis inferior** (p^1), the **sulcus postcentralis superior** (p^2), the **sulcus interparietalis proprius (ramus horizontalis)** (p^3), and the **sulcus paroccipitalis (ramus occipitalis)** (p^4), which ends in the **sulcus occipitalis transversus.**

These four furrows develop quite independently one of the other, the postcentral sulci as the posterior boundary of the sensory territory, the paroccipital sulcus as the supero-lateral boundary of the visual territory, and the more variable horizontal ramus (the sulcus interparietalis, in the strict sense of the term) as a demarcation between the two parietal lobules. The four furrows may unite to form any possible combination.

The superior parietal lobule is composed of moderately thick cortex (2·5 to

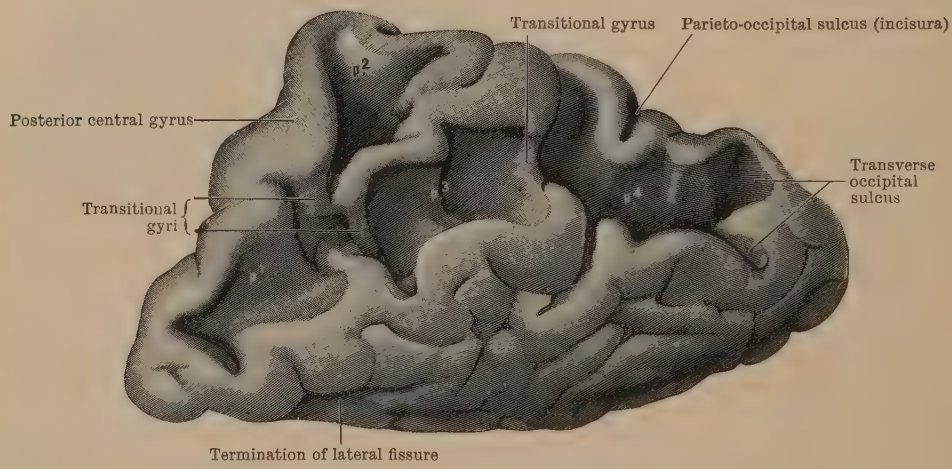

FIG. 561.—THE FOUR SULCI OF THE INTERPARIETAL COMPLEX OPENED UP, so as to show the deep transitional gyri intervening between them.

p^1. Sulcus postcentralis inferior.
p^2. Sulcus postcentralis superior.
p^3. Ramus horizontalis (sulcus interparietalis proprius).
p^4. Ramus occipitalis (sulcus paroccipitalis).

3 mm.) placed between the interparietal sulcus (ramus horizontalis) and the superior border of the hemisphere, where it becomes continuous on the medial surface with the precuneus. Each of these parts is subdivided by a transverse sulcus, the superior lobule by the **sulcus parietalis superior** and the precuneus by the **sulcus præcunei** (Fig. 557).

The latter sulcus usually joins a small inverted ∪-shaped furrow (**sulcus subparietalis**), which encloses a cortical territory of distinctive structure—the **area parasplenalis [præcunei].**

The **inferior parietal lobule**, which from its position is the natural meeting-place for impressions coming from the visual, acoustic, and tactile territories, is naturally a region of great functional significance. It is composed of a series of areas differing in thickness and texture. The anterior region forms a convolution (**gyrus supramarginalis**) surrounding the upturned extremity of the lateral fissure; behind it there is a second convolution called the **gyrus angularis**, which surrounds a vertical **sulcus angularis**, often described as the extremity of the sulcus temporalis superior; but in reality it is quite independent of the latter furrow, but it often becomes confluent with it. Behind the gyrus angularis and separated from it by a transverse furrow (**sulcus occipitalis anterior**) there is a cortical territory (**area parieto-occipitalis**) which may perhaps be looked upon as a specialised and outlying part of the peristriate area of the visual cortex.

THE FRONTAL REGION.

The frontal region is the biggest of the main cortical areas—the so-called "lobes." On the lateral surface of the hemisphere, it is bounded behind by the sulcus centralis and below, in part, by the lateral fissure. It presents a lateral surface, a medial surface, and an inferior or orbital surface.

On its lateral aspect the surface is broken up by a large series of furrows, which exhibit considerable variability.

The **inferior precentral sulcus** consists of a vertical and an oblique part. The *vertical portion* lies in front of the inferior part of the sulcus centralis, whilst the *oblique part* extends forwards and upwards (Fig. 562).

The **superior precentral sulcus** is a short vertical sulcus which lies at a higher level than the inferior precentral sulcus, in front of the upper part of the sulcus centralis. It is almost invariably connected with the posterior end of the superior frontal sulcus.

The **anterior central gyrus** is a long continuous gyrus, which is limited in front by the two precentral furrows and behind by the sulcus centralis. Inferiorly it is continuous with the area subcentralis which links it to the posterior central gyrus. The area subcentralis is limited in front and behind by the *anterior and posterior subcentral sulci* (not labelled in Fig. 562).

The **superior frontal sulcus** extends forwards in a more or less horizontal direction from the sulcus præcentralis superior.

The **gyrus frontalis superior** is the narrow convolution between the supero-medial border of the hemisphere and the superior frontal sulcus and the continuation of this convolution into a broad area upon the medial surface.

The **inferior frontal sulcus** occupies a lower level than the superior frontal sulcus. Its posterior end is placed in the angle between the vertical and horizontal parts of the inferior precentral sulcus, and is not infrequently confluent with one or other of these. It proceeds forwards towards the superciliary margin of the hemisphere and ends a short distance from this in a terminal bifurcation (Fig. 562).

The **gyrus frontalis medius** is the name given to the broad convolution which lies between the superior and inferior frontal sulci.

The **gyrus frontalis inferior** is that portion of the lateral surface of the frontal region which is placed in front of the inferior precentral sulcus and below the inferior frontal sulcus. The inferior frontal convolution includes three cortical areas (Fig. 562) differing in structure the one from the other. The **sulcus diagonalis** separates the intermediate of these from the posterior.

The **sulcus frontalis medius** begins midway between the anterior ends of the superior and inferior frontal sulci and proceeds obliquely forwards towards the frontal pole. When the furrow reaches the superciliary margin of the hemisphere it ends near a transverse furrow, called the **fronto-marginal sulcus.**

On the *medial aspect of the frontal lobe* there are two convolutions, the larger peripheral area which forms part of the gyrus frontalis superior and a smaller inner part encircling the corpus callosum, which is called the **gyrus cinguli.** These gyri are separated by the **sulcus cinguli** (Fig. 556).

The posterior part of the sulcus cinguli is genetically distinct from the anterior part and it circumscribes a broader area, the **lobulus paracentralis**, which is continuous with the gyri centrales of the lateral surface of the hemisphere.

On the *orbital aspect of the frontal region* there are two sulci, viz., the olfactory and the orbital.

The **olfactory sulcus** is a straight furrow which runs parallel to the medial orbital border of the hemisphere. It is occupied by the olfactory tract and bulb, and it cuts off a narrow strip of the orbital surface close to the medial border, which receives the name of **gyrus rectus.**

The **orbital sulcus** is a composite furrow which assumes many different forms. It consists essentially of a U-shaped furrow, the convexity of which is directed anteriorly (Fig. 551), and one or two variable branches passing forwards from it.

The conventional manner of subdividing the cortical territory anterior to the

sulcus centralis into gyri, which has just been sketched, is apt to convey a misleading idea of the distribution of the anatomical areas of differentiated cortex.

The gyrus centralis anterior together with the major portion of the paracentral lobule and the posterior part of the middle and superior frontal gyri form a natural subdivision of the cortex, which Brodmann calls the **regio præcentralis**. It is composed of a series of areas of different structure, which may be grouped as the **area præcentralis posterior** (the true motor area) the **area præcentralis intermedius**, and

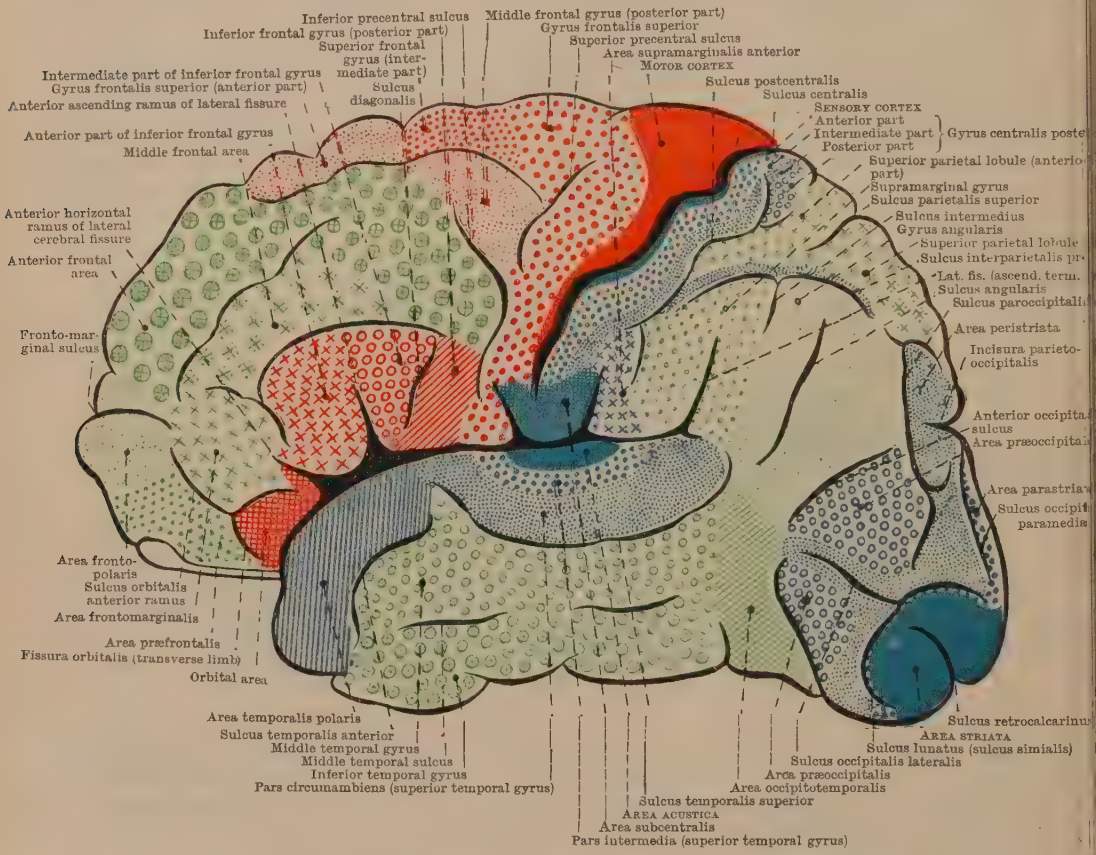

Fig. 562.—Areas on Lateral Aspect of Left Cerebral Hemisphere.

The superior, middle, and inferior frontal sulci are not labelled. The middle is in the midst of the green area, the superior and inferior respectively at its superior and inferior boundaries.

the **area præcentralis anterior** (Fig. 562). Most of the motor area is hidden in the sulcus centralis, but towards the supero-medial margin of the hemisphere a considerable area emerges upon the surface of both the gyrus centralis anterior and the paracentral lobule.

Brodmann calls the rest of the frontal territory the **regio frontalis**; but in the colour scheme adopted in Figs. 562, 557, and 552 the inferior frontal gyrus and the orbital area posterior to the orbital sulcus have been associated with the "precentral" rather than the "frontal" regions.

Weight of the Brain.

The average weight of the adult male brain may be said to be about 1360 grammes. The female brain weighs rather less, but this is to be expected from the smaller bulk of the female body. Probably the relative weight of the brain in the two sexes is very much the same. The variations met with in brain-weight are very great, but it is doubtful if normal intellectual functions could be carried on in a brain which weighs less than 960 grammes. In microcephalic idiots brains of extremely small size are met with.

THE MENINGES OF THE ENCEPHALON AND MEDULLA SPINALIS.

The brain and spinal medulla are enclosed within three membranes, which are termed the meninges or meningeal membranes. From without inwards these are: (1) the dura mater, (2) the arachnoid, and (3) the pia mater. The space between the dura mater and the arachnoid receives the name of subdural space, while the much more roomy interval between the arachnoid and the pia mater is called the subarachnoid space.

Dura Mater.

The dura mater is a dense and thick fibrous membrane which possesses a very considerable degree of strength. Its arrangement within the cranial cavity is so different from that within the vertebral canal that it is customary to speak of it as consisting of two parts, viz., a cranial and a vertebral, although in adopting this subdivision it must be clearly understood that both portions are continuous with each other at the foramen magnum.

Dura Mater Encephali.—The cranial dura mater is adherent to the inner surface of the cranial wall, and performs a double office. It serves as an internal periosteum for the bones which it lines and it constitutes an envelope for the brain. Its inner surface, which bounds the subdural space, is smooth and glistening, and is covered with a layer of endothelial cells. The outer surface, when separated from the cranial wall, is rough, this being due to numerous fine fibrous processes and blood-vessels which pass between it and the bones. Its degree of adhesion to the cranial wall differs considerably in different regions. To the vault of the cranium, except along the lines of the sutures, the connexion is by no means strong, and in the intervals between the fibrous processes which pass into the bone there are small lymph spaces (epidural spaces) where the outer surface of the membrane is covered by endothelial cells. So long as the sutures are open the dura mater is connected with the periosteum on the exterior of the skull, along the sutural lines, by a thin layer of fibrous tissue which intervenes between the bony margins. Around the foramen magnum, and on the floor of the cranium, the dura mater is very firmly adherent to the bone. This is more particularly marked in the case of the projecting parts of the cranial floor, as, for example, the petrous portions of the temporal bones, the clinoid processes, and so on. This firm adhesion in these regions is still further strengthened because the nerves, as they leave the cranium through the various foramina, are followed by sheaths of the fibrous dura mater. Outside the cranium these prolongations of the membrane blend with the fibrous sheaths of the nerves, and likewise become connected with the periosteum on the exterior of the skull. In the child, during the growth of the cranial bones, and also in old age, the dura mater is more adherent to the cranial wall than during the intermediate portion of life.

The cranial dura mater is composed of two layers intimately connected with each other, but yet capable of being demonstrated in most regions of the cranium. Along certain lines these two layers separate from each other so as to form channels lined with endothelium. These channels are the **venous blood-sinuses** which receive the blood from veins which come from various parts of the brain. They are described in the section dealing with the Vascular System.

Strong fibrous partitions or septa are given off along certain lines from the deep surface of the dura mater. These project into the cranial cavity, and subdivide it partially into compartments which all freely communicate with each other, and each of which contains a definite subdivision of the brain. These septa are: (1) the falx cerebri; (2) the tentorium cerebelli; (3) the falx cerebelli; and (4) the diaphragma sellæ.

The **falx cerebri** is a sickle-shaped partition which descends in the great longitudinal fissure between the two hemispheres of the cerebrum. In front it is narrow,

and attached to the crista galli of the ethmoid bone. As it is followed backwards it increases in breadth, and posteriorly it is attached, along the median plane, to the upper surface of the tentorium. The anterior narrow part of the falx is frequently cribriform, and is sometimes perforated by apertures to such an extent that it almost resembles lace-work. Along each border it splits into two layers, so as to enclose a blood-sinus. Along its superior convex attached border runs the *superior sagittal sinus*; along its concave free border sometimes courses the much smaller *inferior sagittal sinus*; whilst along its attachment to the tentorium is enclosed the *straight sinus*.

The **tentorium cerebelli** is a large crescentic partition of dura mater, which forms a membranous tent-like roof for the posterior cranial fossa, and thus intervenes between the posterior portions of the cerebral hemispheres and the cerebellum. It

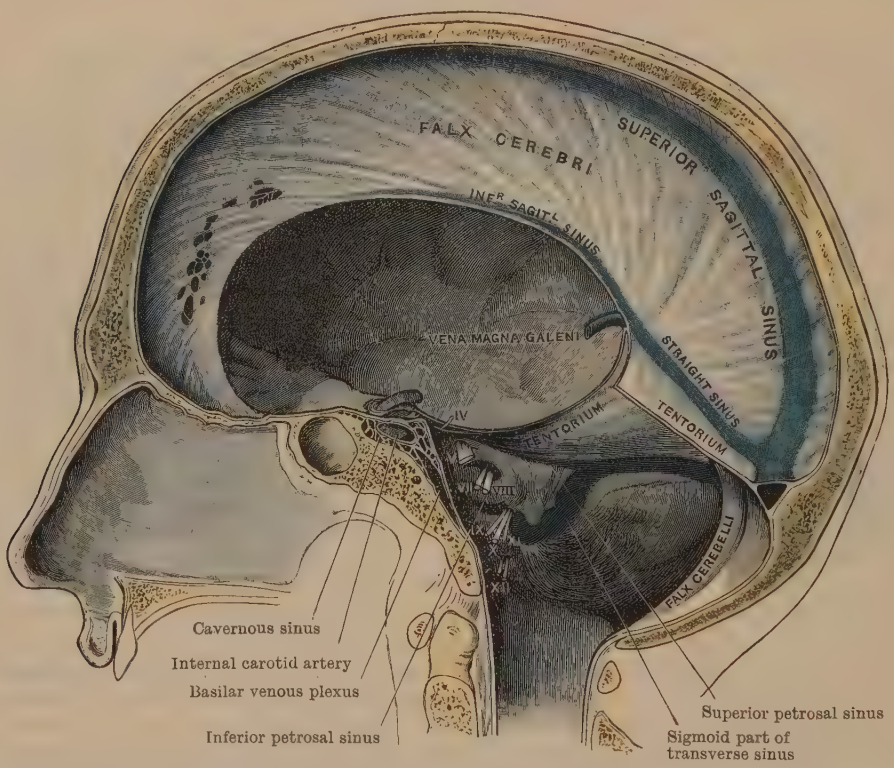

FIG. 563.—SAGITTAL SECTION THROUGH THE SKULL, A LITTLE TO THE LEFT OF THE MEDIAN PLANE to show the arrangement of the dura mater.

The cerebral nerves are indicated by numerals.

is accurately applied to the superior surface of the cerebellum. Thus, its highest point is in front and in the median plane, and from this it slopes downwards towards its attached border. It is kept at a high degree of tension, and this depends on the integrity of the falx cerebri, which is attached to its superior aspect in the median plane.

The *posterior border* of the tentorium is convex, and is attached to the horizontal ridge which marks the deep surface of the occipital bone. Beyond this, on each side, it is fixed to the postero-inferior angle of the parietal bone, and then forwards and medially along the superior border of the petrous portion of the temporal bone. From the internal occipital protuberance to the postero-inferior angle of the parietal bone this border encloses the *sinus transversus*, whilst along the superior border of the petrous bone it encloses the *superior petrosal sinus*. The *anterior border* of the tentorium is sharp, free, and concave, and forms with the dorsum sellæ an oval opening shaped posteriorly like a pointed arch. This opening receives the name of the **incisura tentorii**, and within it is placed the mesencephalon,

or the stalk of connexion between the parts which lie in the posterior cranial fossa and the cerebrum. Beyond the apex of the petrous part of the temporal bone the two margins of the tentorium cross each other like the limbs of the letter X; the free margin is continued forwards, to be attached to the anterior clinoid process, whilst the attached border proceeds medially, to be fixed to the posterior clinoid process.

The **falx cerebelli** is a small, sickle-shaped process of dura mater placed below the tentorium, which projects forwards in the median plane from the internal occipital crest. It occupies the notch which separates the two hemispheres of the cerebellum posteriorly. Inferiorly it bifurcates into two small diverging ridges which gradually fade away as they are traced forwards on each side of the foramen magnum.

The **diaphragma sellæ** is a small circular fold of dura mater which forms a roof for the fossa hypophyseos. A small opening is left in its centre for the transmission of the infundibulum.

Dura Mater Spinalis.—In the vertebral canal the dura mater forms a tube which encloses the spinal medulla, and which extends from the foramen magnum above to the level of the second or third piece of the sacrum below. It is very loosely applied to the spinal medulla and the nerve-roots which form the cauda equina; in other words, it is very capacious in comparison with the volume of its contents. Moreover, its calibre is not uniform. In the cervical and lumbar regions it is considerably wider than in the thoracic region, whilst in the sacral canal it rapidly contracts, and finally ends by blending with the filum terminale externum, the chief bulk of which it forms. At the superior end of the vertebral canal the spinal dura mater is firmly fixed to the third cervical vertebra, to the epistropheus vertebra, and around the margin of the foramen magnum. In the sacral canal the filum terminale externum, with which it blends, extends downwards to the back of the coccyx, to the periosteum of which it is fixed. The inferior end of the tube is thus securely anchored and held in its place.

Within the cranial cavity the dura mater is closely adherent to the bones, and forms for them an internal periosteum. As it is followed into the vertebral canal its two constituent layers separate. The inner layer is carried downwards as the long cylindrical tube which encloses the spinal medulla. The outer layer, which is much thinner, becomes continuous behind and on each side of the foramen magnum with the periosteum on the exterior of the cranium, whilst in front it is prolonged downwards into the vertebral canal in connexion with the periosteum and ligaments on the anterior wall of the canal. The spinal dura mater, therefore, corresponds to the inner layer of the cranial dura mater, and to it alone. It is separated from the walls of the vertebral canal by an interval, the **cavum epidurale**, which is occupied by soft fat and a plexus of thin-walled veins. In connexion with the spinal dura mater there are no blood-sinuses such as are present in the cranial cavity, but it should be noted that the veins in the epidural space, placed as they are between the periosteum of the vertebral canal and tube of dura mater, occupy the same morphological plane as the cranial blood-sinuses. Another feature which serves to distinguish the spinal dura mater from the cranial dura mater consists in the fact that it gives off from its deep surface no partitions or septa.

The cylindrical tube of spinal dura mater does not lie quite free within the vertebral canal. Its attachments, however, are of such a character that they in no way interfere with the free movement of the vertebral column. On each side the spinal nerve-roots, as they pierce the dura mater, carry with them into the intervertebral foramina tubular sheaths of the membrane, whilst in front loose fibrous prolongations—more numerous above and below than in the thoracic region—connect the tube of dura mater to the posterior longitudinal ligament of the vertebral column. No connexion of any kind exists between the dura mater and the posterior wall of the vertebral canal.

When the interior of the tube of spinal dura mater is inspected, the series of apertures of exit for the roots of the spinal nerves is seen. These are ranged in pairs opposite each intervertebral foramen.

Viewed from the inside of the tube of dura mater, each of the two roots of a

spinal nerve is seen to carry with it a special and distinct sheath. When examined on the outside, however, the appearance is such that one might be led to conclude that both roots are enveloped in one sheath of dura mater. This is due to the fact that the two sheaths are firmly held together by intervening connective tissue. The two tubular sheaths remain distinct as far as the ganglion on the posterior root, and then blend with each other.

Cavum Subdurale.—The dura mater and the arachnoid are closely applied to each other, and the capillary interval between them is termed the **subdural space.** It contains a minute quantity of fluid, which is just sufficient in amount to moisten the opposed surfaces of the two bounding membranes.

The subdural space in no way communicates with the subarachnoid space. The fluid which it contains is led into the venous blood-sinuses around the arachnoideal granulations (O.T. Pacchionian bodies), and thus gains exit. The subdural space is carried outwards for a very short distance on the various nerves which are connected with the brain and the spinal medulla, and it has a free communication with the lymph-paths present in these nerves. In the case of the optic nerve the sheath of dura mater is carried along its whole length, and with it the subdural space is likewise prolonged to the back of the eyeball.

Arachnoidea.

The **arachnoid** is a very thin membrane, remarkable for its delicacy and transparency, which envelops both the brain and the spinal medulla between the dura mater and the pia mater. The cranial part of the arachnoid or the **arachnoidea**

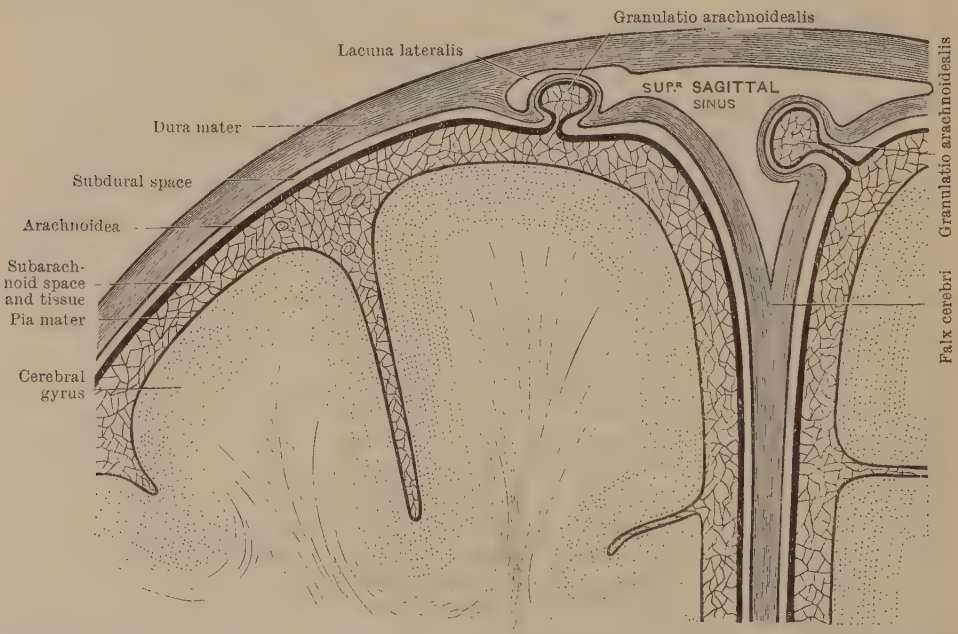

Fig. 564.—Diagram to show the relations of the membranes of the brain to the cranial wall and the cerebral gyri, and also of the arachnoideal granulations to the superior sagittal sinus and the lateral lacunæ.

encephali, except in the case of the longitudinal and the lateral fissures, does not dip into the sulci on the surface of the brain. In this respect it differs from the pia mater. It bridges over the inequalities on the surface of the brain. Consequently, on the basal aspect of the encephalon it is spread out in the form of a very distinct sheet over the medulla oblongata, the pons, and the hollow which lies in front of the pons, and in certain of these regions it is separated from the brain-surface by wide intervals.

The spinal part of the arachnoid or **arachnoidea spinalis**, which is directly continuous with the cranial arachnoidea, forms a loose wide investment for the

spinal medulla. This arachnoideal sac is most capacious towards its inferior part, where it envelopes the inferior end of the spinal medulla and the collection of long nerve-roots which constitute the cauda equina.

As the nerves, both from the brain and the spinal medulla, pass outwards they receive an investment from the arachnoid, which runs for a short distance upon them and then comes to an end.

Cavum Subarachnoideale.—The interval between the arachnoidea and the pia mater receives the name of the **subarachnoid space.** It contains the cerebro-spinal fluid, and communicates freely, through certain well-defined apertures, with the ventricular cavities in the interior of the brain (aperturæ ventriculi quarti).

Within the cranium the subarachnoid space is broken up by a meshwork of fine filaments and trabeculæ, which connects the two bounding membranes (viz., the arachnoidea and the pia mater) in the most intimate manner, and forms a delicate sponge-like interlacement between them. Where the arachnoidea passes over the summit of a cerebral gyrus, and is consequently closely applied to the subjacent pia mater, the meshwork is so dense and the trabeculæ so short that it is hardly possible to discriminate between the two membranes. To all intents and purposes they form in these localities one lamina. In the intervals between the rounded margins of adjoining gyri, however, distinct angular spaces exist, where the subarachnoid trabecular tissue can be studied to great advantage. These intervals on the surface of the cerebrum constitute numerous communicating channels which serve for the free passage of the subarachnoid fluid from one part of the brain to another. The larger branches of the arteries and veins of the brain traverse the subarachnoid space; their walls are directly connected with the subarachnoid trabeculæ, and are bathed by subarachnoid fluid.

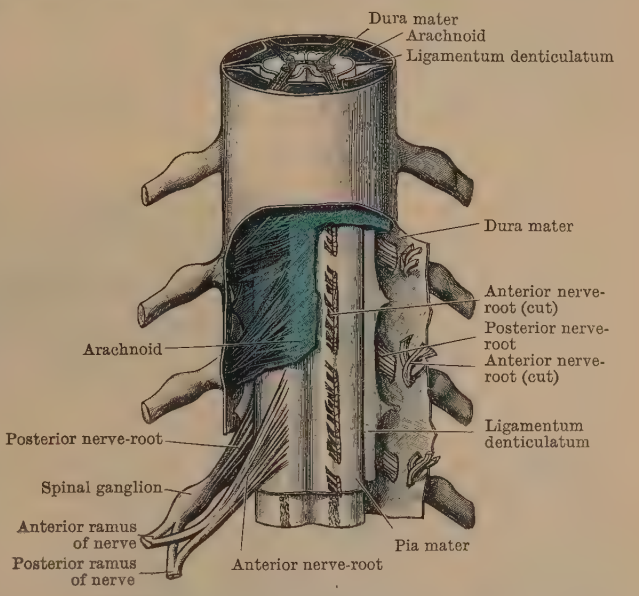

FIG. 565.—MEMBRANES OF THE SPINAL MEDULLA, AND THE MODE OF ORIGIN OF THE SPINAL NERVES.

In certain situations within the cranium the arachnoidea is separated from the pia mater by intervals of considerable width and extent. These expanded portions of the subarachnoid space are termed **cisternæ subarachnoideales.** In these the subarachnoid tissue is much reduced. There is no longer a close meshwork; the trabeculæ connecting the two bounding membranes take the form of long filamentous intersecting threads which traverse the spaces. All the subarachnoid cisterns communicate in the freest manner with each other and also with the narrow channels on the surface of the cerebrum.

Certain of these cisterns require special mention. The largest and most conspicuous is the **cisterna cerebellomedullaris.** It is formed by the arachnoid membrane bridging over the wide interval between the posterior part of the inferior surface of the cerebellum and the medulla oblongata. It is continuous through the foramen magnum with the posterior part of the wide subarachnoid space of the spinal medulla.

The **cisterna pontis** is the continuation upwards on the floor of the cranium of the anterior part of the subarachnoid space of the spinal medulla. In the region of the medulla oblongata it is continuous behind with the cisterna cerebello-

medullaris, so that this subdivision of the brain, like the spinal medulla, is surrounded by a wide subarachnoid space.

In front of the pons the arachnoidea bridges across between the projecting temporal lobes, and covers in the deep hollow in this region of the brain. This space is called the **cisterna interpeduncularis,** and within it are placed the large arteries which take part in the formation of the arterial circle (of Willis). Leading out from the interpeduncular cistern there are certain wide subarachnoid channels. Two of these are prolonged into the lateral fissures, and in these are accommodated the middle cerebral arteries. Anteriorly the interpeduncular cistern passes into a space in front of the **optic chiasma (cisterna chiasmatis)**, and from this it is continued into the longitudinal fissure above the corpus callosum. In this subarachnoid passage the anterior cerebral arteries are lodged.

The spinal part of the subarachnoid space is a very wide interval which is partially subdivided into compartments by three incomplete septa. One of these is a median partition called the **septum posterius**, which connects the pia mater covering the posterior aspect of the spinal medulla with the arachnoid. In the upper part of the cervical region the septum posterius is imperfect, and is represented merely by some strands passing between the two membranes; in the inferior part of the cervical region and in the thoracic region it becomes more complete. The other two septa are formed by the **ligamenta denticulata** which spread

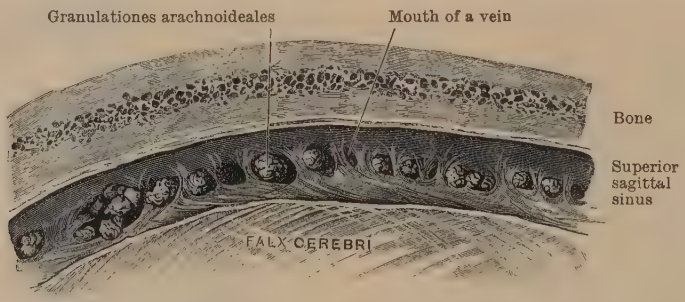

Fig. 566.—Median Section through the Cranial Vault in the Frontal Region, Enlarged. Displays a portion of the superior sagittal sinus and the arachnoideal granulations protruding into it.

laterally one from each side of the spinal medulla. These will be described with the pia mater.

Granulationes Arachnoideales.—When the surface of the dura mater is inspected after the removal of the calvaria, a number of small fleshy-looking excrescences, purplish-red in colour, are seen ranged in clusters on each side of the superior sagittal sinus, and when this sinus is opened they are also observed protruding in considerable numbers into its interior. These are the arachnoideal granulations (O.T. Pacchionian bodies), and they are found also, in smaller numbers and distinctly smaller size, in connexion with other blood-sinuses, such as the transverse sinus, the straight sinus, and the cavernous sinus. At first sight they appear to belong to the dura mater, but in reality they are projections from the arachnoid. In the child they are exceedingly small and rudimentary, and it is only as life advances that they become large and conspicuous.

Each granulation is a bulbous protrusion of the arachnoid. It is attached to the arachnoid by a narrow pedicle, and into its interior there is prolonged, through this pedicle, a continuation of the subarachnoid space and its characteristic meshwork. The granulations do not pierce the dura mater. As they push their way into a blood-sinus they carry before them a thin covering continuous with the sinus wall. On each side of the superior sagittal sinus there is a number of irregular spaces in the dura mater which communicate with the sinus either by a small aperture or a narrow channel. These spaces are called the **lacunæ laterales**, and certain of the meningeal veins and some of the diploic veins open into them. Granulations push themselves into the lateral lacunæ from below in such a manner that they receive a complete covering from the layer of dura mater which forms the sinus floor. Nor does the bone escape. As the granulations enlarge they

cause absorption of the cranial wall, and small pits are hollowed out on its internal surface for their reception. It must be clearly understood, however, that in such cases the granulation is separated from the bone by the following: (1) A continuation round the granulation of the subdural space; (2) the thinned floor of the lateral lacuna; (3) the lumen of the sinus; and (4) the greatly thinned upper wall of the sinus.

The granulations have a special function to perform. Through them fluid can pass from the subarachnoid space into the venous sinuses with which they stand in connexion. Whenever the pressure of blood in the sinuses is lower than that of the fluid in the subarachnoid space and the ventricles of the brain, the cerebro-spinal fluid filters through the granulations into the blood-sinuses. This is not the only way that subarachnoid fluid may obtain exit. The subarachnoid space is carried outwards for a short distance on the nerves in connexion with their arachnoideal sheaths, and communicates with the lymph channels of the nerves. This connexion is more complete in the case of the olfactory, the optic, and the acoustic nerves than in other nerves. A very free communication is said to exist between the subarachnoid space and the lymph vessels of the nasal mucous membrane.

The Pia Mater.

The pia mater forms the immediate investment of the brain and spinal medulla. It is a delicate and very vascular membrane.

Pia Mater Encephali.—The pia mater which covers the brain is finer and more delicate than that which clothes the spinal medulla. It follows closely all the inequalities on the surface of the brain, and in the case of the hemisphere it dips into each sulcus in the form of a fold which lines it completely. On the cerebellum the relation is not so intimate; it is only into the larger fissures that it penetrates in the form of folds.

The larger blood-vessels of the brain lie in the subarachnoid space. The finer twigs ramify in the pia mater before they proceed into the substance of the brain. As they enter they carry with them sheaths derived from the pia mater. When a portion of the membrane is raised from the surface of the encephalon, numerous fine processes are withdrawn from the cerebral surface. These are the blood-vessels with their sheaths, and they give the deep surface of the pia mater a rough and flocculent appearance.

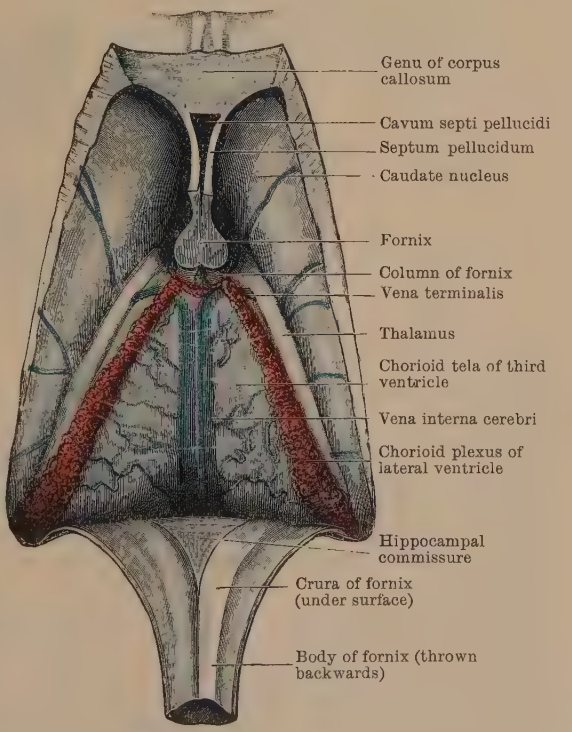

Fig. 567.—Dissection to show the Chorioid Tela of the Third Ventricle, and the Parts in immediate Relation to it.

As the pia mater is carried over the inferior part of the roof or posterior wall of the fourth ventricle of the brain it receives the name of the **tela chorioidea ventriculi quarti**, and it is in connexion with this portion of the pia mater that the chorioid plexuses of that cavity are developed. The **tela chorioidea ventriculi tertii** (O.T. **velum interpositum**) is a fold of pia mater which is invaginated into the brain, so that it comes to lie over the third ventricle and to project, in the shape of chorioid plexuses, into the lateral ventricles. This invagination requires special notice.

The **tela chorioidea ventriculi tertii** (O.T. **velum interpositum**) is a double layer or fold of pia mater which intervenes between the body of the fornix, which lies above it, and the epithelial roof of the third ventricle and the two thalami, which lie below it. Between its two layers are blood-vessels, and some subarachnoid trabecular tissue. In shape the chorioid tela of the third ventricle is triangular, and the narrow anterior end or apex reaches forwards as far as the interventricular foramina. The base lies under the splenium of the corpus callosum, and here the two layers of the tela separate and become continuous with the investing pia mater on the surface of the brain by passing out through a cleft called the **transverse fissure.**

Along each margin the tela chorioidea of the third ventricle is bordered by the chorioid plexus of the central part of the lateral ventricle, which projects into the ventricular cavity from under cover of the free margin of the fornix. It should be borne in mind that the epithelial lining of the ventricle gives a complete covering to the chorioid plexus. Posteriorly the chorioid plexus is continuous with the similar structure in the inferior horn of the ventricle, whilst in front it narrows greatly, and becomes continuous across the median plane with the corresponding plexus of the opposite side, behind the epithelial layer which lines the interventricular foramen. From this median junction two much smaller chorioid plexuses run backwards on the under surface of the tela chorioidea,

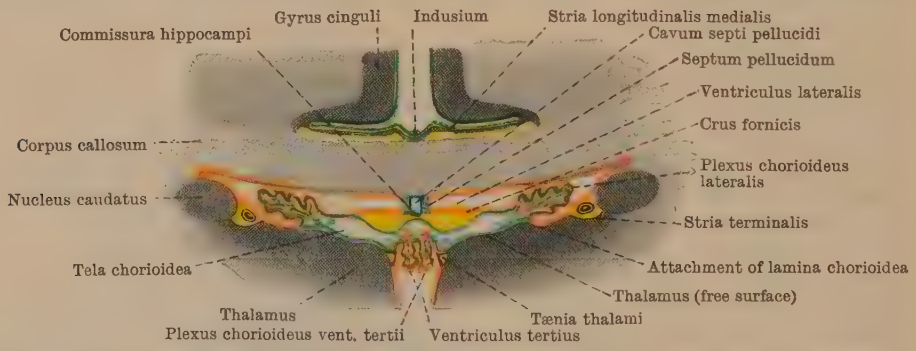

FIG. 568.—DIAGRAM OF A FRONTAL SECTION ACROSS THE CHORIOID TELA OF THE THIRD VENTRICLE.

and project downwards into the third ventricle. These are the chorioid plexuses of the third ventricle.

The most conspicuous blood-vessels in the tela chorioidea are the two internal cerebral veins, which run backwards, one on each side of the median plane. In front, each is formed at the apex of the fold by the union of the vena terminalis and a large vein issuing from the chorioid plexus; behind, they unite to form the **vena cerebri magna** [**Galeni**], and this pours its blood into the anterior end of the straight sinus (Fig. 567, p. 671).

The continuous cleft in the brain through which the chorioid tela of the third ventricle and the chorioid plexuses of the inferior horns of the two lateral ventricles are introduced into the interior of the brain is sometimes called the **transverse fissure.** It consists of a superior intermediate part and two lateral parts. The former passes forwards between the corpus callosum and the fornix above and the roof of the third ventricle and the thalami below. It is limited on each side by the epithelial covering of the chorioid plexuses, which shuts out these structures from the cavity of the lateral ventricles. The lateral part is the **chorioidal fissure.** This is continuous with the intermediate part, and has already been described in connexion with the inferior horn of the lateral ventricle (p. 634).

Pia Mater Spinalis.—The pia mater of the spinal medulla is thicker and denser than that of the brain. This is largely due to the addition of an outside fibrous layer, in which the fibres run chiefly in the longitudinal direction. The pia mater is very firmly adherent to the surface of the spinal medulla, and in front it sends a fold into the anterior-median fissure of the spinal medulla. The

posterior median septum is likewise firmly attached to its deep surface. In front of the anterior-median fissure of the spinal medulla the pia mater is thickened in the form of a longitudinal glistening band, termed the **linea splendens**, which runs along the whole length of the spinal medulla, and blends with the filum terminale below. The blood-vessels of the spinal medulla lie between the two layers of the pia mater.

The nerves which leave both the brain and spinal medulla receive closely applied sheaths from the pia mater. These blend with the connective-tissue sheaths of the nerves.

The **ligamentum denticulatum** is a strong fibrous band which stretches out like a wing from the pia mater on each side of the spinal medulla, so as to connect the pia mater with the dura mater. The pial or medial attachment of the ligament extends in a continuous line between the anterior and posterior nerve-roots, from the level of the foramen magnum above to the level of the first lumbar vertebra below. Its lateral margin is serrated or denticulated, and for the most part free. From twenty to twenty-two denticulations may be recognised. They occur in the intervals between the spinal nerves, and, pushing the arachnoid before them, they are attached by their pointed ends to the inner surface of the dura mater. The ligamenta denticulata partially subdivide the wide subarachnoid space in the vertebral canal into an anterior and a posterior compartment. The anterior nerve-roots traverse the anterior compartment, whilst the posterior nerve-roots traverse the posterior compartment. Further, the posterior compartment is imperfectly subdivided into a right and a left half by the septum posterius.

By means of the ligamenta denticulata the spinal medulla is suspended in the middle of the tube of dura mater.

II.—THE PERIPHERAL NERVOUS SYSTEM.

By A. Melville Paterson, M.D., F.R.C.S.,
Late Professor of Anatomy in the University of Liverpool.

Revised and partly rewritten by S. E. Whitnall, M.A., M.D.,
Professor of Anatomy, McGill University, Montreal.

The Peripheral Nervous System, as distinct from the Central Nervous System comprised by the brain and spinal medulla, is broadly divisible into three series of fibres. (I.) The **cerebral nerves**, which are attached to the brain and pass through openings in the base of the skull, to be distributed for the most part to the head region. (II.) The **spinal nerves**, which are attached to the spinal medulla, pass through the intervertebral foramina, and innervate the trunk and limbs, that is, the somatic area of the body (these two sets of fibres being sometimes grouped together as the cerebro-spinal system of nerves). (III.) The **sympathetic system** of nerves and ganglia, which is connected chiefly with the spinal nerves and also, though less obviously, with the cerebral ones. It lies for the greater part of its bulk in the body cavity, and governs the visceral or splanchnic area of the body. No one of these three groups can be considered wholly apart from the others, since, although presenting certain differences in structure, arrangement, and distribution, they are not independent or separate systems; the subdivision is, however, the most convenient one for descriptive purposes.

Number.	Name.	Function.	Superficial Attachment to Brain.
I.	**Olfactory**	Smell	Olfactory bulb.
II.	**Optic**	Sight	Optic chiasma.
III.	**Oculo-motor**	Motor to most of the muscles of eyeball and orbit	Cerebral peduncle.
IV.	**Trochlear**	Motor to superior oblique muscle of eyeball	Anterior medullary velum.
V.	**Trigeminal**	Sensory to face, tongue, and teeth; motor to muscles of mastication	Pons.
VI.	**Abducent**	Motor to lateral rectus muscle of eyeball	Junction of pons and medulla oblongata.
VII.	**Facial**	Motor to muscles of scalp and face, sensory to tongue	Medulla oblongata.
VIII.	**Acoustic**	Hearing and equilibrium	Medulla oblongata.
IX.	**Glossopharyngeal**	Sensory to tongue and pharynx; motor to stylo-pharyngeus	Medulla oblongata.
X.	**Vagus**	Sensory to pharynx, œsophagus, and stomach, and respiratory organs	Medulla oblongata.
XI.	**Accessory**	(*a*) **Accessory to vagus.**—Motor to muscles of palate, pharynx, œsophagus, stomach and intestines, and respiratory organs; inhibitory for the heart	Medulla oblongata.
		(*b*) **Spinal part.**—Motor to trapezius and sterno-mastoid	Spinal medulla.
XII.	**Hypoglossal**	Motor to muscles of the tongue	Medulla oblongata.

I. THE CEREBRAL NERVES.

The cerebral nerves are twelve pairs of symmetrically arranged nerves which are attached to the brain, leave the skull through foramina at its base, and are generally distributed to the various structures of the head. The site where the nerve fibres composing it enter or leave the brain surface is usually termed the **superficial origin** of the nerve, and the more deeply placed group of cells from which the fibres arise or about which they terminate is called the **nucleus of origin** or of **reception** respectively, and forms the **deep origin** of the nerve. It is also customary to trace the course of a nerve from its superficial origin to the periphery

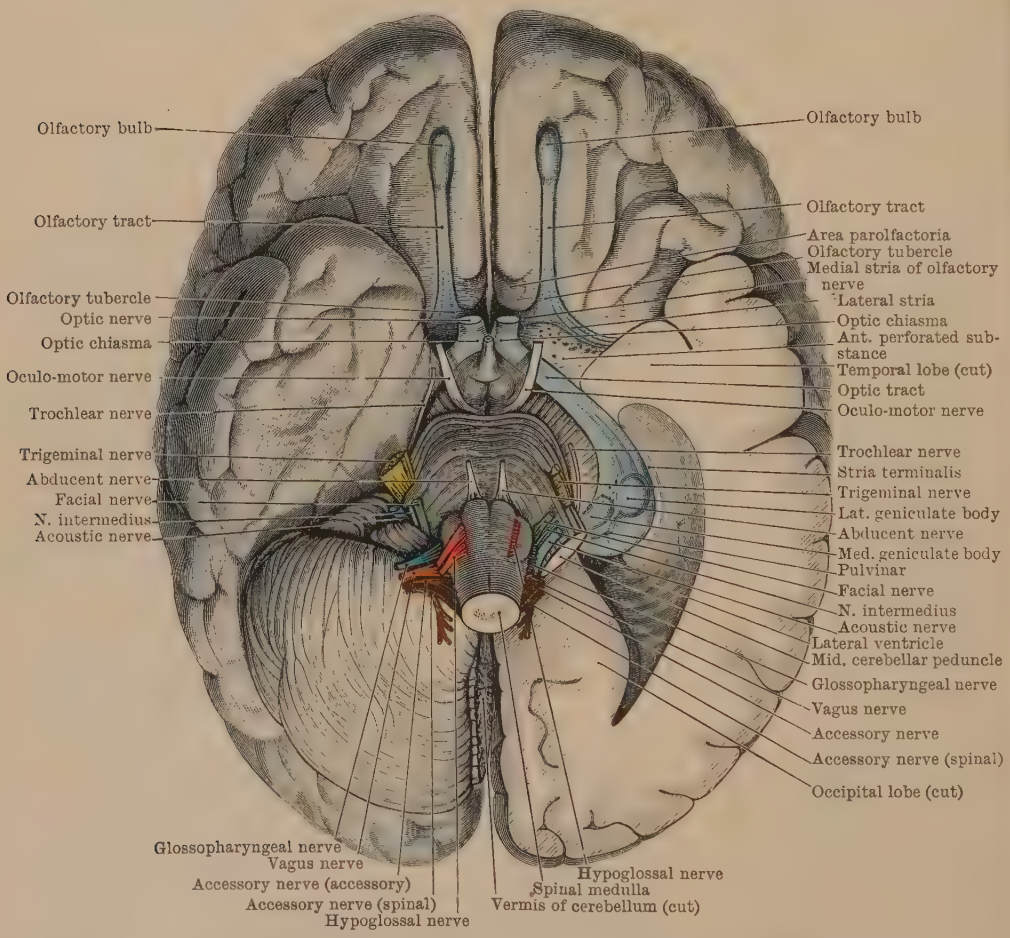

FIG. 569.—VIEW OF THE INFERIOR SURFACE OF THE BRAIN,
with the lower portion of the temporal and occipital lobes, and the cerebellum on the left side removed, to show the origins of the cerebral nerves.

irrespective of the actual direction of the impulses carried by it. In this chapter the cerebral nerves are described from their superficial origins onwards; their deep origins and intra-cerebral connexions are dealt with in the section which treats of the Brain (pp. 590-609), and certain general points in connexion with them are also touched upon in the chapter introductory to the Nervous System (p. 498 *et seq.*).

Classification of the Cerebral Nerves.—Recent studies of the central connexions and peripheral distribution of the cerebral nerves would point to those designated as the fifth, seventh, and eighth under the customary terminology, being each really divisible, both anatomatically and physiologically, into two components, which are given separate names. None of the cerebral nerves corresponds closely to a typical spinal nerve with motor and sensory roots. The fifth nerve,

sometimes so compared, might well be considered as composed of a sensory nerve, the trigeminal, allied to a separate motor nerve, the *masticator* (nervus masticatorius or motor root of the fifth) which accompanies for part of its course the mandibular division only of the former. Similarly, the usually designated seventh nerve can be resolved into two components, the facial proper and the *glossopalatine* (nervus intermedius or intermediate part of the seventh), the latter including the genicular ganglion and chorda tympani nerve (see note on p. 695). The separation of the eighth nerve into two entirely different functional elements, the cochlear and vestibular divisions, though both are sensory, is more obvious. Such a re-classification would give fifteen pairs of nerves instead of the customary twelve.

Nervi Olfactorii.

In the older accounts, the **first** or **olfactory nerve** is described as consisting of several parts: (1) a series of fine **nerves**, which arise from (2) the **olfactory bulb**. This again is connected by (3) the **olfactory tract** with the brain, to which it is attached by (4) two **striæ** or roots (Fig. 569).

The anatomy of the olfactory bulb, the olfactory tract and its roots is described on pp. 621 to 624; and the histology of the cells on p. 621.

The **olfactory nerve** consists of about twenty separate filaments which arise in the olfactory mucous membrane and terminate in the olfactory bulb. The fibres

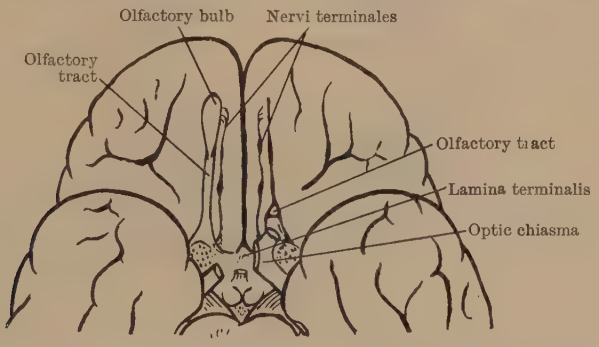

Fig. 570.—Diagram of part of the Ventral Surface of an Adult Human Brain to show the position of the central parts of the Nervi Terminales and their relations to the Olfactory Tracts and Gyri Recti. (After Brookover).

The olfactory bulb and part of the tract have been removed on the left side, and the right optic nerve and the greater part of the optic chiasma have been cut away to expose the lamina terminalis.

are non-medullated. After their origins from the olfactory cells of the olfactory region on the upper third of the nasal septum and nearly the whole of the opposed superior nasal concha (Figs. 146, 147), the nerve fibres form fine plexuses from which the terminal filaments pass through the cribriform plates of the ethmoid on their way to the olfactory bulb. Each filament has a sheath of dura mater.

Two other pairs of nerves have been found related to the olfactory system in lower vertebrates and in mammals with a well-developed sense of smell. Both are closely related to the olfactory nerve itself throughout its course. These are: (1) the *vomero-nasal nerve*, which supplies the vomero-nasal (Jacobson's) organ, and in the domestic animals joins the olfactory nerve itself to terminate in an accessory olfactory bulb; in man Jacobson's organ is rudimentary after birth, and the nerve is absent; (2) the terminal nerve.

The **terminal nerve** (*nervus terminalis*) has been found present in all groups of vertebrates, in the human embryo, and recently in the human adult. It is a very fine plexiform nerve consisting of non-medullated fibres with small groups of ganglion cells, and may be discovered in the cranial cavity as two or three strands in the pia mater covering the gyrus rectus along the medial side of the olfactory tract. Peripherally (anteriorly) its fibres join the olfactory nerve filaments and have a similar distribution to the nasal mucosa; in some mammals they have been traced to end in the walls of the anterior cerebral artery and in the vascular

plexus of the nasal septum up to the region of the vomero-nasal organ. Centrally, the nerve strands pass over the medial olfactory stria towards the anterior perforated substance. The evidence points to the conclusion that the nerve is functional in mammals, and, from the appearance of its fibres and ganglia, among other features, it may eventually be recognised as related in part at least to the sympathetic system rather than as representing a separate nerve (Johnstone, Brookover, Larsell).

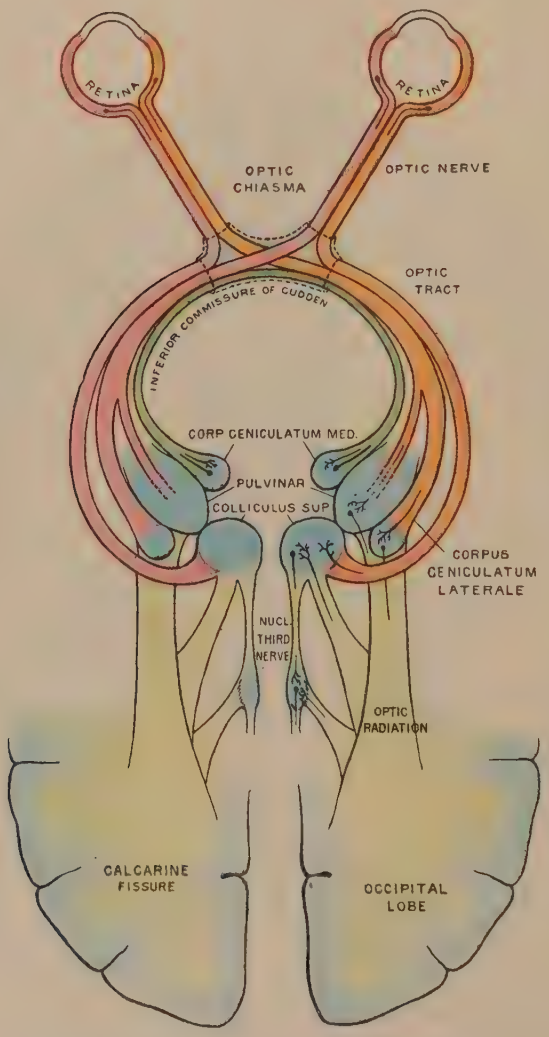

Fig. 571.—Central Connexions of the Optic Nerve and Optic Tracts.

Nervus Opticus.

The **second** or **optic nerve** consists of nerve fibres which spring from the ganglion cells of the retina, and converge to the optic papilla, where they are grouped together to form the optic nerve. The nerve pierces the outer layers of the retina, the chorioid, and the sclera. It pierces the sclera 3 mm. (one-eighth of an inch), to the medial side of the posterior pole of the eyeball, and enters the orbital fat, surrounded by the ciliary vessels and nerves. It then runs backwards and slightly medially towards the apex of the orbit, being crossed by the ophthalmic artery and naso-ciliary nerve, and is pierced on its inferior surface by the central artery of the retina. It is surrounded by sheaths from all three membranes of the

brain, that formed by the dura being especially robust, and by prolongations of the subdural and subarachnoid spaces which lie between them. At the apex of the orbit it passes through the annulus tendineus communis of Zinn, from which the four recti muscles of the eyeball arise, to enter the optic foramen of the sphenoid bone. In the foramen it is separated from the sphenoidal air sinus by only a thin plate of bone, and the ophthalmic artery accompanies it on its lateral side. It then enters the middle fossa of the skull and ends in the optic chiasma, which lies at the base of the brain, anterior to the interpeduncular area and between the right and the left anterior perforated substance. The chiasma is in close relation on either side to the internal carotid artery, but lies a little distance superior to the hypophysis cerebri.

From each of the two postero-lateral angles of the optic chiasma an optic tract sweeps round to the back of the thalamus and to the mid-brain, between the pedunculus cerebri and the hippocampal gyrus of the corresponding side, and each tract terminates in connexion with the pulvinar, the lateral geniculate body, the superior brachium, and the medial geniculate body—all of the same side.

When the optic nerve reaches the optic chiasma some of its fibres pass to the optic tract of the same side and some to the optic tract of the opposite side. Therefore, each optic nerve is connected with both sides of the brain. But each optic tract, in addition to some fibres of both optic nerves, contains also fibres passing from the medial geniculate body of one side to the medial geniculate body of the opposite side; these fibres constitute the inferior commissure of Gudden (p. 616).

Nervus Oculomotorius.

The **third** or **oculo-motor nerve** supplies the levator palpebræ superioris, and all the ocular muscles, save the lateral rectus and superior oblique. It arises from the brain, in the region of the posterior perforated substance, by several fila

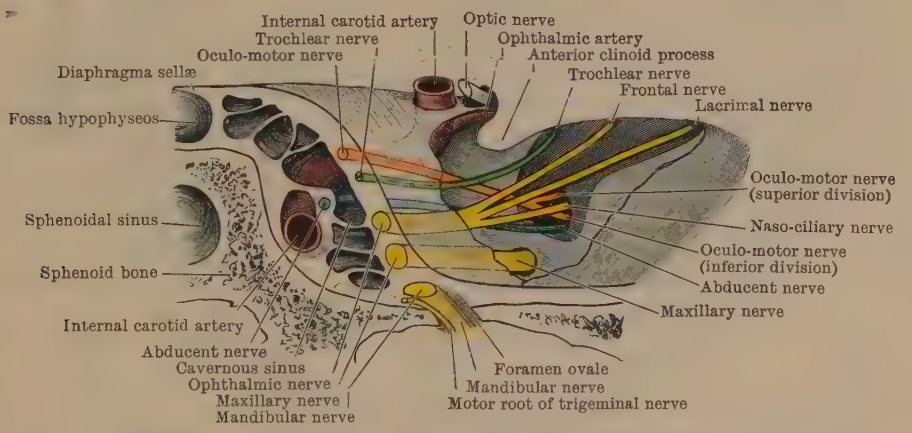

Fig. 572.—Relations of Structures in the Cavernous Sinus and Superior Orbital Fissure.

radicularia (radicles) emerging from the **oculo-motor sulcus**, on the medial side of the cerebral peduncle, just in front of the pons (Fig. 569). Passing forwards, between, and close to the posterior cerebral and superior cerebellar arteries, then along the lateral aspect of the posterior communicating artery through the cisterna interpeduncularis, the nerve pierces the dura mater beside the posterior clinoid process, in a small triangular space between the free and attached borders of the tentorium cerebelli. Embedded in the dura mater the nerve courses through the lateral wall of the cavernous sinus, above the trochlear nerve, and enters the orbit through the superior orbital fissure and then lies within the *annulus tendineus communis* of Zinn from which the four recti muscles arise. The space within the annulus not occupied by the optic nerve is termed in

consequence the **oculo-motor foramen** (Fig. 579, p. 686). At this point of entry into the orbit the nerve divides into upper and lower branches, separated by the naso-ciliary nerve.

Branches.—The **superior branch** of the nerve supplies two muscles of the orbit —the superior rectus and the levator palpebræ superioris.

The **inferior branch** passes forwards, and after giving branches to the medial and inferior recti, ends in the inferior oblique muscle.

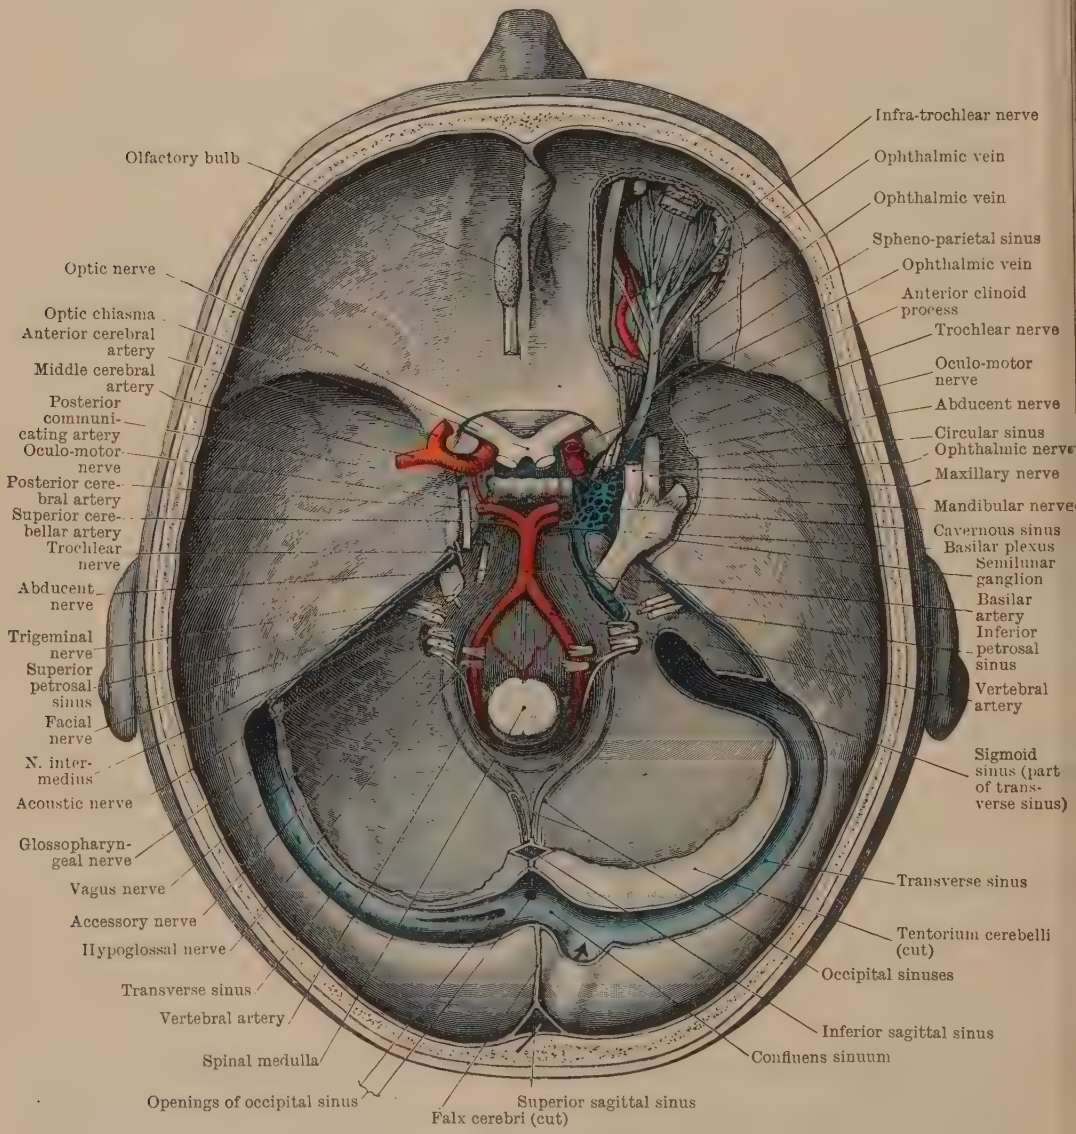

FIG. 573.—THE BASE OF THE SKULL, to show the dura mater, sinuses, arteries, and nerves.

Communications.—1. In the cavernous sinus the oculo-motor nerve is usually stated to receive filaments from the sympathetic cavernous plexus on the internal carotid artery. 2. In the cavernous sinus it also receives a slender sensory communication from the ophthalmic division of the trigeminal nerve. 3. The **short motor root of the ciliary ganglion** passes upwards from the branch of the nerve which supplies the inferior oblique muscle, by means of which the ciliary and sphincter pupillæ muscles of the eyeball are innervated.

Nervus Trochlearis.

The **fourth** or **trochlear nerve** supplies only the superior oblique muscle of the eyeball. It emerges from the dorsal surface of the mid-brain. It arises at the side of the *frenulum veli* from the anterior end of the anterior medullary velum, just behind the inferior corpora quadrigemina (Fig. 483, p. 577). It is extremely slender, and of considerable length. Passing round the cerebral peduncle, the nerve appears at the base of the brain behind the optic tract, in the interval between the cerebral peduncle and the temporal lobe of the brain, and between the superior cerebellar and posterior cerebral arteries. Continued forwards to the base of the skull, it pierces the free border of the tentorium cerebelli, postero-lateral to the oculo-motor nerve, and proceeds forwards, in the lateral wall of the cavernous sinus, to the superior orbital fissure, lying between the oculo-motor nerve and the ophthalmic division of the trigeminal nerve. It enters the orbit above the muscles of the eyeball, turns medially between the levator palpebræ superioris and the periosteum of the orbital roof, and terminates in the orbital (superior) surface of the superior oblique muscle.

Communications.—In the cavernous sinus the nerve receives (1) probably a communicating branch from the cavernous or carotid plexus on the internal carotid artery, and (2) a slender filament from the ophthalmic division of the trigeminal nerve.

Nervus Trigeminus.

The **fifth** or **trigeminal nerve**, the largest of the cerebral nerves, is the nerve of common sensation to the superficial and deep parts of the face and is motor to the muscles of mastication (see summary of distribution on p. 691).

It arises from the inferior surface of the pons in its lateral part by two roots, a large **sensory root** and a small **motor root** (Fig. 569, p. 676). The two roots proceed forwards in the posterior fossa of the skull, and piercing the dura mater beneath the attachment of the tentorium cerebelli to the superior angle of the petrous part of the temporal bone, enter a cavity in the dura mater (*cavum Meckelii*) over the apex of the petrous bone. The large sensory root gradually conceals the small motor root in its course forwards, and expands beneath the dura mater into a large flattened ganglion—the **semilunar** (O.T. **Gasserian**) **ganglion.** This ganglion occupies an impression on the apex of the petrous portion of the temporal bone, and from it three large trunks arise—the **ophthalmic** or first, the **maxillary** or second, and the **mandibular** or third **divisions** of the nerve. The small motor root of the nerve passes forward beneath the ganglion, and is incorporated wholly with the mandibular division of the nerve; on developmental and functional grounds it is sometimes described as a separate nerve, the **masticator** (*nervus masticatorius*).

Nervus Ophthalmicus.

The **ophthalmic nerve** passes forwards to the orbit through the middle fossa of the skull, in the dura mater. It lies in the lateral wall of the cavernous sinus, at a lower level than the trochlear nerve, and reaches the orbit through the superior orbital fissure (Fig. 573).

In the wall of the cavernous sinus the ophthalmic nerve gives off (1) a small recurrent branch to the dura mater (*n. tentorii*), (2) communicating branches to the cavernous plexus of the sympathetic on the internal carotid artery, and (3) small communicating sensory twigs to the trunks of the oculo-motor, trochlear, and abducent nerves.

In the superior orbital fissure the nerve divides into three main branches—lacrimal, frontal, and naso-ciliary (Fig. 579).

N. Lacrimalis.—The **lacrimal nerve** enters the orbit through the lateral angle of the superior orbital fissure, above the orbital muscles. It passes forwards, between the periosteum and the orbital contents, to the anterior part of the orbit, and ends by supplying branches (*a*) to the lacrimal gland, (*b*) to the conjunctiva, and (*c*) to the skin of the lateral commissure of the eye.

The lacrimal nerve *communicates* in the orbit with the zygomatic branch of the maxillary nerve (whereby secretory fibres are conveyed to the lacrimal gland), and on the face, by its terminal branches, with the temporal branches of the facial nerve.

N. Frontalis.—The **frontal nerve** enters the orbital cavity through the superior orbital fissure, courses forwards above the ocular muscles, and divides at a variable point into two branches—a larger supra-orbital and a smaller supra-trochlear nerve.

N. Supraorbitalis.—The **supra-orbital nerve** passes directly forwards, and leaves the orbit, through the supra-orbital groove or foramen, to reach the forehead. It gives off the following secondary branches: (1) the **frontal** branches **(rami frontales)** are distributed to the forehead and scalp, reaching backwards as far as the vertex; (2) small branches supply the upper eyelid; and (3) twigs are distributed to the frontal sinus. On the forehead the supra-orbital nerve communicates with the temporal branches of the facial nerve.

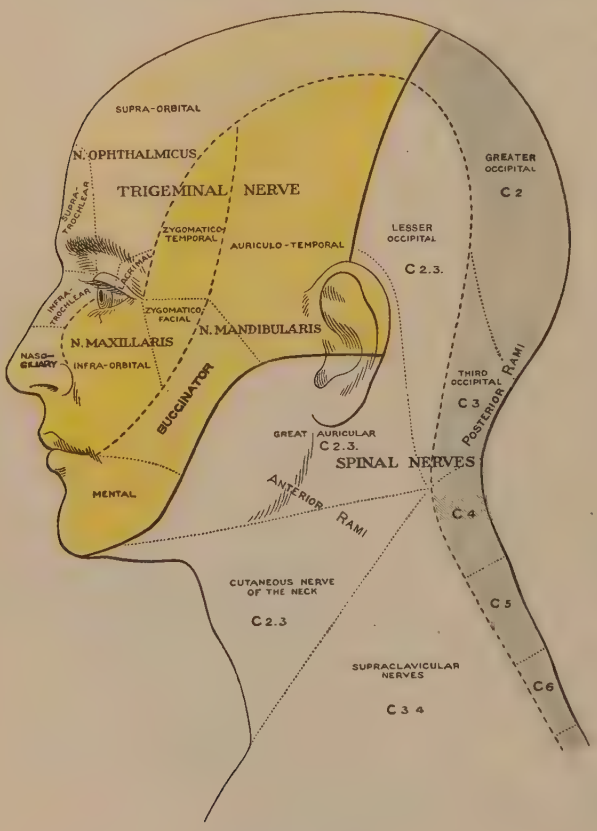

FIG. 574.—DISTRIBUTION OF SENSORY NERVES TO THE HEAD AND NECK.

N. Supratrochlearis.—The **supra-trochlear nerve** courses obliquely forwards and medially, above the tendon of the superior oblique muscle, to reach the medial side of the supra-orbital arch, where it leaves the cavity of the orbit; it is distributed to the skin of the medial part of the forehead, the root of the nose, and the medial commissure of the eye.

It communicates with the infra-trochlear branch of the naso-ciliary nerve, either before or after leaving the orbital cavity.

N. Nasociliaris.—The **naso-ciliary nerve** (O.T. **nasal**) enters the orbit through the superior orbital fissure, inside the annulus of Zinn, and between the two divisions of the oculo-motor nerve (Fig. 579, p. 686). It crosses the orbital cavity obliquely to reach the anterior ethmoidal foramen, lying in its course below the superior rectus and superior oblique muscles, and above the optic nerve and medial rectus muscle. The nerve is transmitted, under the name of *anterior ethmoidal*, through the anterior ethmoidal foramen into the cranial cavity, where it lies embedded in dura mater on the lamina cribrosa of the ethmoid bone. It enters the nasal cavity through the nasal fissure, and terminates by dividing into medial and lateral branches. The medial division supplies the mucous membrane over the upper and anterior part of the nasal septum. The lateral branch, after supplying collateral offsets to the lateral wall of the nasal cavity, finally appears on the face, as the **external nasal nerve**, between the nasal bone and lateral cartilage, and supplies branches to the skin of the lower part and tip of the nose. The anterior ethmoidal nerve supplies, then, the cartilaginous end of the nose, both internally and externally.

The **branches** of the naso-ciliary nerve may be divided into three sets, arising (*a*) in the orbit, (*b*) in the nose, and (*c*) on the face.

In the orbit the branches are given off in three situations—lateral to, above, and

medial to the optic nerve. (*a*) As the nerve lies on the lateral side of the optic nerve, it gives off the **radix longa ganglii ciliaris (long or sensory root of the ciliary ganglion).** (*b*) As it crosses above the optic nerve, **nn. ciliares longi (two long ciliary branches)** arise, and pass forwards alongside the optic nerve to the eyeball. They convey fibres to the dilatator pupillæ muscle of the iris. (*c*) On the medial side of the optic nerve the **n. infratrochlearis (infra-trochlear nerve)** arises, a slender branch which courses forwards below the pulley of the superior oblique muscle to the front of the orbit. It ends on the face by supplying the skin of the root of the nose and the eyelids, and communicates either in the orbit or on the face with the supra-trochlear nerve. On the face it also communicates with zygomatic branches of the facial nerve. A minute *posterior ethmoidal branch* may arise from the nerve near the back of the orbit, and enter the foramen of the same name to be distributed to the sphenoidal sinus and posterior ethmoidal cells.

In the nose the **rami nasales mediales (medial nasal branches)** supply the mucous membrane of the anterior part of the nasal septum; the **rami nasales laterales (lateral nasal branches)** supply the anterior part of the lateral wall of the nasal cavity.

On the face the terminal filaments of the nerve are distributed, as the **ramus nasalis externus (external nasal branch)**, to the skin of the lower half and tip of the nose. The terminal branch communicates with the zygomatic branches of the facial nerve.

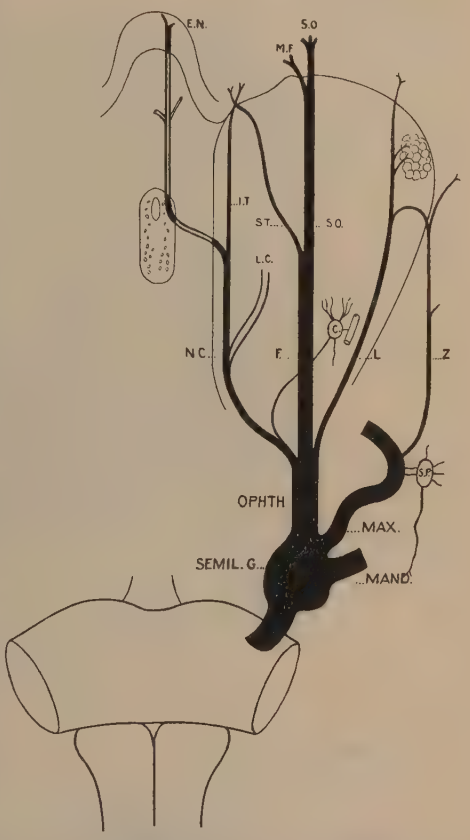

FIG. 575.—SCHEME TO SHOW THE DISTRIBUTION OF THE OPHTHALMIC DIVISION OF THE TRIGEMINAL NERVE.

F., frontal nerve, giving off the supra-trochlear branch (S.T.) and afterwards being known as the supra-orbital (S.O.), which may divide before leaving the orbit into a medial frontal branch (M.F.) and a lateral frontal or supra-orbital proper.

N.C., the naso-ciliary nerve; it is shown to give off the sensory root to the ciliary ganglion (C.), the two long ciliary nerves (L.C.) to the eyeball, and, just before leaving the orbit through the anterior ethmoidal canal, the infra-trochlear nerve (I.T.); the rest of its course up to its termination on the nose as the external nasal nerve (E.N.) illustrates the description given in the text.

L., the lacrimal nerve, the anastomosis of which with the zygomatico-temporal branch of the zygomatic nerve (Z.) is represented.

S.P., the spheno-palatine ganglion.

Ganglion Ciliare.—The **ciliary (lenticular** or **ophthalmic) ganglion**, though associated with the naso-ciliary branch of the ophthalmic nerve and with the inferior division of the oculo-motor nerve, is regarded more properly as belonging to the sympathetic system (see p. 692). It is a small reddish ganglion, about the size of a pin's head, placed near the back of the orbit, between the lateral rectus muscle and the optic nerve, and in front of the ophthalmic artery. Its *roots* are three in number: (1) **sensory** or long, derived from the naso-ciliary branch of the ophthalmic nerve; (2) **motor** or short, derived from the inferior division of the oculo-motor nerve; and (3) **sympathetic**, a slender filament from the cavernous plexus on the internal carotid artery, which may exist as an independent root or may be incorporated with the long root from the naso-ciliary nerve. The branches from the ganglion are twelve to fifteen **nn. ciliares breves (short ciliary nerves)**, which pass to the eyeball in two groups above and below the optic nerve. They convey motor fibres (from the third nerve) to the constrictor pupillæ fibres of the iris and the ciliary muscle, sympathetic fibres to the blood-vessels, and they carry sensory fibres from all parts of the eyeball.

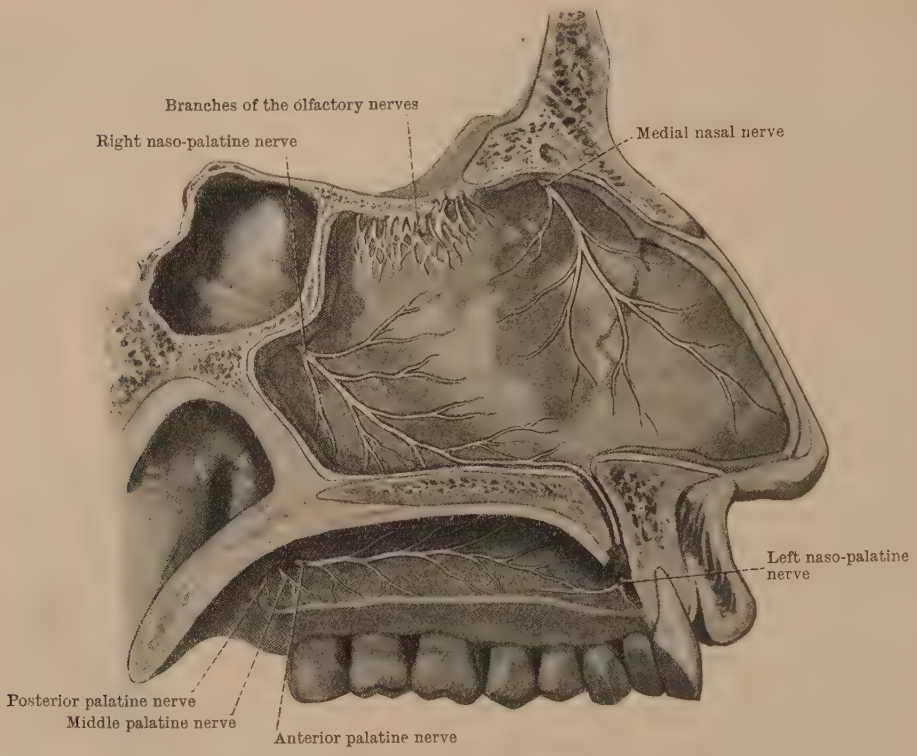

FIG. 576.—INNERVATION OF NASAL SEPTUM AND PALATE.

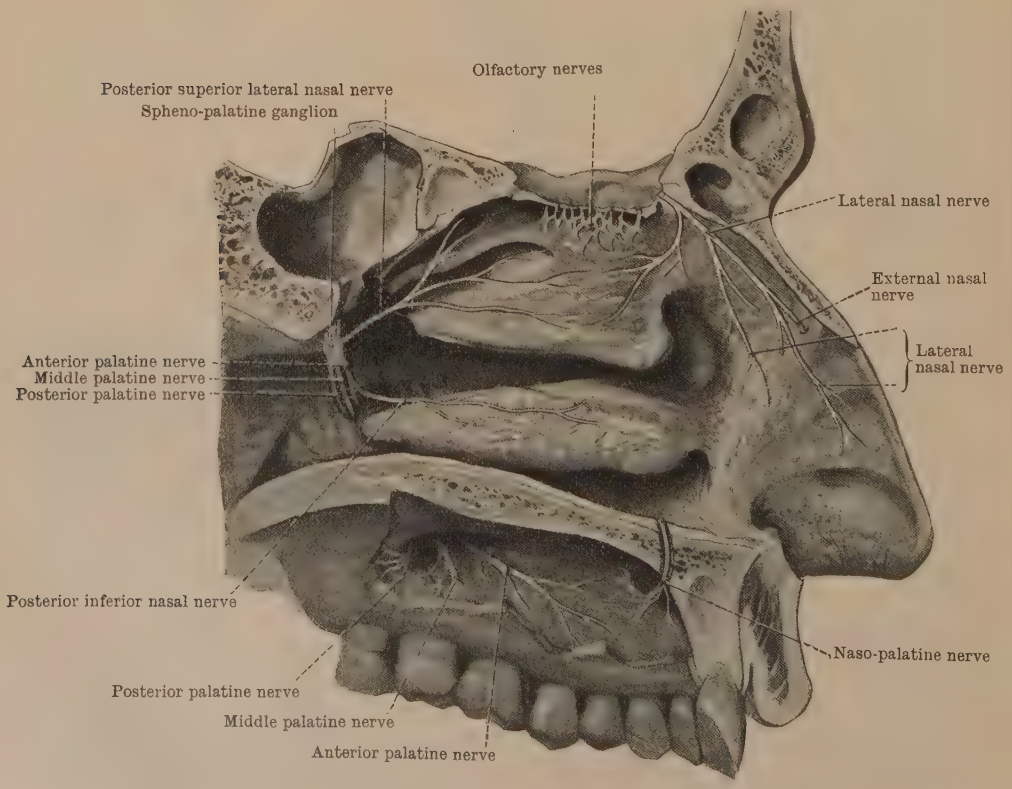

FIG. 577.—INNERVATION OF LATERAL WALL OF NASAL CAVITY AND PALATE.

Nervus Maxillaris.

The Maxillary Nerve.—This large nerve courses forwards from its origin in the semilunar ganglion through the middle fossa of the skull, in the dura mater, and in relation to the lower part of the cavernous sinus (Fig. 573, p. 680). It passes through the foramen rotundum, traverses the pterygo-palatine fossa, and enters the orbit as the infra-orbital nerve, through the inferior orbital fissure. In the orbit it occupies successively the infra-orbital groove and canal, and it finally appears on the face through the infra-orbital foramen (Fig. 581).

The branches and communications of this nerve occur (*a*) in the cavity of the cranium, (*b*) in the pterygo-palatine fossa, (*c*) in the infra-orbital canal, and (*d*) on the face.

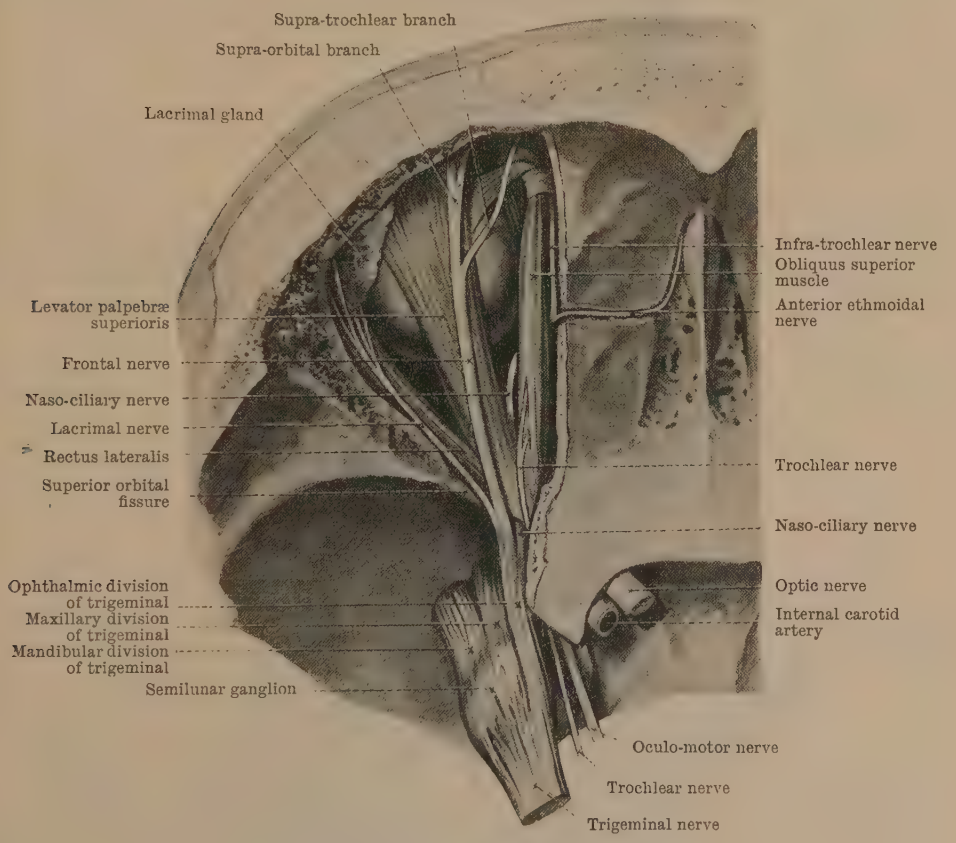

Fig. 578.—The Nerves of the Orbit from above.

In the cavity of the cranium the nerve gives off a minute (**n. meningeus medius**) **middle meningeal nerve** (O.T. **recurrent nerve**) to the dura mater of the middle fossa of the skull.

In the pterygo-palatine fossa the nerve gives off—(1) two short thick **spheno-palatine nerves**, the sensory roots of the spheno-palatine ganglion. Most of their fibres, however, do not traverse the ganglion but pass over it to enter its branches.

(2) **Posterior superior alveolar nerves**, usually two, descend through the pterygo-maxillary fissure to the posterior surface of the maxilla, and proceed forwards along the alveolar arch, in company with the posterior superior alveolar artery. They supply the gum and the upper molar teeth by branches which perforate the bone to reach the alveoli; they also supply the mucous membrane of the maxillary antrum. The nerves form a fine superior dental plexus, which is joined by the middle alveolar nerve before finally reaching the teeth.

(3) A small **orbital branch**, the *nervus zygomaticus*, enters the orbital cavity through the inferior orbital fissure, and proceeding along the lateral wall, divides

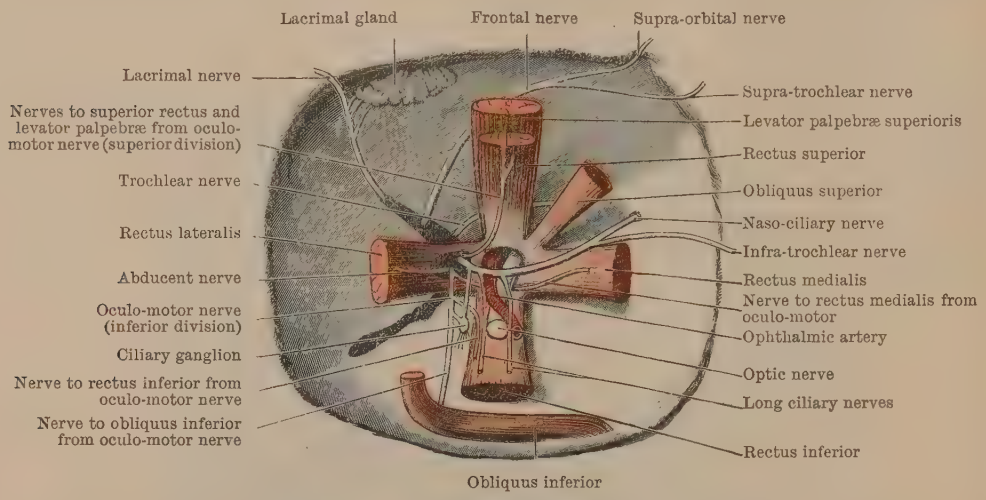

FIG. 579.—SCHEMATIC REPRESENTATION OF THE NERVES WHICH TRAVERSE THE CAVITY OF THE ORBIT.

Note that the lacrimal, frontal, and trochlear nerves, after entering the orbit through the superior orbital fissure, pass outside the annulus tendineus communis of Zinn from which the recti muscles arise; whilst the oculo-motor, abducent, and naso-ciliary nerves, together with the optic nerve and ophthalmic artery, enter the orbit within the annulus, and therefore lie at first within the cone formed by the ocular muscles as they diverge forwards from it.

into two branches. The **zygomatico-facial branch** appears on the face, after traversing the zygomatic bone through the zygomatic foramen, and supplies

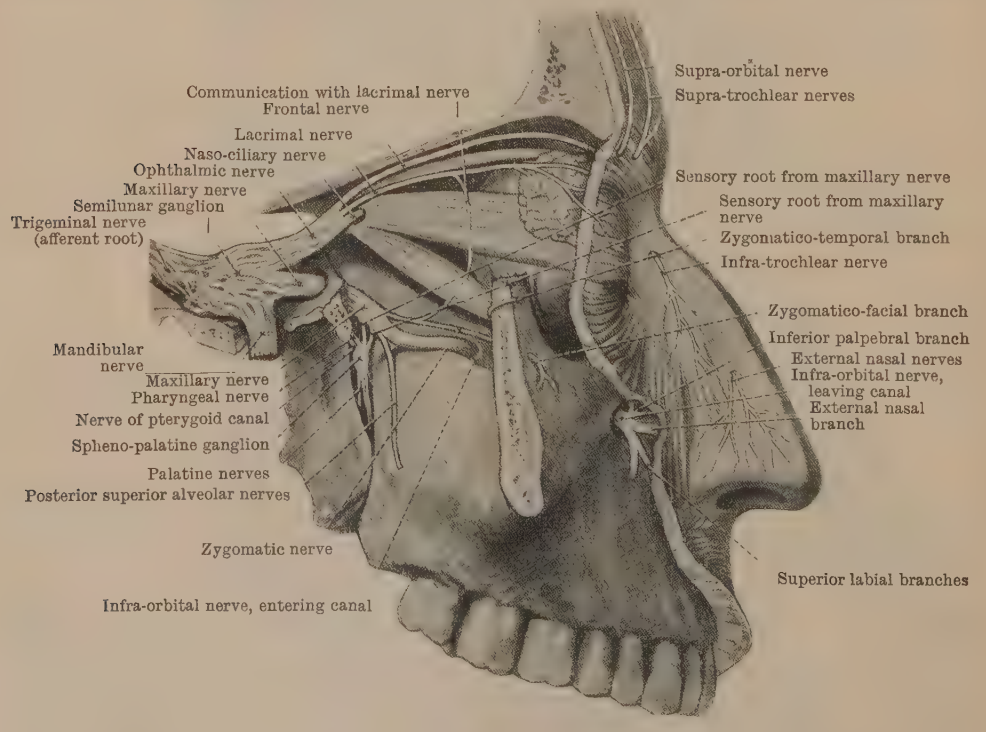

FIG. 580.—THE COURSE OF THE OPHTHALMIC AND MAXILLARY NERVES.

the skin over that bone. It communicates with the zygomatic branches of the facial nerve. The **zygomatico-temporal branch** perforates the temporal surface of the zygomatic bone, or passes through the spheno-zygomatic suture, and is

distributed, after piercing the temporal fascia, to the skin over the anterior part of the temple. In the orbit it communicates with the lacrimal nerve, and on the face with the temporal branches of the facial nerve. It may be very minute, and not pass further than the temporal fascia, between the two layers of which it may form a communication with the facial nerve.

(4) The **infra-orbital nerve** is the terminal branch of the maxillary nerve, which enters the orbit through the inferior orbital fissure and traverses the infra-orbital canal to reach the face.

In the infra-orbital canal the infra-orbital nerve supplies one and sometimes two branches to the teeth—the **middle** and **anterior superior alveolar nerves.** The former may be only a secondary branch of one of the latter nerves, or it may arise independently from the infra-orbital nerve. However formed, the nerves descend, in bony canals which may form internal bony ridges in the wall of the maxillary sinus (to the lining of which branches are given), and reach the alveolar

arch, where they form minute plexuses containing gangliform enlargements, and supply the teeth (joining posteriorly with the branches of the posterior superior alveolar nerves). The anterior superior alveolar nerve supplies the incisor and canine teeth, and also gives off a nasal branch which enters the nasal fossa through a minute foramen to supply the forepart of the inferior concha and nasal floor; the middle superior alveolar nerve supplies the premolar teeth.

After emerging on the face from the infra-orbital foramen, the infra-orbital nerve divides into a number of radiating branches arranged in three sets—(*a*) **inferior palpebral (rami palpebrales inferiores)**, for the skin and conjunctiva of the lower eyelid; (*b*) **external nasal**, for the skin of the side of the nose; and (*c*) **superior labial**, for the cheek and upper lip. These branches form communications with the zygomatic branches of the facial nerve, and give rise to the *infra-orbital plexus* (Fig. 580, p. 686).

Ganglion Spheno-palatinum (see note on p. 782).—The **spheno-palatine** (O.T. **Meckel's**) **ganglion** lies deeply in the upper part of the pterygo-palatine fossa, close to the spheno-palatine foramen. It is a small reddish-gray ganglion, suspended from the maxillary nerve by the two **spheno-palatine branches** which

constitute its sensory roots. The **motor** and **sympathetic roots** of the ganglion are derived from the **nerve of the pterygoid canal** (O.T. **Vidian Nerve**). This nerve is formed in the cranial cavity, upon the cartilage filling up the foramen lacerum, by the union of the *greater superficial petrosal nerve*, from the genicular ganglion of the facial nerve, with the *deep petrosal nerve*, a branch of the sympathetic plexus on the internal carotid artery; it also receives a communication from the otic ganglion. The nerve of the pterygoid canal passes through the pterygoid canal (which may form a ridge in the wall of the sphenoidal air sinus) to the pterygo-palatine fossa, where it joins the spheno-palatine ganglion.

The **branches from the ganglion** are seven in number. They pass backwards to the pharynx, downwards to the palate, inwards to the nasal cavity, and upwards to the orbit.

(*a*) The **pharyngeal** branch passes backwards through the pharyngeal canal to supply the mucous membrane of the roof of the pharynx.

(*b*) **Nervi Palatini.**—The **palatine nerves**, three in number, are directed downwards to the palate through the palatine canals.

The **anterior** or **great palatine nerve** emerges on the under surface of the palate through the greater palatine foramen, and at once separates into numerous branches for the supply of the mucous membrane of the soft and the hard palate, which they groove. Its anterior filaments reach to the incisor teeth and communicate with branches of the naso-palatine nerve. The main nerve gives off, as it lies in the palatine canal, a small **posterior inferior lateral nasal nerve**, which enters the nasal cavity and supplies the mucous membrane of the inferior concha.

The **middle** or **external palatine nerve** descends through a small palatine canal, and, piercing the pyramidal process of the palate bone, is distributed to the mucous membrane of the soft palate, uvula, and palatine tonsil.

The **posterior** or **small palatine nerve** consists of one or more small twigs which pass through the lesser palatine canals, and supply branches to the mucous membrane of the tonsil, soft palate, and uvula. It was formerly thought to convey motor fibres from the facial nerve to the levator veli palatini and uvular muscles, but these are now considered to be supplied by the accessory nerve through the pharyngeal plexus.

(*c*) The branches directed medially from the spheno-palatine ganglion enter the nasal cavity through the spheno-palatine foramen. They are two in number—the posterior superior lateral nasal and the naso-palatine. (1) The **posterior superior lateral nasal branch** is a small nerve destined for the mucous membrane of the superior and middle conchæ of the nasal cavity. (2) The **naso-palatine nerve**, after passing through the spheno-palatine foramen, crosses the roof of the nasal cavity, and extends obliquely downwards and forwards along the nasal septum, grooving the vomer, in its course between the mucous membrane and periosteum, to reach the incisive foramen near the front of the hard palate. The nerves pass through the subordinate median foramina (of Scarpa), the left nerve in front of the right. In the incisive foramen the two nerves communicate together. They then turn backwards and supply the mucous membrane of the hard palate. They communicate posteriorly with terminal filaments of the anterior palatine nerves. In its course through the nasal cavity each naso-palatine nerve furnishes collateral branches to the mucous membrane of the roof and septum of the nose (*posterior superior medial branches*) (Fig. 576, p. 684).

(*d*) **Rami Orbitales.**—The **orbital branches**, one or more minute branches, pass upwards to the periosteum of the orbit from the spheno-palatine ganglion.

Nervus Mandibularis.

The **mandibular nerve** is formed by the union of two roots; a large **sensory root**, from the semilunar ganglion, and the small **motor root** of the trigeminal nerve, which is wholly incorporated with the mandibular trunk. The two roots pass together, in the dura mater of the middle fossa of the base of the skull, to the foramen ovale, through which they emerge into the infra-temporal fossa.

Outside the skull they combine to form a single trunk, which soon separates into anterior and posterior divisions, as noted above. The motor root is sometimes considered as a separate nerve.

At its emergence from the skull the nerve is deeply placed beneath the middle of the zygomatic arch, and is concealed by the ramus of the mandible, and by the masseter, temporal, and external pterygoid muscles; behind it lies the middle meningeal artery.

The branches of the nerve may be divided into two series—(1) those derived from the undivided nerve, and (2) those derived from its terminal divisions.

The branches of the undivided nerve are two in number, and arise from its medial aspect. (*a*) A small **nervus spinosus** (O.T. **recurrent nerve**) arises just outside the skull, and accompanying the middle meningeal artery through the

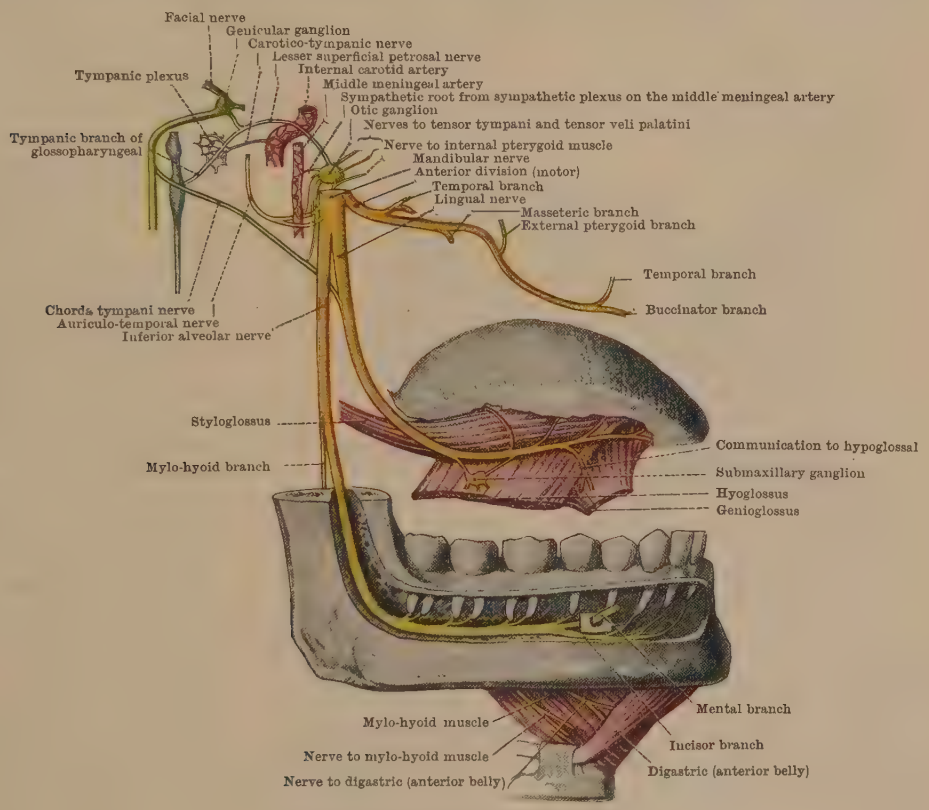

FIG. 582.—THE MANDIBULAR NERVE.

foramen spinosum, supplies the dura mater and mastoid cells. (*b*) In the infra-temporal region a small branch arises for the supply of the **internal pterygoid muscle.** This nerve forms a connexion with the otic ganglion, through which fibres are conveyed to the tensor tympani and tensor veli palatini muscles.

The terminal divisions of the nerve are a small anterior and a large posterior trunk.

The small **anterior trunk (nervus masticatorius** or **masticator nerve)** passes downwards and forwards medial to the external pterygoid muscle, and separates into the following branches: (1) A branch for the external pterygoid muscle, which supplies it on its deep surface; (2) a branch to the masseter muscle, which passes over the superior border of the external pterygoid and through the mandibular notch of the mandible and gives a filament to the temporo-mandibular joint; (3) and (4) two deep temporal branches, an anterior (which often accompanies the nerve to the buccinator) and a posterior (with sometimes a third, the middle) to the temporal muscle, which also ascend above the external

pterygoid muscle; and (5) the buccinator nerve, which passes obliquely forwards between the two heads of the external pterygoid to reach the buccinator muscle. *This nerve is sensory*, and its fibres are, in part, distributed to the skin of the cheek (communicating with buccal branches of the facial nerve, which supplies the muscle itself); they are also, in part, distributed to the mucous membrane of the inside of the mouth, to reach which they pierce the fibres of the buccinator muscle.

The large **posterior trunk** extends downwards a short way medial to the external pterygoid muscle. After giving off, by two roots, the auriculo-temporal nerve, it ends by dividing into two, the lingual and the inferior alveolar nerves.

N. Auriculotemporalis.—The **auriculo-temporal nerve** is formed by the union of two roots which embrace the middle meningeal artery. The nerve passes backwards, medial to the external pterygoid muscle and between the spheno-mandibular ligament and the neck of the mandible. After passing through the parotid gland, it is directed upwards to the temple over the zygoma, in company with the superficial temporal artery. It is finally distributed as a cutaneous nerve of the temple and scalp, and reaches almost to the vertex of the skull.

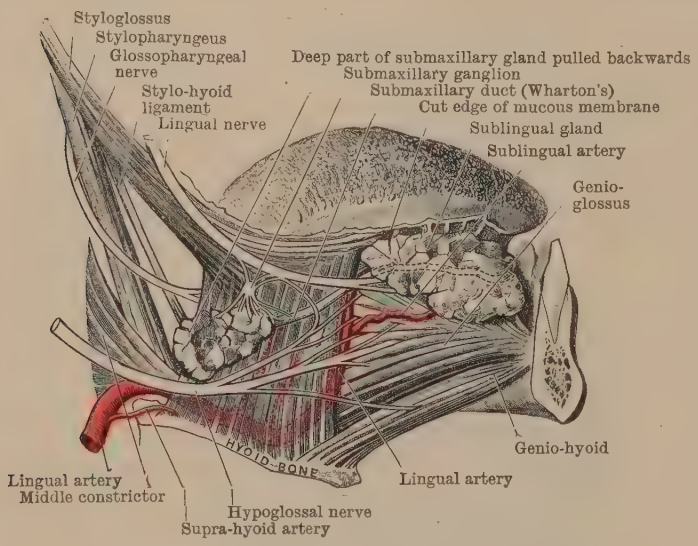

Fig. 583.—The Lingual and Hypoglossal Nerves in the Submaxillary Region.

The auriculo-temporal nerve gives off the following branches: (1) A small branch to the mandibular articulation. (2) Branches to the parotid gland. (3) A twig for the supply of the skin of the external acoustic meatus and membrana tympani. (4) Branches to the superior half of the auricle on its lateral aspect. (5) Terminal branches to the skin of the temple and scalp.

It has the following **communications** with other nerves: (1) Important communications are effected by the roots of the nerve, which are separately joined by small branches from the otic ganglion; these probably convey secretory fibres from the glosso-pharyngeal nerve and the sympathetic system to the parotid gland. (2) The parotid and temporal branches of the nerve are connected with branches of the facial nerve in the substance of the gland.

N. Lingualis.—The **lingual nerve** is the smaller of the two terminal branches of the posterior division of the mandibular trunk. It proceeds downwards in front of the inferior alveolar nerve, medial to the external pterygoid muscle, to its inferior border. After passing between the internal pterygoid muscle and the ramus of the mandible close to the last molar tooth, it crosses beneath the mucous membrane of the floor of the mouth in the interval between the mylo-hyoid and hyoglossus muscles, first lateral to, then beneath the duct of the submaxillary gland. It sweeps forwards and medially to the side of the tongue, to the mucous membrane over the anterior two-thirds of which it is distributed.

Three nerves communicate with the lingual nerve in its course to the tongue: (1) The **chorda tympani branch** of the facial nerve joins it at an acute angle medial to the external pterygoid muscle, and is incorporated with it in its distribution to the tongue. (2) At a lower level it usually communicates with the inferior alveolar nerve. (3) The **hypoglossal nerve** forms larger or smaller

loops of communication with the lingual nerve as they course forwards together over the hyoglossus muscle (**rami anastomotici cum nervo hypoglosso**).

Besides supplying the aforesaid branches to the mucous membrane over the sides and dorsum of the tongue in its anterior two-thirds, the lingual nerve supplies the mucous membrane of the side wall and floor of the mouth and the sublingual gland. It also assists, along with the chorda tympani nerve, in forming the roots of the submaxillary ganglion.

Ganglion Submaxillare (see note on p. 692).—The **submaxillary ganglion** is a minute reddish ganglion placed on the hyoglossus muscle, between the lingual nerve and the duct of the submaxillary gland. It is suspended from the former by two trunks, consisting for the most part of fibres of the lingual and chorda tympani nerves, which at that point become separated from the lingual nerve and incorporated with the ganglion. The **roots** of the ganglion are—(1) a sensory root, derived from the lingual nerve; (2) a motor root, derived from the chorda tympani; and (3) a sympathetic root, from the sympathetic plexus upon the external maxillary artery.

The **branches from the ganglion** are distributed to the submaxillary gland and duct (**rami submaxillares**), and by fibres which become reunited with the trunk of the lingual nerve, to the sublingual gland.

N. Alveolaris Inferior.—The **inferior alveolar nerve** is larger than the lingual nerve. It passes from beneath the inferior border of the external pterygoid muscle to reach the interval between the ramus of the mandible and the spheno-mandibular ligament. It enters the mandibular canal through the mandibular foramen in company with the inferior alveolar artery, traverses the substance of the ramus and body of the mandible, distributing branches to the teeth in its course, and terminates by emerging on the face through the mental foramen.

Branches.—(1) The **mylo-hyoid nerve** is a small branch arising just before the inferior alveolar nerve passes through the mandibular foramen. Piercing the spheno-mandibular ligament and grooving the ramus in its course, it descends into the submaxillary triangle on the superficial aspect of the mylo-hyoid muscle. Concealed in this situation by the submaxillary gland and the external maxillary artery, it is distributed to the mylo-hyoid muscle and the anterior belly of the digastric muscle. (2) The **dental branches** arise from the nerve whilst in the mandibular canal, and form a fine inferior dental plexus from which filaments supply the molar and bicuspid teeth and adjacent gums. (3) The **mental branch** of the inferior alveolar nerve is a trunk of considerable size arising from the main nerve in the mandibular canal. It emerges from the mandible through the mental foramen, and is distributed by many branches to the chin and lower lip. It communicates, under cover of the facial muscles, with the ramus marginalis mandibulæ of the facial nerve (Fig. 586, p. 694). (4) The **incisor branch** is the terminal part of the inferior alveolar nerve remaining after the origin of the mental branch. It supplies the canine tooth and the incisor teeth.

Ganglion Oticum.—The **otic ganglion** is situated deep to the mandibular nerve just below the foramen ovale, at the posterior border of the internal pterygoid muscle. Like the other ganglia described above, it possesses three roots: (1) A *motor root*, derived from the nerve to the internal pterygoid muscle; (2) a *sensory root*, formed by the *lesser superficial petrosal nerve* from the tympanic plexus (through which communications are effected with the tympanic branch of the glossopharyngeal nerve, and a branch from the genicular ganglion of the facial nerve); (3) a *sympathetic root*, from the plexus on the middle meningeal artery (Fig. 585).

Five **branches** arise from the ganglion—three communicating and two motor branches. The three **communicating nerves** are fine branches which join respectively the nerve of the pterygoid canal (sphenoidal branch), the roots of the auriculo-temporal nerve, and the chorda tympani nerve. The two **motor nerves** supply the tensor tympani and tensor veli palatini muscles.

Summary.—The trigeminal, the largest and most complex of the cerebral nerves, is (1) the chief sensory nerve for the face, the anterior half of the scalp, the orbit and eyeball, the nose and nasal cavity and accessory sinuses, the lips, teeth, mouth, and anterior two-thirds of the tongue;

(2) the motor fibres of the nerve supply the muscles of mastication, the mylo-hyoid and anterior belly of the digastric, and the tensor tympani and tensor veli palatini muscles (through the otic ganglion); (3) it supplies the salivary glands, the temporo-mandibular joint, and the dura mater; (4) through the ganglia placed on the three divisions of the nerve, not only are important organs, areas, and muscles innervated, but communications are also effected with the sympathetic system, with the oculo-motor nerve (ciliary ganglion), facial nerve (spheno-palatine and otic ganglia), and glossopharyngeal nerve (otic ganglion).

In its distribution to the skin of the face the branches of the fifth nerve present two striking peculiarities: (1) While the branches to the skin reach the surface at many points and in diverse ways, the three main divisions are severally, by their branches, responsible for the supply of three clearly demarcated cutaneous areas (Fig. 574, p. 682). Moreover, since in embryonic life the general distribution of the nerve is outlined by the outgrowth from the semilunar ganglion of the three main divisions, ophthalmic, maxillary, and mandibular, into the fronto-nasal, maxillary, and mandibular processes respectively, each nerve trunk supplies, broadly speaking, the deeper structures of the face lying behind its own area of cutaneous distribution. (2) By numerous communications with the facial nerve, sensory fibres are given to the muscles of expression supplied by the facial nerve.

Though the **ganglia associated with the fifth nerve**, namely, the ciliary, spheno-palatine, otic, and submaxillary, are conveniently described in their relations to its branches, it should be realised that functionally this nerve has less to do with them than any of the other cerebral nerves with which they are connected. These ganglia properly belong to the sympathetic system; they may be considered to represent an upward extension of the ganglia of the paired sympathetic trunks lying alongside the vertebral column, and can be termed the principal **cephalic sympathetic ganglia** (p. 782). In structure they largely consist of the stellate or multipolar neurones characteristic of this system elsewhere; and developmentally they are formed by cell bodies which have migrated from the semilunar ganglion along the branches of the trigeminal nerve, an origin paralleled by that of the ganglia of the trunks in the lower part of the system. Moreover, the fibres they receive from other nerves (the ciliary ganglion from the oculo-motor, the submaxillary and spheno-palatine ganglia from the facial, and the otic ganglion from the glossopharyngeal) may be likened to the splanchnic efferent fibres received by the ganglia of the sympathetic cord through the white rami of the spinal nerves. Their development is described together with that of the Sympathetic System on p. 780.

Each of the ganglia contains three varieties of fibres: (1) sensory, visceral, and somatic; (2) motor, visceral, derived from one of the cerebral nerves; and (3) sympathetic, which may be somatic motor and sensory, or visceral sensory in character, and are derived from the superior cervical ganglia. Many of the roots and branches are mixed, though they are generally named according to the predominating kind of fibres they contain. Lastly, it is to be noted that nearly all the fibres of a so-called sensory root pass uninterruptedly through a ganglion to reach their destination.

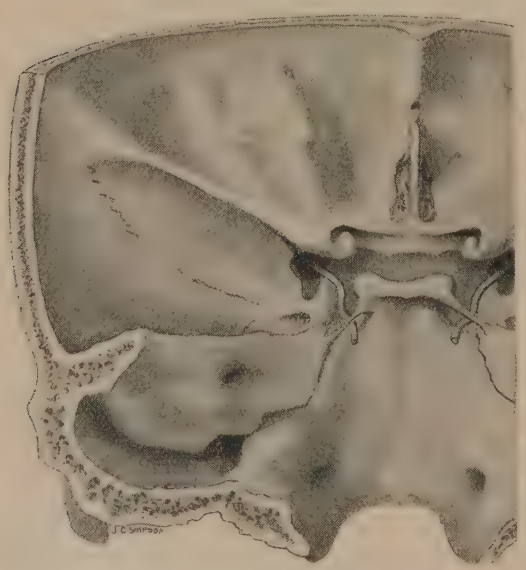

FIG. 584.—THE PETRO-SPHENOIDAL LIGAMENT. The interior of the base of the skull viewed from behind to illustrate a dissection of the abducent nerve passing beneath the ligament before entering the cavernous sinus. The ligament, which is formed by the deeper or osteogenetic layer of the dura mater, presents differences in its extent and attachments, as is illustrated on the two sides.

NERVUS ABDUCENS.

The **sixth** or **abducent nerve** supplies only the lateral rectus muscle of the eyeball. It issues from the brain at the inferior border of the pons, just above the pyramid of the medulla oblongata (for the deep origin, see p. 598). It is directed forwards, it pierces the dura mater in the posterior fossa of the base of the skull alongside the dorsum sellæ, passing beneath the petro-sphenoidal ligament (Fig. 584), and enters the cavernous sinus (Fig. 572, p. 679). In the sinus it is placed close to the lateral side of the internal carotid artery. After it leaves the sinus it passes through the superior orbital fissure below the oculo-motor and naso-ciliary nerves and enters the orbit within the annulus of Zinn

(Fig. 579, p. 686). In the cavity of the orbit it supplies the lateral rectus muscle on its deep (ocular) surface.

Communications.—In the cavernous sinus the sixth nerve receives two communicating filaments: (1) From the carotid plexus of the sympathetic, and (2) from the ophthalmic division of the trigeminal nerve.

Nervus Facialis.

The **seventh** or **facial nerve** is a mixed nerve, and consists of two parts, a larger motor, which supplies all the superficial muscles of the scalp, face, and neck, and some of the deep ones, and a smaller sensory part, the *nervus intermedius*, or nerve of Wrisberg, which contains taste fibres for the anterior two-thirds of the tongue. It emerges from the brain at the inferior border of the pons, below the trigeminal nerve and medial to the acoustic nerve (for the deep origin, see p. 596). Between it and the acoustic nerve is the minute *nervus intermedius* (Fig. 587, p. 696). The facial nerve enters the internal acoustic meatus, and passing through

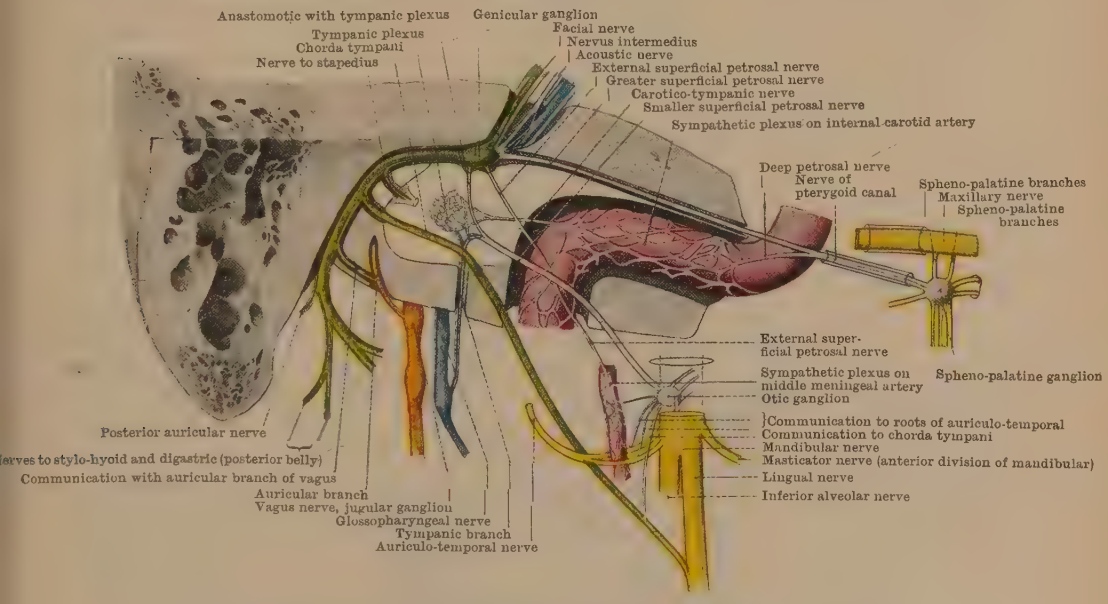

Fig. 585.—The Connexions of the Facial Nerve in the Temporal Bone.

the canalis facialis in the petrous portion of the temporal bone, emerges at the base of the skull by the stylo-mastoid foramen, and passes forwards through the parotid gland to supply the muscles of the face. *In the internal acoustic meatus* the nerve is placed upon the acoustic nerve, the *nervus intermedius* intervening, and all three are surrounded by sheaths of the dura, arachnoid, and pia. *In the canalis facialis* the nerve first passes forwards and laterally to the hiatus of the canal, then abruptly backwards on the medial side of the tympanum, and finally downwards behind the tympanum, in the medial wall of the tympanic antrum. *In the parotid gland* it crosses the external carotid artery and the posterior facial vein superficially. *On the face* its branches radiate from the anterior border of the parotid gland and enter the deep surface of the facial muscles.

Branches and Communications.—(i.) *In the internal acoustic meatus* the nervus intermedius, lying between the facial and acoustic nerves, sends communicating branches to both of them. The branch to the acoustic nerve probably separates from it again to join the genicular ganglion of the facial nerve (Fig. 587, p. 696).

(ii.) *In the canalis facialis* the **ganglion geniculi** is formed at the point where the facial nerve bends backwards (the genu). It is an oval swelling on the nerve, and is joined by a branch from the upper (vestibular) trunk of the acoustic nerve, by which it probably receives fibres of the nervus intermedius. From the ganglion

three small nerves arise: (1) The **greater superficial petrosal nerve** passes forwards through the hiatus canalis facialis to the middle fossa of the skull. It contains chiefly sensory fibres, derived from the intermediate nerve, which, after traversing the spheno-palatine ganglion, are distributed by the middle and posterior palatine nerves to the mucous membrane of the soft palate. It receives a twig from the tympanic plexus and probably also contains a few motor fibres. In the upper part of the foramen lacerum it is joined by the **deep petrosal nerve** from the sympathetic plexus on the internal carotid artery to form the nerve of the pterygoid canal (O.T. Vidian nerve), which, after traversing the pterygoid canal, ends in the spheno-palatine ganglion. (2) A minute nerve (*ramus anastomoticus cum plexu*

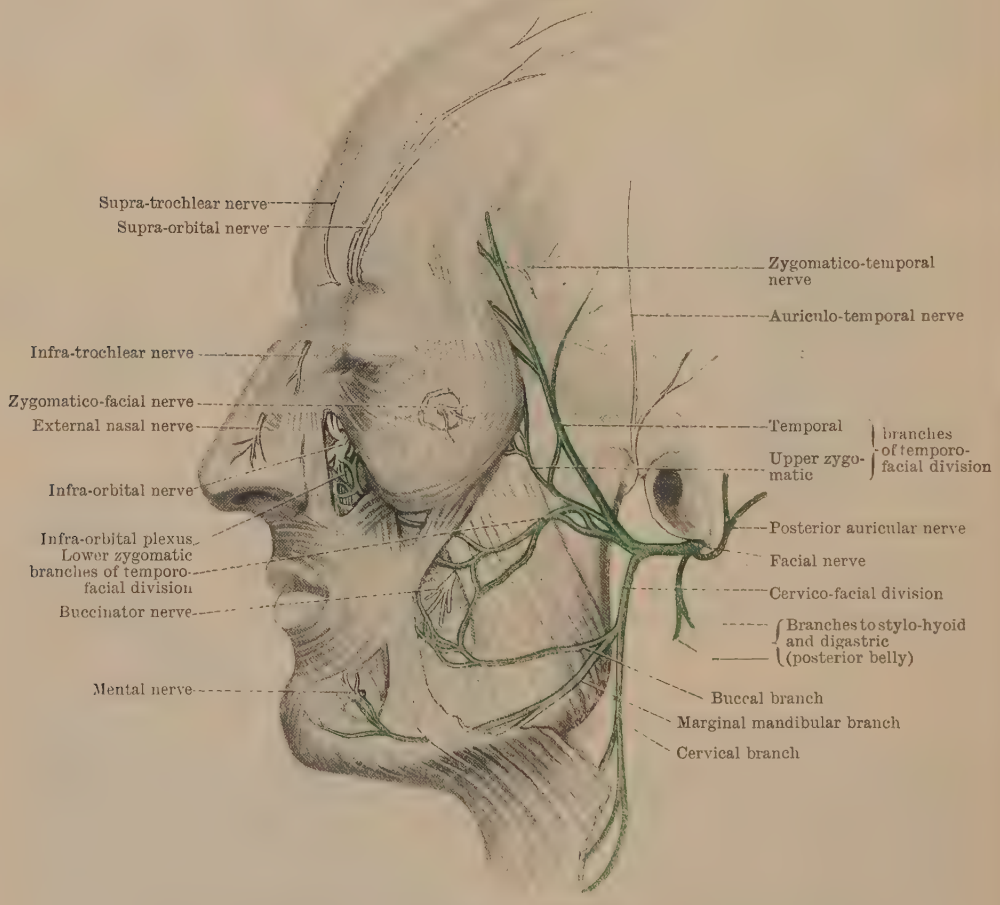

Fig. 586.—The Distribution of the Trigeminal and Facial Nerves on the Face.

tympanico) pierces the temporal bone and joins the tympanic branch of the glosso-pharyngeal in the substance of the bone. By their union the **lesser superficial petrosal nerve** is formed, which pierces the temporal bone and ends in the otic ganglion. (3) The **external superficial petrosal nerve** is a minute inconstant branch which joins the sympathetic plexus on the middle meningeal artery.

In the course of the facial nerve in the lower part of the canalis facialis, behind the tympanum, three branches arise: (1) **N. Stapedius.**—The small nerve to the **stapedius muscle**, which passes forwards to the tympanum. (2) **Chorda Tympani.**—The **chorda tympani nerve** (associated with the nervus intermedius; see note on p. 695), which enters the tympanic cavity through the *tympanic aperture of the canaliculus chordæ*, passes over the membrana tympani and the handle of the malleus, and leaves the cavity through the *medial end of the petro-tympanic*

fissure to reach the infra-temporal fossa. Medial to the external pterygoid muscle, after receiving a fine communication from the otic ganglion, it becomes incorporated with the lingual branch of the mandibular nerve, and in its further course is inseparable from that nerve. It supplies a root to the submaxillary ganglion, and is finally distributed to the side and dorsum of the tongue in its anterior two-thirds. It largely consists of sensory (taste) fibres derived from the genicular ganglion, but also contains some secretory ones which enter the submaxillary ganglion and thence supply the submaxillary and sublingual glands. (3) Before it leaves the canalis facialis a fine **communicating branch** arises from the facial nerve to join the auricular branch of the vagus nerve.

(iii.) *In the neck* the facial nerve gives off three muscular branches: (1) and (2) **Ramus Stylohyoideus, Ramus Digastricus.** — Small branches, frequently arising together, supply the **stylo-hyoid** and the posterior belly of the **digastric**, the latter nerve sometimes communicating with the glossopharyngeal. (3) **N. Auricularis Posterior.**—The **posterior auricular nerve** bends backwards and upwards over the anterior border of the mastoid process along with the posterior auricular artery. It divides into two branches—an *auricular branch* for the posterior auricular muscle and the intrinsic muscles of the auricle, and an *occipital branch* for the occipital belly of the epicranius muscle. The posterior auricular nerve, in its course, communicates with the great auricular, lesser occipital, and auricular branch of the vagus nerves.

(iv.) *In the parotid gland* the facial nerve spreads out in an irregular series of branches (**plexus parotideus** or *pes anserinus*), indefinitely divided into an upper temporo-facial and a lower cervico-facial division. Communications occur in the substance of the gland between the main trunks and the great auricular and auriculo-temporal nerves.

The **temporo-facial division** gives off two series of subordinate branches which radiate forwards and upwards from the parotid gland.

1. **Rami Temporales.**—The **temporal branches** are of large size, and, sweeping out of the parotid gland over the zygomatic arch, are distributed to the orbicularis oculi, frontalis, corrugator supercilii, auriculares anterior and superior. The temporal branches communicate in their course with the auriculo-temporal, zygomatico-temporal, lacrimal, and supra-orbital branches of the trigeminal nerve.

2. **Rami Zygomatici.**—The **upper zygomatic branches** are small, and sometimes are inseparable from the temporal or lower zygomatic nerves. Extending forwards across the zygomatic bone, they supply the orbicularis oculi and zygomatic muscles, and communicate with the zygomatico-facial branch of the maxillary nerve.

The lower **zygomatic branches** are of considerable size. Passing forwards over the masseter muscle in company with the parotid duct, they supply the orbicularis oculi, the zygomaticus, buccinator, and the muscles of the nose and upper lip. The **infra-orbital plexus** is formed by the union of these nerves with the infra-orbital branch of the maxillary nerve below the lower eyelid. Smaller communications occur with the infra-trochlear and nasal nerves on the side of the nose.

The **cervico-facial division** of the facial nerve supplies three series of secondary branches.

1. **Rami Buccales.**—The **buccal branch** (or branches) extends forwards to the angle of the mouth to supply the muscles converging to the mouth, including the buccinator. It communicates with the buccinator branch of the mandibular nerve in front of the anterior border of the masseter muscle.

2. **Ramus Marginalis Mandibulæ.**—The **marginal branch of the mandible** passes along the mandible to the interval between the lower lip and chin, and supplies the triangularis oris, quadratus labii inferioris, and orbicularis oris. It communicates with the mental branch of the inferior alveolar nerve.

3. **Ramus Colli.**—The **cervical branch** emerges from the parotid gland near its lower end, and sweeps forwards, below the angle of the mandible, to the front of the neck. It supplies the platysma, and forms loops of communication with the nervus cutaneus colli.

Though the facial nerve is commonly described as above, as a mixed nerve, the sensory or intermediate part can be considered, on the basis of its origin and distribution, as well as on the

really mixed nature of its fibres, as a separate nerve, the **glossopalatine**. Under this term are included the so-called sensory root of the facial, the pars intermedia, genicular ganglion, chorda tympani, and part of the greater superficial petrosal nerve. Its central connexions and peripheral distribution resemble those of the glossopharyngeal nerve, and suggest its being considered as an aberrant part of the latter.

Nervus Acusticus.

The **eighth** or **acoustic nerve** (O.T. **auditory**) consists of two functionally entirely different parts, the vestibular nerve, concerned with equilibration, and the cochlear nerve, the true nerve of hearing; they differ also in their peripheral endings and central connexions.

The combined trunk arises from the brain by two roots, medial and lateral. The **medial, vestibular root** emerges between the olive and the restiform body. The **lateral, cochlear root**, continuous through the cochlear nucleus with the striæ medullares of the fourth ventricle, winds round the lateral side of the restiform body (for the deep connexions, see p. 602). The two roots unite with one another

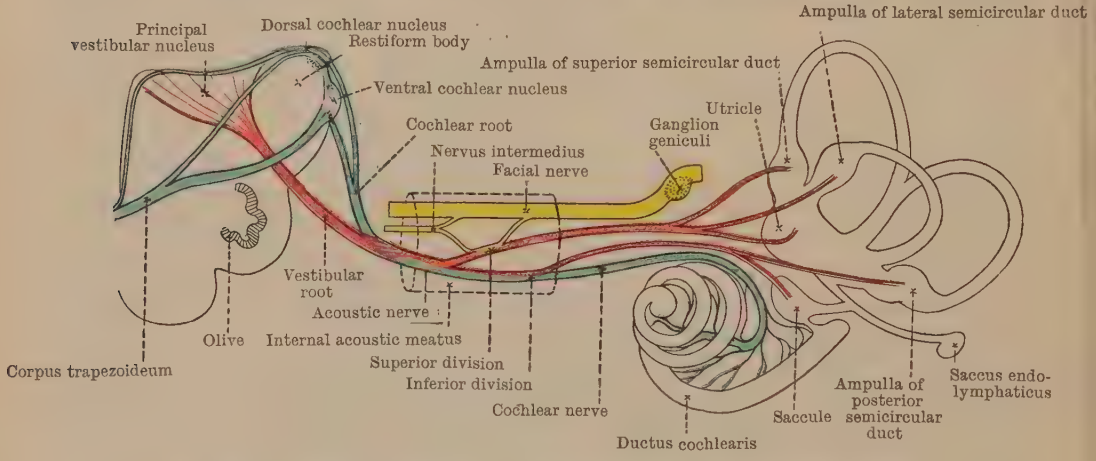

Fig. 587.—Scheme of the Origin and Distribution of the Acoustic Nerve.

to form the trunk of the acoustic nerve, which is attached to the brain on the lateral side of the facial nerve and nervus intermedius, at the lower border of the pons (Fig. 569, p. 676).

The nerve passes laterally through the internal acoustic meatus, lying below the facial nerve and nervus intermedius (Fig. 573, p. 680). In the meatus the trunk separates into two divisions, an upper consisting of vestibular fibres only, and a lower which consists mainly of cochlear fibres but contains also some vestibular fibres. The divisions subdivide, and their branches pass through the lamina cribrosa, to supply the several parts of the labyrinth.

The **superior division** in the internal acoustic meatus usually receives fibres from the nervus intermedius, and gives off a communicating branch to the genicular ganglion of the facial nerve. It then separates into three terminal branches which pierce the lamina cribrosa. (1) **N. Utricularis.**—The **utricular nerve** supplies the macula acustica of the **utricle.** (2) and (3) **Nn. Ampullaris Superior et Lateralis.**—The **superior** and **lateral ampullary nerves** supply the ampullæ of the **superior** and **lateral semicircular ducts.**

The **inferior division** gives off (1) **n. saccularis,** a **saccular nerve** to the macula acustica of the **saccule,** (2) **n. ampullaris inferior,** an **inferior ampullary nerve** to the ampulla of the **posterior semicircular duct,** and (3) is continued through the lamina cribrosa to the labyrinth as the **cochlear nerve**, which is distributed through the modiolus and osseous spiral lamina to the organ of Corti in the cochlea.

Both the vestibular and cochlear nerves contain among their fibres collections of bipolar nerve cells, forming in each nerve a distinct ganglion—the **vestibular ganglion** on the vestibular trunk at the bottom of the internal acoustic meatus, and the **spiral ganglion of the cochlea** on the cochlear trunk within the modiolus.

Nervus Glossopharyngeus.

The **ninth** or **glossopharyngeal nerve** is a mixed nerve, consisting of a smaller motor element which supplies the stylopharyngeus, and a larger sensory part which supplies the pharynx and tongue. It arises from the brain by five or six fine fila radicularia (radicles) which emerge from the medulla oblongata, between the posterior and lateral columns, close to the facial nerve above, and in series with the fila of the vagus nerve below (Fig. 569, p. 676; for the deep connexions, see p. 595). The fila combine to form a nerve which passes through the jugular foramen, along with the vagus and accessory nerves, but separated from them by the inferior petrosal sinus and enveloped in a separate sheath of dura mater (Fig. 573, p. 680). Reaching the neck, the nerve arches downwards and forwards to the interval between the hyoid bone and the mandible. In its course to the side of the pharynx it lies at first between the internal carotid artery and the internal jugular vein, and then lower down between the internal and external carotid arteries. Passing medial to the styloid process, it sweeps round the lower border of, and then crosses, the stylopharyngeus muscle and the stylo-hyoid ligament, and disappears medial to the hyoglossus muscle, to reach its termination in the tongue (Fig. 588).

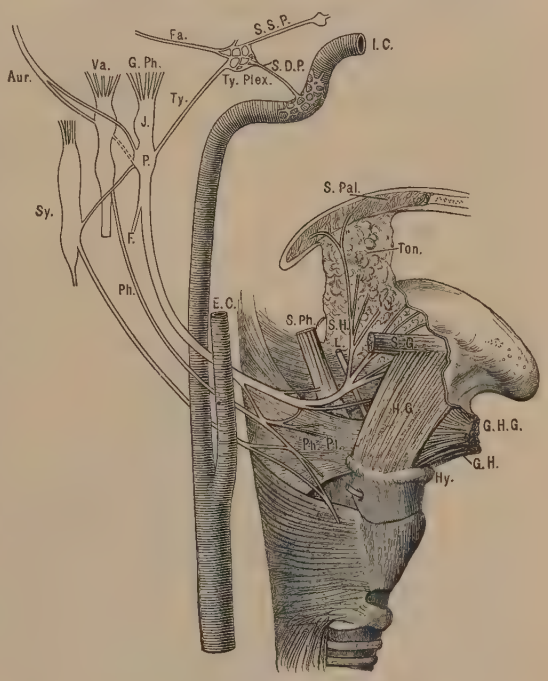

Fig. 588.—Scheme of the Distribution of the Glossopharyngeal Nerve.

Pal., Soft palate; G.H.G., Genioglossus; G.H., Genio-hyoid; Hy., Hyoid bone.

The **branches** of the nerve may be classified in three series according to their origin—(i.) in the jugular foramen; (ii.) in the neck; (iii.) in relation to the tongue.

In the jugular foramen there are two enlargements upon the trunk of the nerve—the superior and petrous ganglia. The **superior ganglion** is small, does not implicate the whole width of the nerve, and may be fused with the petrous ganglion, or even absent altogether. No branches arise from it.

Ganglion Petrosum. — The **petrous** or **inferior ganglion** is distinct and constant. It is placed upon the nerve at the lower part of its course through the jugular foramen.

Branches and Communications of the Petrous Ganglion.—N. Tympanicus.—The **tympanic branch** is the most important offset from this ganglion. It passes through a small canal in the bridge of bone between the jugular foramen and the carotid canal to reach the cavity of the tympanum, where it breaks up into branches, to form, along with the carotico-tympanic branches from the carotid plexus of the sympathetic on the internal carotid artery (*nn. caroticotympanici superior et inferior*, O.T. *small deep petrosal*), and a twig from the genicular ganglion of the facial nerve, the **tympanic plexus**. This plexus lies on the promontory of the medial wall of the middle ear, and supplies the mucous lining

of the tympanum, mastoid cells, and auditory tube (Fig. 585, p. 693). The fibres of the tympanic branch of the glossopharyngeal nerve become reunited to form, by their union with a small nerve from the genicular ganglion of the facial nerve (*anastomotic with the tympanic plexus*), the **lesser superficial petrosal nerve** in the substance of the temporal bone. This passes forwards through the temporal bone, and eventually joins the otic ganglion.

Besides forming the tympanic branch, the petrous ganglion of the glossopharyngeal nerve communicates with three other nerves—(1) with the superior cervical ganglion of the sympathetic ; (2) with the auricular branch and sometimes with the jugular ganglion of the vagus ; and (3) sometimes with the facial nerve.

In the neck the glossopharyngeal nerve gives off two groups of branches : (1) As it crosses over the **stylopharyngeus muscle** it supplies the nerve to that muscle, fibres of which pierce the muscle to reach the mucous membrane of the pharynx. (2) The **pharyngeal branches** of the nerve supply the mucous membrane of the pharynx directly after piercing the superior constrictor muscle, and indirectly after joining, along with the pharyngeal offsets from the vagus and the superior cervical ganglion of the sympathetic, in the formation of the **pharyngeal plexus** (Fig. 589).

The **terminal branches** of the nerve supply the mucous membrane of the tongue and adjacent parts. A **tonsillar branch** forms a plexus to supply the mucous membrane covering the palatine tonsil, the adjacent part of the soft palate, and the palatine arches. **Lingual branches** supply the mucous membrane and vallate papillæ of the dorsal third and lateral half of the tongue, extending backwards to the glosso-epiglottic folds and the front of the epiglottis.

Nervus Vagus.

The **tenth** or **vagus nerve** is a mixed nerve, and is the most widely distributed of the cerebral nerves, passing through the neck and thorax to reach the abdomen. It supplies sensory fibres chiefly to the pharynx, œsophagus, stomach, larynx, trachea, and lungs ; motor fibres to the unstriped musculature of the same series of organs, as well as to most of the voluntary muscles of the soft palate, pharynx, and larynx ; and special fibres to the heart and abdominal viscera. Each nerve is connected with the seventh, ninth, eleventh, and twelfth cranial nerves (the cerebral part of the eleventh contributing most of the motor fibres of the vagus) with the first and second cervical spinal nerves, and with the sympathetic system.

It arises from the brain by numerous fila radicularia attached to the floor of the postero-lateral sulcus of the medulla oblongata, in series with the glossopharyngeal nerve above and the accessory nerve below it (for the deep connexions, see p. 594). The fila of the nerve unite to form a single trunk which emerges into the neck through the jugular foramen.

In the jugular foramen the nerve occupies the same sheath of dura mater as the accessory nerve, it is placed behind the glossopharyngeal nerve, and a small ganglion—the **jugular ganglion**—is developed upon it.

In the neck the vagus nerve pursues a vertical course in front of the vertebral column. It occupies the carotid sheath, lying between and behind the internal and common carotid arteries and the internal jugular vein. It enters the thorax behind the large veins : *on the right side,* after crossing over the first part of the subclavian artery ; *on the left side,* in the interval between the left common carotid and subclavian arteries. In the upper part of the neck, immediately below the jugular foramen, a second and larger ganglion—the **ganglion nodosum**—is developed on the trunk of the nerve.

In the thorax the nerves occupy the superior and posterior mediastinal spaces, and their relations are different on the two sides. (*a*) *In the superior mediastinum* the *right nerve* continues its course alongside the innominate artery and the trachea, and behind the right innominate vein and superior vena cava, to the posterior surface of the root of the lung. The *left nerve* courses downwards between the left common carotid and subclavian arteries, and behind the left innominate vein

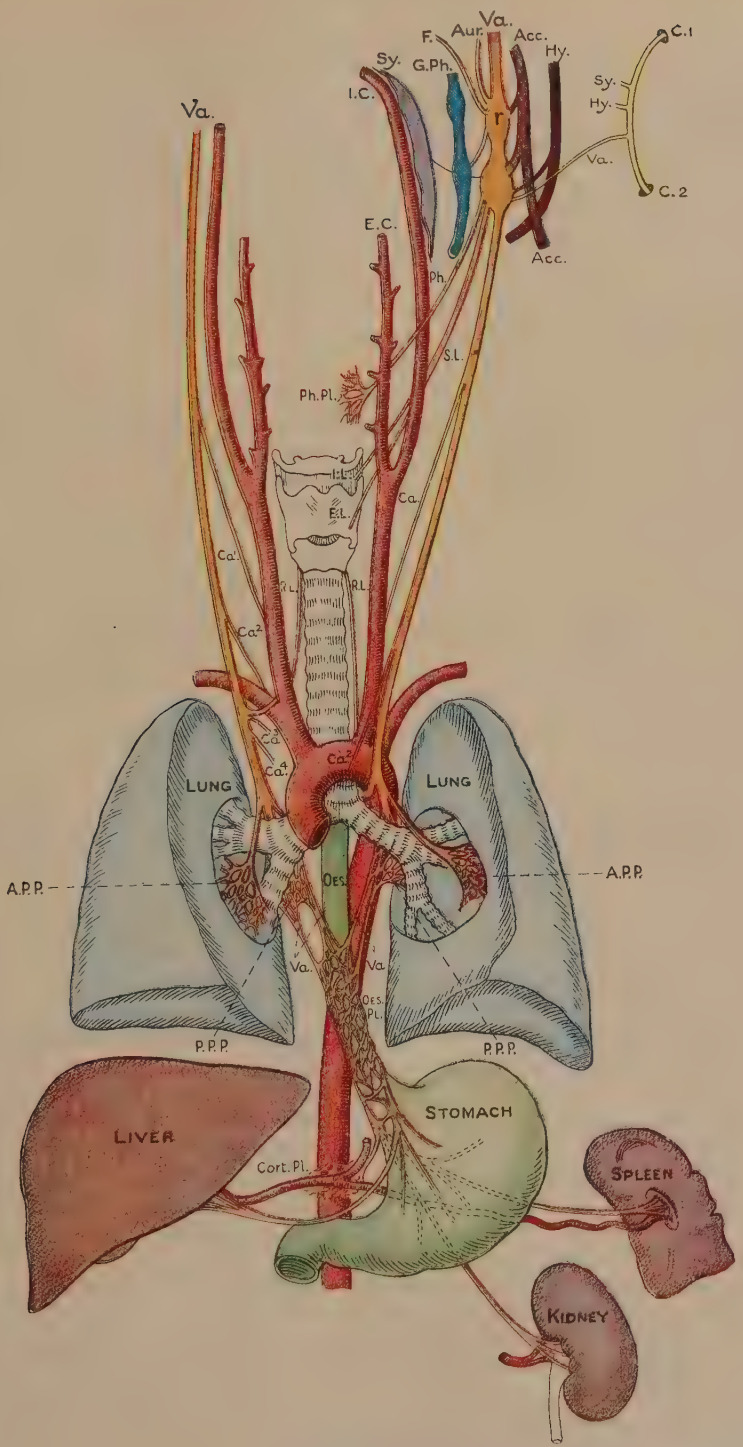

FIG. 589.—THE DISTRIBUTION OF THE VAGUS NERVE.

and the phrenic nerve. It passes over the aortic arch, and then proceeds to the posterior surface of the root of the left lung. (*b*) *In the posterior mediastinum* the vagi nerves are concerned in the formation of two great plexuses—the pulmonary and the œsophageal. Behind the root of each lung both nerves break up to form the large **posterior pulmonary plexus**, from the lower end of which two nerves emerge on each side. These nerves on the right side pass obliquely over the vena azygos; on the left side they cross the descending thoracic aorta. Both series reach the œsophagus, and divide into small anastomosing branches which form the **œsophageal plexus**. At the œsophageal opening of the diaphragm two single nerves become separated from the plexus, and entering the abdomen—the left nerve in front of the œsophagus, the right nerve behind it—they terminate by supplying the stomach and other abdominal organs.

The **communications** and **branches** of the vagus nerve may be described as (i.) ganglionic, (ii.) cervical, (iii.) thoracic, and (iv.) abdominal (Fig. 589).

Ganglion Jugulare.—The **jugular ganglion** (O.T. **ganglion of the root**) is small and spherical. It occupies the jugular foramen, and gives off two branches—meningeal and auricular.

The **meningeal branch** passes backwards to supply the dura mater of the posterior fossa of the skull.

The **auricular branch** (O.T. **nerve of Arnold**) ascends to the ear through the mastoid canaliculus on the lateral aspect of the jugular fossa. It receives near its origin a twig from the tympanic branch of the glossopharyngeal nerve, and, as it traverses the temporal bone, usually communicates with the facial nerve by a branch arising from the latter in the canalis facialis. The nerve escapes through the tympano-mastoid fissure and is distributed to the back of the auricle and the external acoustic meatus, and communicates superficially with the posterior auricular nerve.

Communications.—Besides supplying the meningeal and auricular branches, this ganglion receives communications from (1) the superior cervical ganglion of the sympathetic; (2) the accessory nerve; and (3) (sometimes) the petrous ganglion of the glossopharyngeal nerve (*ramus anastomoticus cum nervo glossopharyngeo*).

Ganglion Nodosum.—The **ganglion nodosum**, placed immediately below the preceding, is large and fusiform. Like the jugular ganglion, it supplies two branches—the pharyngeal and superior laryngeal nerves.

The **pharyngeal branch** (usually double) receives its motor fibres (through the ganglion) from the accessory nerve. It passes obliquely downwards and medially to the pharynx between the internal and external carotid arteries, and combines with the pharyngeal branches from the glossopharyngeal and superior cervical ganglion of the sympathetic to form the **pharyngeal plexus**, which lies on the wall of the pharynx at the level of the middle constrictor (Fig. 589, p. 699). From this plexus the muscles of the pharynx and soft palate (except the stylopharyngeus and tensor veli palatini) are supplied. The **lingual branch** is a minute nerve which separates itself from the plexus and joins the hypoglossal nerve in the anterior triangle of the neck.

The **superior laryngeal nerve**, which likewise receives its motor fibres from the accessory nerve, passes obliquely downwards and medially, medial to the external and internal carotid arteries, towards the thyreoid cartilage. It is joined by twigs from the sympathetic and the pharyngeal plexus, and is said to give a filament to the internal carotid artery. It ends by dividing in its course into two unequal parts—a larger internal and a smaller external laryngeal branch.

The **internal laryngeal branch** passes medially into the larynx between the middle and inferior constrictor muscles of the pharynx and through the thyreo-hyoid membrane, in company with the corresponding branch of the superior laryngeal artery. It supplies the mucous membrane of the larynx, reaching upwards to the epiglottis and base of the tongue, and forms communications beneath the lamina of the thyreoid cartilage with the branches of the inferior laryngeal nerve (*ramus anastomoticus cum nervo laryngeo inferiore*).

The **external laryngeal branch** passes downwards beneath the infra-hyoid muscles

and upon the inferior constrictor muscle of the pharynx. It supplies branches to that muscle, and ends in the crico-thyreoid muscle.

Communications.—Besides supplying these pharyngeal and laryngeal nerves, this ganglion has the following communications with other nerves: (1) with the superior cervical ganglion of the sympathetic; (2) with the hypoglossal; (3) with the loop between the first and second cervical nerves; and (4) with the accessory nerve. This nerve applies itself to the ganglion, and thereby supplies to the vagus nerve the inhibitory fibres for the heart, as well as the motor fibres for the pharynx, œsophagus, stomach and intestines, larynx and respiratory organs.

Branches of the Vagus in the Neck. — In the neck the vagus nerve supplies cardiac branches and (on the right side) the recurrent (laryngeal) nerve (Fig. 589).

The **superior** or **cervical cardiac branches** are **upper** and **lower.** *On the right side* both cardiac branches pass downwards into the thorax behind the subclavian artery, and proceed alongside the trachea to join the deep cardiac plexus. *On the left side* the two nerves separate on reaching the thorax. The *upper nerve* passes deeply alongside the trachea to join the deep cardiac plexus. The *lower nerve* accompanies the vagus nerve over the aortic arch, along with the superior cervical cardiac branch of the sympathetic, to end in the superficial cardiac plexus.

The **right recurrent (laryngeal) nerve** arises at the root of the neck, as the vagus crosses in front of the first part of the subclavian artery. It hooks round the artery, and passes obliquely upwards and medially behind the subclavian and the common carotid, and either in front or behind the inferior thyreoid artery; it then ascends in the groove between the œsophagus and trachea, along the medial side of the corresponding lobe of the thyreoid gland. It finally disappears beneath the inferior border of the inferior constrictor muscle, and, receiving the name of **inferior laryngeal nerve,** it ends in supplying the muscles of the larynx. In its course it gives off the following branches:—

(1) **Cardiac branches** arise as the nerve winds round the subclavian artery, and course downwards alongside the trachea to end in the deep cardiac plexus. These branches are grouped below with the rami cardiaci inferiores.

(2) **Communicating branches** to the inferior cervical ganglion of the sympathetic arise from the nerve behind the subclavian artery.

(3) **Muscular branches** supply the trachea, œsophagus, and the inferior constrictor of the pharynx.

(4) **Terminal branches** supply the muscles of the larynx (except the crico-thyreoid) and communicate beneath the lamina of the thyreoid cartilage with branches of the internal laryngeal nerve.

Branches of the Vagus in the Thorax.—In the thorax the vagi form the great pulmonary and œsophageal plexuses. The right nerve, in addition, furnishes cardiac branches; and the left nerve gives off the recurrent (laryngeal) nerve.

The **left recurrent (laryngeal) nerve** differs from the nerve of the right side mainly in its point of origin and in the early part of its course. It springs from the vagus as it crosses the aortic arch, and, after hooking round the arch, lateral to the *ligamentum arteriosum,* it passes upwards in the superior mediastinum to the neck, where its course and relations are similar to those of the nerve of the right side. The branches of the nerve are the same as those of the right nerve. The **cardiac branches** are larger, and, arising below the aortic arch, proceed to the deep cardiac plexus.

The **inferior cardiac** or thoracic branches on the right side are derived both from the trunk of the vagus as it lies beside the trachea and from its recurrent branch; on the left side they arise only from its recurrent branch. All join the deep cardiac plexus.

Branches of the Vagus in the Abdomen.—After the formation of the œsophageal plexus the two vagi nerves resume their course, and passing along with the gullet through the diaphragm, terminate by supplying the stomach. The *right nerve* enters the abdominal cavity behind the gullet, and is distributed to the posterior surface of the stomach. It sends communicating offsets to the

cœliac, splenic, and renal plexuses of the sympathetic system. The *left nerve* applies itself to the anterior surface and small curvature of the stomach, to which it is distributed. It sends communicating offsets along the small curvature of the stomach to the right vagus, and between the layers of the gastro-hepatic ligament to the hepatic plexus.

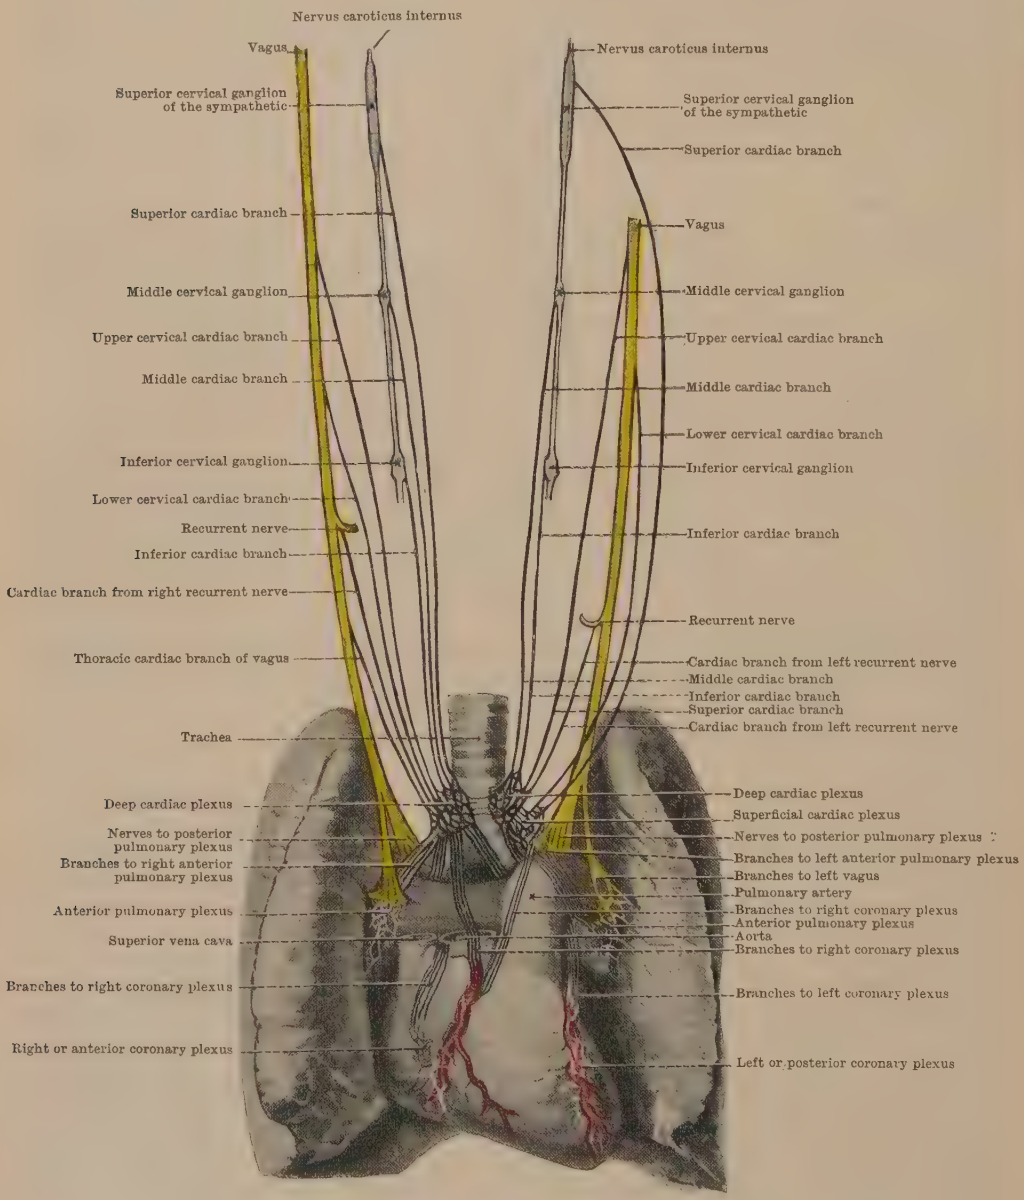

FIG. 590.—THE CARDIAC BRANCHES OF THE VAGUS, AND THE PULMONARY PLEXUSES.

Certain **asymmetrical features** of the two vagus nerves are explained by a reference to the process of development. The recurrent course of the inferior laryngeal nerves is explained by the absence of neck in the early embryo, and by the primitive aortic arches between which they passed having occupied a higher position before the heart descended into the thorax, when it dragged these branches of the nerves down with it. The corresponding arches (the fourth pair), beneath which they originally passed, develop into the subclavian artery on the right side, the aorta on the left (see Fig. 598, p. 699). The distribution of the right vagus to the posterior surface of the stomach and the left nerve to the anterior aspect is explained by the turning over on its right side of this originally symmetrically situated organ.

Plexus Thoracales.

Of the plexuses formed by the vagus nerves in the thorax—cardiac, pulmonary, and œsophageal—the **cardiac plexuses** are described under the sympathetic system, on p. 787.

Pulmonary Plexuses.—As already stated, the vagus nerve on each side, on reaching the back of the root of the lung, breaks up into numerous plexiform branches for the formation of the posterior pulmonary plexus. From each nerve a few fibres pass to the front of the root of the lung, above its upper border, to form the much smaller anterior pulmonary plexus. These plexuses communicate freely with each other, and are intimately connected with the cardiac plexuses.

The **anterior pulmonary plexus** on each side is joined by a few fibres from the corresponding part of the deep cardiac plexus, and on the left side from the superficial cardiac plexus as well. It surrounds and supplies the constituents of the root of the lung anteriorly.

The **posterior pulmonary plexus,** placed behind the root of the lung, is formed by the greater part of the vagus nerve, reinforced by fine branches from the second, third, and fourth thoracic ganglia of the sympathetic. Numerous branches proceed from it in a plexiform manner along the bronchi and vessels into the substance of the lung.

The Œsophageal Plexus.—The œsophagus in the thorax is supplied by the vagus nerve both in the superior and posterior mediastina. *In the superior mediastinum* it receives branches from the vagus nerve on the right side, and from its recurrent branch on the left side.

In the posterior mediastinum the gullet is surrounded by the œsophageal plexus, formed from the trunks of the vagi nerves emerging from the posterior pulmonary plexuses, which form a large plexus surrounding the gullet. This part of the œsophagus also receives fibres from the greater splanchnic nerve and ganglion. From the œsophageal plexus branches supply the muscular wall and mucous membrane of the œsophagus.

Pericardiac branches are also supplied from the plexus to the posterior surface of the pericardium.

Nervus Accessorius.

The **eleventh** or **accessory nerve** (O.T. **spinal accessory**) consists of two essentially separate parts, different both in origin and in distribution. One, the cerebral or bulbar portion, is **accessory to the vagus nerve,** and arises, in series with the fila of that nerve, from the side of the medulla oblongata; its fibres are contributed to the pharyngeal, laryngeal, and cardiac branches of that nerve. The other, the **spinal portion,** arises from the lateral aspect of the spinal medulla, between the anterior and posterior roots of the spinal nerves, its origin extending from the level of the accessory portion as low as the origin of the fifth or sixth cervical nerve (for the deep origin, see p. 593). This portion of the nerve supplies the sterno-mastoid and trapezius muscles. Successively joining together, the fila form a trunk which ascends in the subdural space of the spinal medulla, posterior to the ligamentum denticulatum, to the foramen magnum. There the two portions unite into a single trunk, which leaves the cranial cavity through the jugular foramen in the same compartment of dura mater as the vagus nerve (Fig. 573, p. 680).

Ramus Internus.—In the jugular foramen the **accessory portion of the nerve** or **internal ramus** (after furnishing a small branch to the jugular ganglion of the vagus) applies itself to the ganglion nodosum, and in part joins the ganglion, in part the trunk of the nerve beyond the ganglion. Its fibres are distributed mainly to the pharyngeal and superior laryngeal branches of the vagus; some probably enter the cardiac branches as well and convey cardio-inhibitory impulses, though there are conflicting views as to this distribution.

Ramus Externus.—The **spinal portion** of the nerve, or **external ramus,** extends

into the neck, where at first it lies along with other nerves, in the interval between the internal carotid artery and the internal jugular vein. Passing obliquely downwards and laterally over (sometimes under) the vein, under cover of the posterior belly of the digastric, it descends close beneath the sterno-mastoid muscle, which it supplies as it pierces it on its deep surface. It appears at the posterior border of the muscle, at or below the junction of the upper and middle thirds, and about the level of the upper border of the thyreoid cartilage. After crossing the posterior triangle obliquely downwards the nerve ends by supplying the trapezius muscle on its deep surface. This portion of the nerve *communicates* in three situations with nerves from the cervical plexus—(1) in or beneath the sterno-mastoid, with the branch for the muscle derived from the second cervical nerve; (2) in the posterior triangle, with branches from the third and fourth cervical nerves; (3) beneath the trapezius, with the branches for the muscle derived from the third and fourth cervical nerves.

NERVUS HYPOGLOSSUS.

The **twelfth** or **hypoglossal nerve** is a purely motor nerve, supplying all the muscles of the tongue both intrinsic and extrinsic. It arises by numerous fila radicularia from the front of the medulla oblongata between the pyramid and the olive (Fig. 569, p. 676; for the deep origin, see p. 593). The fila arrange themselves in two bundles which separately pierce the dura mater, and unite in the hypoglossal canal, or after emerging from the skull. In the neck the nerve arches downwards and forwards towards the hyoid bone, and then turns medially among the supra-hyoid muscles to the tongue. At first it is placed deeply, along with other cerebral nerves, on the medial side of the internal jugular vein and internal carotid artery; it then curves forwards round the ganglion nodosum of the vagus, and passes downwards between the above two vessels, lying medial to the digastric and stylo-hyoid muscles. It then crosses the external carotid artery, hooking round the occipital artery, and passes forwards beneath the tendon of the digastric muscle just above the hyoid bone. Above the greater cornu of the hyoid bone the nerve conceals the lingual artery; and it then disappears between the mylo-hyoid and hyoglossus muscles to reach the tongue, in the muscular substance of which it terminates (Fig. 583, p. 690).

Communications.—In its course the hypoglossal nerve has the following communications with other nerves: Near the base of the skull it is connected by small branches with (1) the superior cervical ganglion of the sympathetic; (2) the ganglion nodosum of the vagus; (3) by a larger branch, with the loop between the first two cervical nerves; (4) as it crosses the external carotid artery it receives a communication from the pharyngeal plexus (*lingual branch of the vagus*); and (5) medial to the mylo-hyoid muscle, at the anterior border of the hyoglossus, it forms loops of communication with the lingual branch of the mandibular nerve.

The **branches** of the nerve are: (1) Recurrent; (2) Descending; (3) Thyreo-hyoid; and (4) Lingual.

The **recurrent (meningeal) branch** passes from the nerve near its origin to

supply the dura mater of the posterior fossa of the base of the skull. It probably derives its fibres from the communication with the first and second cervical nerves.

The **descending branch of the hypoglossal nerve** is the chief branch given off in the neck. It arises from the hypoglossal nerve as it crosses the internal carotid artery, and descends in the anterior triangle superficial to the carotid sheath. It is joined about the middle of the neck by the **descending cervical nerve** (from the second and third cervical nerves). By their union the **ansa hypoglossi (hypoglossal loop)** is formed, from which branches are distributed to

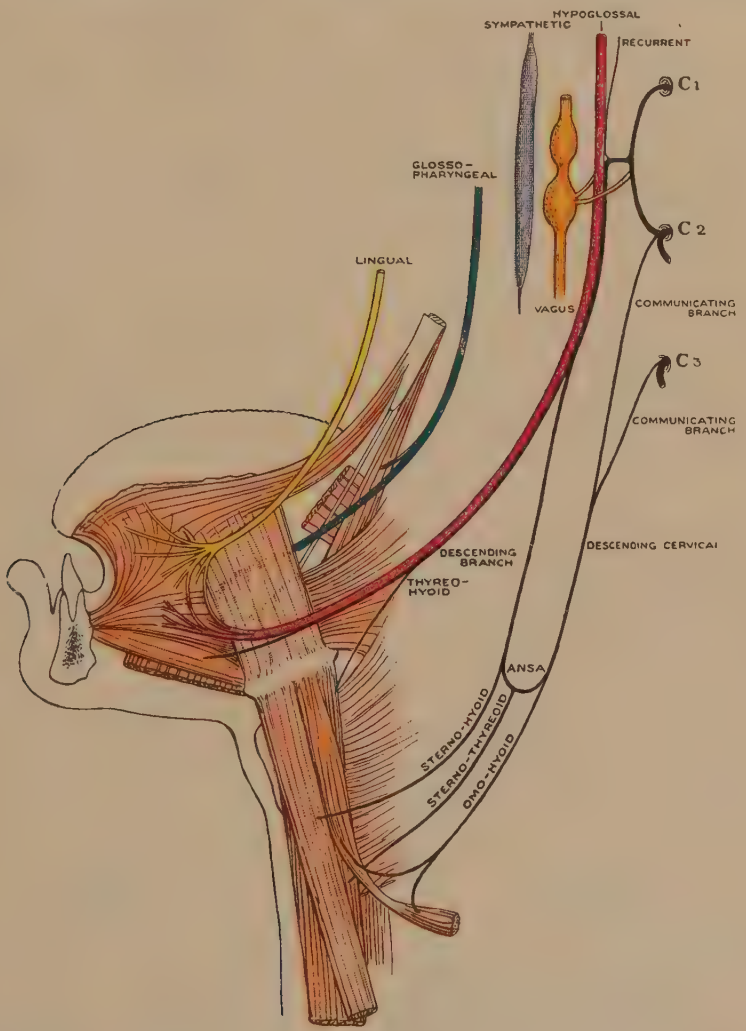

FIG. 592.—THE MUSCLES OF THE HYOID BONE AND STYLOID PROCESS, AND THE EXTRINSIC MUSCLES OF THE TONGUE, WITH THEIR NERVES.

the majority of the infra-hyoid muscles—both bellies of the omo-hyoid, the sterno-hyoid, and the sterno-thyreoid. The descending branch of the hypoglossal nerve derives its fibres from the communication to the hypoglossal nerve from the loop between the first and second cervical nerves; so that the ansa hypoglossi is made up of fibres of the first three cervical nerves.

The **nerve to the thyreo-hyoid muscle** is a small branch which arises from the hypoglossal nerve before it passes medial to the mylo-hyoid muscle. It descends behind the greater cornu of the hyoid bone to reach the muscle. When traced backwards this nerve is found associated with the loop between the first and second cervical nerves.

The **lingual branches** of the hypoglossal nerve are distributed to the

hyoglossus, genio-hyoid, and genioglossus, and to all the intrinsic muscles of the tongue. The nerve to the genio-hyoid is said to be derived from the loop between the first and second cervical nerves. It is not known if these two cervical nerves are implicated in the innervation of the proper muscles of the tongue, but it appears certain that the muscles named—the genio-hyoid, thyreo-hyoid, sterno-hyoid, omo-hyoid, and sterno-thyreoid—are not supplied by the hypoglossal, but only by cervical nerves, the genio-hyoid and thyreo-hyoid by the first two, the other muscles by the first three cervical nerves.

COMPONENT FIBRES OF THE CEREBRAL NERVES.

The third, fourth, sixth, eleventh, and twelfth pairs are composed of large and small myelinated fibres; non-myelinated fibres have been found present in the fifth, sixth, ninth, eleventh, and twelfth, of which those in the sixth, eleventh, and twelfth are probably all derived from the sympathetic system (Koch). As regards the function of the fibres, although the cerebral nerves are usually broadly classified as motor and sensory, as well as mixed nerves, it is now recognised that few of them consist exclusively of one or the other order of fibres. The optic nerve itself is described as containing efferent fibres which may control the movements of the retinal elements in response to light. The third, fourth, and sixth nerves are not purely motor in function, as was formerly considered, but contain also some sensory (somatic afferent, proprioceptive) fibres, as well as fibres from the sympathetic system, and the same may prove true for the motor eleventh and twelfth nerves. Indeed the cerebral nerves vary greatly in their functional composition, and, moreover, no nerve, save the olfactory and auditory, is made up of one functional order of fibres.

The animal body is naturally divided into two different areas or regions, the **somatic** area, forming the body wall and limbs, and the **splanchnic** or visceral area, comprising the chief viscera contained within the body cavity. In the head and neck an additional factor has to be considered owing to the presence of the branchial system and its derivatives, for in connexion with this system there have been developed not only an additional set of visceral muscles, requiring motor innervation (*e.g.*, the muscles of mastication, and of the face, palate, and

pharynx), but also visceral sense organs (taste buds). In a regional classification of the nerves on these lines those that supply the derivatives of the branchial system may be termed *special* in contrast with the *general* nerves supplying the rest of the visceral area; similarly in the somatic area the introduction of the ear as a specialised sensory area results in the presence of a special set of somatic afferent fibres. Combining the regional distribution with the function of the fibres, motor or *efferent* and sensory or *afferent*, the nerve fibres may be tabulated as follows (after Herrick):—

Sensory: General somatic afferent (sensory from the skin).
Special somatic afferent (the cochlear and vestibular nerves).
General splanchnic afferent (from the visceral mucous membrane).
Special splanchnic afferent (from organs of taste).
Motor: General splanchnic efferent (to the involuntary musculature).
Special splanchnic efferent (to the branchial muscles).
General somatic efferent (to the skeletal muscles).

It is worthy of note that such a classification serves rightly to emphasise the central connexion, practical continuity, and function of the peripheral nervous system as a whole, since many of the fibre paths designated under this nomenclature traverse both the usually demarked cerebro-spinal and sympathetic systems in reaching their destinations.

On such a basis the **functional composition** of the cerebral nerves is shown in the preceding table.

DEVELOPMENT AND MORPHOLOGY OF THE CEREBRAL NERVES.

In the early human embryo, when the neural plate is folded in to form the neural tube, the cells forming its lateral margins are left as a **neural crest** or ganglion ridge, lying above the tube and connecting it with the surface ectoderm. From the cells of this crest there are developed not only all of the cerebro-spinal and sympathetic ganglia, together with the chromaffin bodies, but all of the *sensory* fibres of the cerebro-spinal system (except those of the first and second cerebral nerves and a few fibres in connexion with the seventh, ninth, and tenth nerves to be mentioned later), whilst from the walls of the **neural tube** all of the *motor* fibres arise.

At a later stage the lateral walls of the neural tube become differentiated into three layers, the **ependymal, mantle**, and **marginal zones**; and the neural canal is somewhat rhomboidal in transverse section, its lateral angles marking the subdivision of the walls into a dorsal part, the **alar lamina**, and a ventral part, the **basal lamina**. Into the alar lamina grow the central processes of the cells situated in the cerebro-spinal ganglia, which have been derived from the neural crest, and it may, therefore, be considered sensory or *afferent* in function, whilst the basal lamina, from whose cells there grow out long peripheral fibres, may be termed motor or *efferent*. Furthermore, in the middle or mantle zone (gray matter) of each lamina the developing neuroblasts become arranged in two longitudinal columns, one having **somatic** (body wall) and the other **splanchnic** (visceral) peripheral connexions. Thus the gray matter of each lateral wall of the neural tube shows four longitudinal cell-columns, which, from their presence throughout the whole length of the neural tube, their peripheral connexions, and their functions may be called:—

1. General somatic afferent cell-column
2. General splanchnic afferent cell-column } in the Alar lamina,
3. General splanchnic efferent cell-column
4. General somatic efferent cell-column } in the Basal lamina,

corresponding to Gaskell's four primary functional divisions of the activities of the organism.

In the hind- and mid-brain regions, however, other cell-columns are added, consequent upon the presence of (1) the great **special sense organs** (nose, eye, ear) which demand specialised somatic sensory (afferent) connexions, and (2) the **branchial system** and its derivatives which, as a specialised part of the visceral area, demand special splanchnic connexions, both sensory (afferent) and motor (efferent). In the developing brain-stem, therefore, three additional cell columns are to be found:—

1. Special somatic afferent cell column
2. Special splanchnic afferent cell column } in the Alar lamina,
3. Special splanchnic efferent cell column in the Basal lamina.

As is pointed out above in the discussion of their components, few of the cerebral nerves are composed exclusively of fibres of one functional order; in most, however, there is such a preponderance of one type that we are justified in grouping them into three series:—

Somatic Afferent.	Somatic Efferent.	Splanchnic Afferent and Efferent.
I. Olfactory.	III. Oculo-motor.	V. Trigeminal.
II. Optic.	IV. Trochlear.	VII. Facial.
VIII. Acoustic.	VI. Abducens.	IX. Glossopharyngeal.
	XII. Hypoglossal.	X. Vagus.
		XI. Accessory.

Though this grouping is purely *functional*, it is, as we might expect, reflected anatomically in development, for the somatic afferent group of nerves (I., II., and VIII.) is connected with the alar lamina, corresponding in this respect to the dorsal roots of the spinal nerves, whilst the somatic efferent group (III., IV., VI., and XII.) arises from the medial part of the basal lamina in line with the ventral roots of the spinal nerves. The splanchnic group (V., VII., IX., X., and XI.), which is composed of sensory and motor nerves specialised in connexion with the branchial system, forms an intermediate series lying between the other two. It must be said, however, that though there is some degree of correspondence between cerebral and spinal nerves, any attempt to show a strict homology leads to insuperable difficulties.

Somatic Afferent Group.

Of the three cerebral nerves composing this group, the eighth only is developed from the neural crest, and is to that extent comparable to the dorsal root of a spinal nerve. It is quite probable, however, that some of its fibres come from cells developed from the ectoderm of the auditory vesicle, and, moreover, its distribution is limited to a specialised sensory area of the ectoderm. The first and second nerves are developed in connexion with outgrowths of the brain; indeed, as we shall see, neither of them is strictly comparable to any of the other nerves, cerebral or spinal.

I. Olfactory Nerve.—At the end of the fourth week an olfactory plate becomes differentiated in the ectoderm lying under the forebrain on each side. By the growth of the medial and lateral

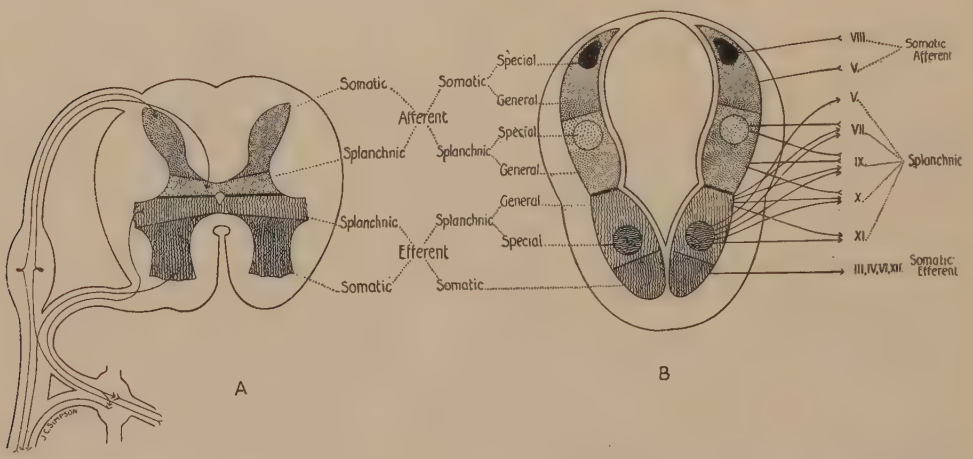

Fig. 593.—Scheme showing a Comparison of the Origins and Composition of the Nerve Roots from the Spinal Medulla and Hind-Brain.

A. Spinal medulla; B. Hind-brain.

nasal processes around it, this plate comes to form the roof of the olfactory pit. The sensory cells of the plate now take on the character of true nerve cells, and send in basal fibres which arborise about the cells of the olfactory bulb. At first the olfactory plates are directly in contact with the bulb, which is developed from the forebrain, but later, by the development of the cribriform plate and meninges, they become pushed apart, and the fibres connecting them are lengthened to form the true olfactory nerves. These nerves are peculiar in that, though sensory, they have no ganglia; the cells giving rise to their fibres remain in the surface epithelium, and the fibres themselves are unmyelinated.

II. Optic Nerve.—The optic nerve is developed in the stalk of the optic vesicle, an outgrowth from the forebrain, and, morphologically, is a part of the central nervous system. When the optic cup is formed (see under Development of the Eye) its inner, or retinal, layer becomes differentiated into the rods and cones (the true neuro-epithelial cells, corresponding to the olfactory cells) and nerve cells, the processes of which grow back along the optic stalk to form the optic nerve, chiasma, and tract. These nerve cells are true intermediate cells, corresponding to those of the gray matter of the central nervous system, and their fibres are largely supported by neuroglia.

VIII. Acoustic Nerve.—The internal ear first arises as an ectodermal plate lying dorsal to the first branchial cleft. This plate invaginates to form a flask-like auditory vesicle (otocyst) from the lining cells of which patches of neuro-epithelium are later differentiated. The vestibular and cochlear ganglia develop between the vesicle and the hind brain in close association with the genicular ganglion of the seventh nerve. Although the origin of the common mass is usually said to be from the neural crest, it is probable that some at least of the cells going to form the acoustic ganglia are derived from the neuro-epithelium of the auditory vesicle. The ganglia grow in direct proportion to the vestibular and cochlear outgrowth of this vesicle, and their central and peripheral fibres form the vestibular and cochlear nerves.

Somatic Efferent Group.

The hypoglossal nerve and the three nerves to the eye muscles all arise from the somatic efferent cell column in the basal lamina of the neural tube, and on this account, as well as by reason of the fact that they innervate somatic muscles, are usually considered as being in series with the ventral roots of the spinal nerves.

Though the primitive vertebrate head undoubtedly was segmental, little reliable evidence remains upon which to base a reconstruction of its segmentation, and various investigators have placed the number of the primitive cephalic segments between eight and nineteen. No distinct myotomes are visible in the head of the human embryo, but a study of the lower vertebrates leads to the conclusion that the pre-muscle mass from which the extrinsic ocular muscles are developed represents the first three cephalic myotomes. The first myotome forms the superior, inferior and medial recti and the inferior oblique, supplied by the oculo-motor nerve; the second myotome forms the superior oblique, supplied by the trochlear nerve; and the third forms the lateral rectus, supplied by the abducent (see Fig. 413, p. 496).

Similar studies tend to show that the intrinsic muscles of the tongue are derived from the last three cephalic myotomes. Between these two sets of persisting myotomes (ocular and lingual) there is a gap which probably represents three or more myotomes which have disappeared.

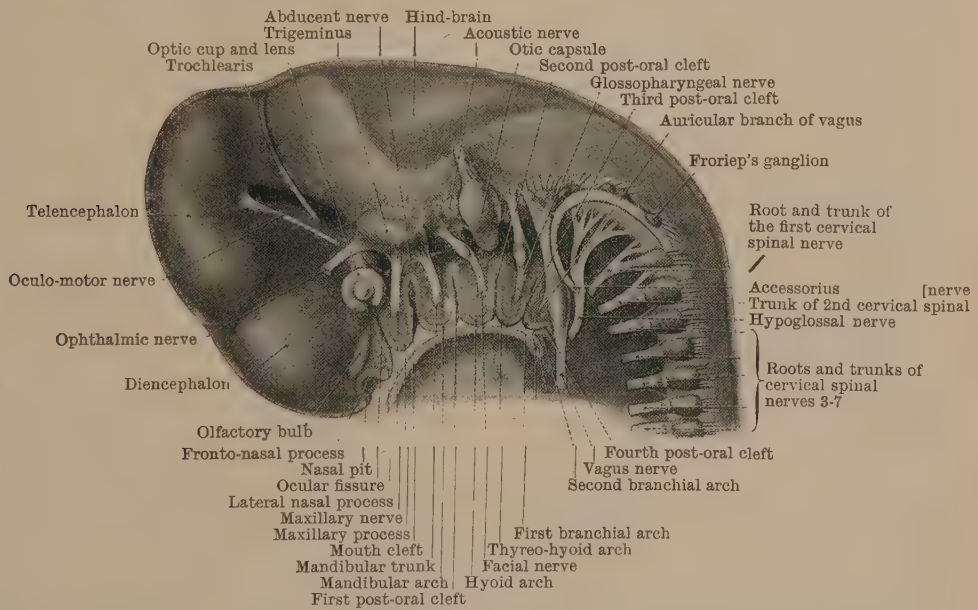

Fig. 594.—The Embryological Arrangement of the Cerebral Nerves. (Modified from Mall.)

III. Oculo-motor Nerve.—This nerve arises from neuroblasts in the basal lamina of the mid-brain. The fibres emerge in small bundles from the ventral surface of the lamina and converge to form the trunk of the nerve, which runs to the premuscle mass from which the extrinsic muscles of the eye (with the exception of the superior oblique and lateral rectus) are formed.

IV. Trochlear Nerve.—The neuroblasts from which this nerve arises lie just caudal to and in line with the nucleus of the third nerve. Instead of leaving the basal lamina by its ventral surface, however, the fibres grow dorsally, curve round the neural canal (aqueduct) and crossing above it, emerge on the opposite side at the junction of the mid- and hind-brain.

VI. Abducent Nerve.—The nucleus of origin lies in the basal lamina of the hind-brain under the floor of the fourth ventricle. The fibres emerge at a point caudal to the future pons and run to the rudiment of the lateral rectus muscle.

XII. Hypoglossal Nerve.—The twelfth is a compound nerve representing the fused motor nerves of three, or possibly more, precervical neural segments. Its fibres take origin from neuroblasts in the somatic efferent cell column and emerge from the walls of the basal lamina in several groups; they then converge ventrally to form the trunk of the nerve and grow upwards to end in the muscle rudiment of the tongue.

Splanchnic (Afferent and Efferent) Group.

The nerves of this group are essentially related to the **branchial arches.** In the embryo each of these arches contains a muscle plate which differs from the myotomes in that it is developed from splanchnic mesoderm. Associated with each arch is a nerve which contains both afferent

and efferent fibres, and runs along the upper or cephalic border of the arch; this nerve sends a small branch (*pretrematic*) around the dorsal end of the gill cleft to run along the lower, or caudal, border of the arch in front of the one from which it arises. The nerve of the first or mandibular arch is the mandibular division of the trigeminal nerve; the nerve of the second arch is the facial, and that of the third is the glossopharyngeal; the nerves of the remaining arches are fused to form the vagus and accessory nerves.

The nerve of each arch has a ganglion developed on its root, and supplies (1) motor (special splanchnic efferent) fibres to the muscle plate, and (2) sensory (general splanchnic afferent) fibres to the pharyngeal mucosa covering the inner surface of the arch and of the branchial cleft in front of it.

Furthermore, in connexion with the branchial system there are in the human embryo vestiges of a series of sense organs which have been lost by the higher vertebrates. These are small areas of modified ectoderm which are found at the dorsal end of each branchial cleft and are known as epibranchial **placodes.** During the fifth week of embryonic development the placodes are in contact with the ganglia of the facial, glossopharyngeal, and vagus nerves, and contribute cells to the formation of their ganglia (genicular, petrous, and nodosum).

Whilst the nerves of the splanchnic group typically do not possess somatic afferent fibres, the trigeminal, in conformity with the large part taken by the first arch in the formation of the face, receives a preponderance of this type of fibre. In reality, however, the trigeminal is a double nerve, and the present tendency is to regard its branchial part as a separate nerve, the masticator; and the remainder as a somatic sensory nerve. The vagus nerve also contains a limited number of somatic afferent fibres which supply the skin around the persistent dorsal part of the first branchial cleft, that is, the external acoustic meatus.

V. Trigeminal Nerve.—The semilunar ganglion arises very early from the neural crest at the extreme cranial end of the hind-brain. Central processes from its cells form the large sensory root of the nerve, and, reaching the hind-brain at the level of the pontine flexure, divide to run up and down in the alar plate, where the descending fibres form the spinal tract of the fifth nerve. The peripheral fibres separate into three large divisions which grow out into the three processes taking part in the formation of the face (the fronto-nasal, maxillary, and mandibular processes) and form the three divisions of the adult nerve.

The motor fibres arise from the special splanchnic efferent column of the basal lamina, where the cell bodies form a dorsal nucleus lying opposite the point at which the sensory fibres enter the brain. The motor fibres emerge as a distinct trunk in the embryo, and, coursing along the medial side of the semilunar ganglion, run to the muscle plate of the first arch which later forms the muscles of mastication. It is this part of the nerve which forms the true branchial nerve.

VII. Facial Nerve.—The facial is composed mainly of motor fibres which arise from a nucleus in the special splanchnic efferent column of the basal lamina. Growing out from this nucleus they emerge from the hind-brain just medial to the acoustic ganglion and run to the muscle plate of the second or hyoid arch from which the platysma group of muscles is later developed. At first the fibres run directly from their nucleus of origin to the lateral surface of the hind-brain, passing above (rostal to) the nucleus of the abducent nerve. Later, however, the facial nucleus shifts downwards (caudally) and ventro-laterally towards the sensory nuclei of the solitary tract and the spinal tract of the trigeminal nerve, following the general law of neurobiotaxis that the chief dendrite and body of a neurone tend to move towards the source of the majority of their afferent impulses.

The sensory fibres are developed from the genicular ganglion, which is derived from the neural crest and lies in close association with the ganglia of the acoustic nerve. It is probable that certain cells are also contributed to this ganglion by the epibranchial placode of the first branchial cleft. The central fibres enter the alar plate and form, together with fibres from the glossopharyngeal nerve, the solitary tract. The peripheral fibres run in front of the branchial cleft and form the chorda tympani and great superficial petrosal nerves which represent the pretrematic branch of the facial nerve.

IX. Glossopharyngeal Nerve.—The motor fibres arise from the large nucleus ambiguus, which is a common nucleus of origin for the motor fibres of the glossopharyngeal, vagus, and accessory nerves and lies in the special splanchnic efferent column in line with the motor nuclei of the fifth and seventh nerves. Emerging from the hind brain they grow out ventrally to meet the muscle plate of the third arch, and eventually supply the pharyngeal muscles derived from this element.

The sensory fibres, which form the larger part of the nerve, are derived from two ganglia, the superior or root ganglion, developed from the neural crest, and the petrosal or trunk ganglion, formed in part from the neural crest, and in part from an epibranchial placode with which it is in contact. Centrally the fibres enter the alar lamina and join fibres from the facial and vagus to form the solitary tract. Most of the peripheral fibres from the ganglia run ventrally to enter the third arch, passing, as a lingual branch, to that part of the tongue which is later developed from it. Some of the peripheral fibres, however, form a pretrematic branch in front of the second branchial cleft, and, as the tympanic nerve, supply the structures derived from the dorsal extremity of the first branchial cleft (tympanum, etc.).

X. Vagus.—The vagus is a composite nerve representing, with the accessory, the union of the nerves of all the branchial arches behind the third. Its sensory fibres, therefore, grow out from several root ganglia developed from the neural crest. The jugular ganglion is the most cephalic of these; the others are vestigial and are called accessory ganglia. The trunk ganglion (ganglion nodosum), like the trunk ganglion of the glossopharyngeal, is developed in contact with an

epibranchial placode, and in all probability receives cells from this source as well as from the neural crest. The central fibres grow towards the alar lamina, and, entering it, turn downward to form, in conjunction with fibres from the facial and glossopharyngeal nerves, the solitary tract. The peripheral fibres grow downward to form the bulk of the vagus nerve.

The motor fibres arise from two nuclei in the basal lamina, the nucleus ambiguus in the special splanchnic efferent column, and a dorsal motor nucleus, which lies in the general somatic efferent column. The fibres from these two sources emerge laterally in two separate bundles and join the sensory fibres to form the trunk of the nerve. Those from the nucleus ambiguus grow out to the muscle plates of the fourth and succeeding arches, from which the laryngeal and part of the pharyngeal muscles are developed. The fibres from the dorsal nucleus run to the sympathetic plexuses of the vagus.

XI. Accessory Nerve.—This nerve is closely associated with the vagus; both embryologically and morphologically it may be regarded as the caudal part of the vagus complex which has become specialised in connexion with the assumption of a new rôle by the branchial muscles which it supplies, these muscles (sternomastoid and trapezius) having been pressed into service as limb-girdle muscles.

The motor fibres, of which alone it is composed, arise from two sources. The larger number grow out from cell groups which are developed in the lateral horn of the upper four or more cervical segments of the spinal medulla (special splanchnic efferent column) in series with the nucleus ambiguus of the tenth. Emerging from the cord laterally, these fibres run upwards along the line of the neural crest as the spinal accessory trunk to join the vagus. Leaving this nerve after a short course, however, they run to their destination. A few fibres of the accessory nerve arise from cells in the dorsal motor nucleus of the vagus, and after pursuing a short course with the accessory proper rejoin the vagus and are distributed to its plexuses.

II. THE SPINAL NERVES.

The spinal nerves are characterised by being attached to the medulla spinalis and by passing from the vertebral canal through the intervertebral foramina. There are usually thirty-one pairs, which are grouped as cervical, thoracic, lumbar, sacral, and coccygeal, in relation to the vertebræ between which they emerge. There are eight cervical nerves, the first passing out of the vertebral canal between the occipital bone and the atlas, and the last appearing between the seventh cervical and first thoracic vertebræ; the other cervical nerves are numbered in correspondence with the vertebræ *above* which they emerge from the canal. There are twelve thoracic, five lumbar, five sacral nerves, and one coccygeal nerve, all appearing *below* the corresponding vertebræ.

The thirty-first nerve is occasionally absent; and there are sometimes one or two additional pairs of minute filaments below the thirty-first, which, however, do not emerge from the vertebral canal. These are rudimentary caudal nerves.

The size of the spinal nerves varies. The largest are those which take part in the formation of the great nerve trunks of the limbs (lower cervical and first thoracic, and lower lumbar and upper sacral nerves); and of these the nerves destined for the lower limbs are the larger. The coccygeal nerve is the smallest of the spinal nerves; the thoracic nerves (except the first) are more slender than the limb nerves; and the cervical nerves diminish in size from below upwards.

Origin of the Spinal Nerves.—Each nerve is attached to the spinal medulla by two roots, one of which is ganglionic and the other not; they are called respectively **posterior** (dorsal, sensory, or afferent) and **anterior** (ventral, motor, or efferent).

The **posterior root** is larger than the anterior root; it contains a larger number of radicular fibres, and the individual fibres are of larger size than in the anterior root. It has a vertical linear attachment to the postero-lateral sulcus of the spinal medulla. The fibres of contiguous posterior roots are in close relation, and, in some instances, overlap. The posterior root separates, as it passes away from the spinal medulla, into two bundles, both of which become connected with the proximal end of a **spinal ganglion**. From the distal end of this ganglion the posterior root proceeds to its junction with the anterior root in the intervertebral foramen.

The **spinal ganglia** are found on the posterior roots of all the spinal nerves. (In the case of the first cervical or sub-occipital nerve, the spinal ganglion may be rudimentary or absent; and the posterior root itself may be wanting, or derived from the accessory nerve.) They occupy the intervertebral foramina, except in the case of the sacral and coccygeal nerves, the ganglia of which lie *within* the

vertebral canal; and the first and second cervical nerves, the ganglia of which lie upon the vertebral arches of the atlas and epistropheus respectively. With the exception of the coccygeal ganglia they are outside the cavity of the dura mater, but are invested by the membrane. The ganglia are of ovoid form, bifurcated in some cases at their proximal ends. They consist of unipolar nerve-cells, whose axons, after a very short course, divide into central (root) and peripheral (trunk) fibres. The central fibres form the portion of the root entering the spinal medulla; the peripheral fibres are continued in a lateral direction from the ganglion into the spinal nerve.

FIG. 595.—DIAGRAM OF THE ORIGIN AND DISTRIBUTION OF A TYPICAL SPINAL NERVE.

Note that the medial division of the posterior ramus is represented as distributed to skin, whilst the lateral division terminates at a deeper level in muscle; in some situations the reverse condition occurs. The medial and lateral divisions of all posterior rami supply muscles.

Ganglia Aberrantia (aberrant spinal ganglia).—Between the spinal ganglion and the spinal medulla small collections of cells are occasionally found on the posterior roots, either as scattered cells or distinct ganglia. They are most frequently met with on the posterior roots of the lumbar and sacral nerves.

The **anterior root** is smaller than the posterior root. It arises from the anterior surface of the spinal medulla (*anterior root zone*) by means of scattered bundles of nerve-fibres, which occupy a greater horizontal area and are more irregular in their arrangement than the radicular fibres of the posterior root. It possesses no ganglion in its course. The rootlets sometimes overlap, and are not infrequently connected with neighbouring radicular fibres above and below.

The dorsal and ventral roots, from their attachment to the spinal medulla, proceed laterally in the vertebral canal towards the intervertebral foramina, where they unite to form the spinal nerve. The direction of the roots of the first two nerves is upwards and laterally; the roots of the remaining nerves course obliquely downwards and laterally, the obliquity gradually increasing until, in the case of the lower lumbar, the sacral and coccygeal nerve-roots, their course is vertically downwards in the vertebral canal. The collection of nerve-roots which occupies the lower part of the canal, below the first lumbar vertebra, and comprises all the nerve-roots below those of the first lumbar nerve, is designated the **cauda equina.**

They arise from the lumbar enlargement and conus medullaris, and surround the filum terminale of the spinal medulla.

Within the vertebral canal the nerve-roots are in relation with the **meninges** of the spinal medulla, and are separated from one another by the ligamentum denticulatum, and, in the neck, by the spinal part of the accessory nerve. Each receives a covering of pia mater, continuous with the neurilemma; the arachnoid invests each root as far as the point where it meets with the dura mater; and each root pierces the dura mater separately. The two roots are thereafter enclosed in a single tubular sheath of dura mater, in which is included the spinal ganglion of the posterior root. The spinal nerve thus ensheathed occupies the intervertebral foramen (except the first two cervical and the sacral and coccygeal nerves).

Divisions of a Spinal Nerve.—After emerging from the intervertebral foramen the nerve immediately divides into two primary divisions, named respectively the **posterior** and **anterior rami**. Just before its division each nerve gives off a minute meningeal **(recurrent) branch,** which re-enters the vertebral canal after effecting a junction with a branch from the sympathetic trunk, and is distributed to the spinal medulla and its membranes.

The **posterior** and **anterior rami** of the spinal nerves are mainly somatic in their distribution, and are responsible for the innervation of the skeletal muscles and of the skin covering the trunk and limbs.

The posterior and anterior rami of the nerves contain fibres from both posterior and anterior roots. Indeed, each root can be seen, on removal of its sheath, to divide into two portions, of which one portion enters into the formation of the posterior ramus, the other into the formation of the anterior ramus. The posterior rami, with the exception of the first two, are smaller than the anterior rami. They are responsible for the innervation of the skin and axial muscles of the back. They do not supply the muscles of the limbs, although in their cutaneous distribution they are prolonged on to the back of the head, the shoulder, and the buttock. They form two small plexuses—the **posterior cervical** and the **posterior sacral plexuses**. The anterior rami are, with the exception of the first two cervical nerves, much larger than the posterior rami. They supply the sides and anterior parts of the body, the limbs, and the perineum. For the most part they have a complicated arrangement. The thoracic or intercostal nerves alone have a simple mode of distribution; the other nerves give rise to the three great **plexuses—cervical, brachial,** and **lumbo-sacral**.

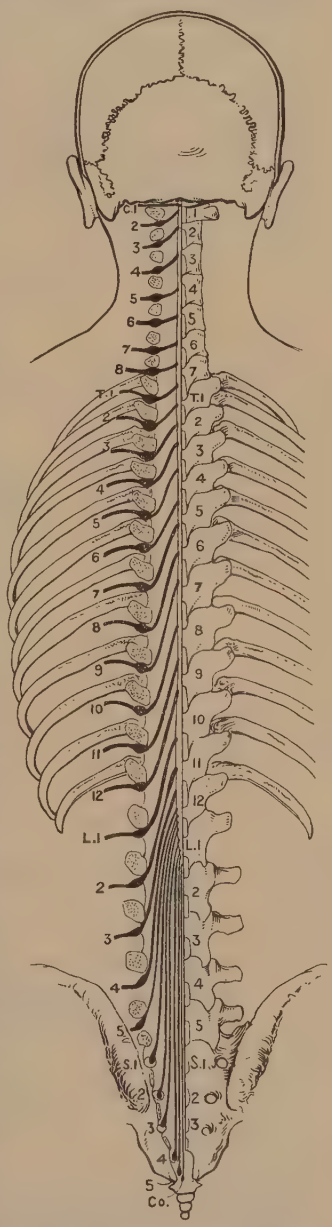

FIG. 596.—DIAGRAMMATIC REPRESENTATION OF THE ORIGIN OF THE SPINAL NERVES, showing the position of their roots and ganglia respectively in relation to the vertebral column. The nerves are shown as thick black lines on the left side.

White Rami Communicantes.—From the anterior rami of certain nerves (first or second thoracic to second lumbar inclusive) a series of fine nerves arises, which serves to connect the spinal with the sympathetic system. These **visceral** or **splanchnic branches**, or **white rami communicantes**, through the medium of the gangliated trunk of the sympathetic, serve to innervate the vessels and viscera in the splanchnic area. A second stream of **pelvic splanchnic nerves**, associated with the

second and third, or third and fourth sacral nerves, connects these spinal nerves with the pelvic sympathetic plexuses (p. 790).

Distribution of the Spinal Nerves.—Although the distribution, like the origin of the spinal nerves, presents primarily and essentially a segmental arrangement, this is masked, and in some instances obliterated, by developmental changes in the parts supplied. In no region can an isolated nerve be traced to a complete segment. The nearest approach to a complete girdle of innervation is found in the thoracic region, in such a nerve as the sixth thoracic nerve. Yet even such a nerve is not distributed to any part entirely alone. In its cutaneous distribution it supplies a complete belt of skin, a distinctly segmental area from the median plane posteriorly to the median plane anteriorly; yet at the same time the adjacent nerves overstep, so to speak, the boundaries of the area and assist in the cutaneous nerve supply. Its muscular distribu-

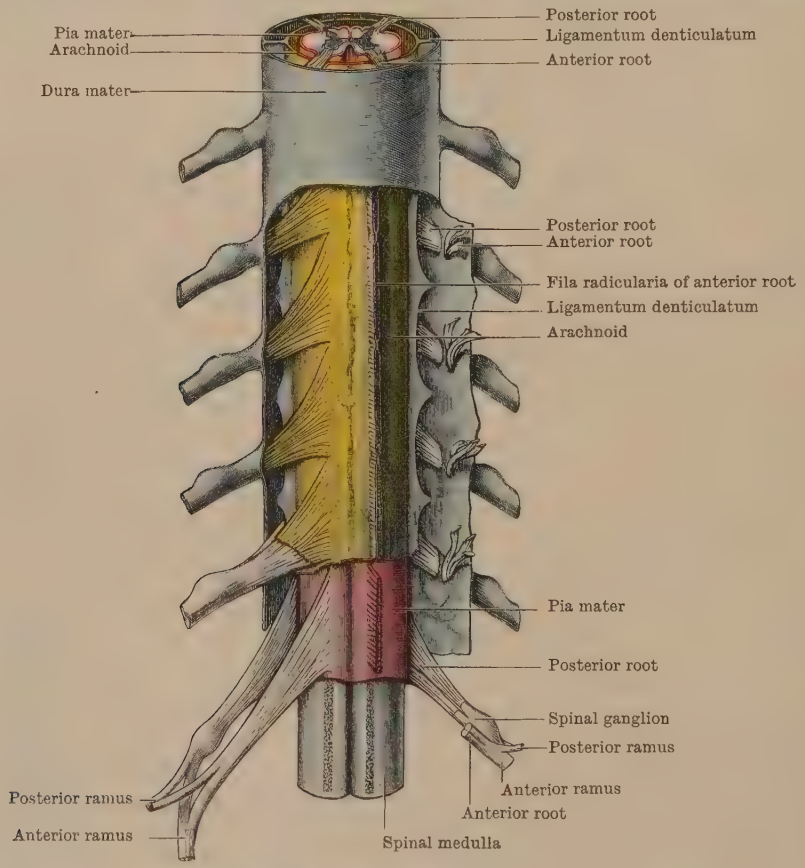

FIG. 597.—SCHEME OF THE ARRANGEMENT OF THE MEMBRANES OF THE SPINAL MEDULLA AND THE ROOTS OF THE SPINAL NERVES.

tion, also, is segmental; the anterior ramus supplies the intercostal muscles of the space in which it lies; but in this it forms communications with adjacent nerves. The posterior ramus supplies axial muscles of the back, not, however, in an obviously segmental manner, on account of the fusion of the segmental myotomes in the formation of complex longitudinal muscles, which are together supplied by the series of muscular branches derived from the posterior rami of contiguous nerves. In other regions still greater changes of structure are accompanied by deviations from a segmental type of distribution, causing the foundation of the nerve-plexuses by which the trunk and limbs are innervated.

POSTERIOR RAMI OF THE SPINAL NERVES.

The **posterior rami** of the spinal nerves innervate both skin and muscles; the skin of the trunk posteriorly, the back of the head, the shoulder and the buttock, and the longitudinal muscles of the back, but not the muscles of the limbs.

Each posterior ramus divides as a rule into two parts, a **medial** and a **lateral trunk** (Fig. 595, p. 712). In the upper half of the body the medial trunks generally supply the cutaneous branches, while the lateral trunks are purely muscular nerves. In the lower part of the body the opposite is the case: the lateral trunks provide the cutaneous nerves and the medial trunks are distributed entirely to muscles. The cutaneous branches have a different course in the two cases. In the upper half of the back they course backwards beneath and among the muscles to within a short distance of the spinous processes of the vertebræ, close to which they become superficial. They then extend laterally in the superficial fascia. In the lower half of the back the cutaneous nerves are directed downwards and laterally among the muscles, and become superficial at a greater distance from the median plane. In both regions the nerves pursue a sinuous course to the surface, and the lower series emerge and become superficial a considerable distance below the level of their spinal origin. There are considerable individual differences in the origin, course, and distribution of the several nerves.

CERVICAL NERVES.

First Cervical Nerve (**N. sub-occipitalis**).—It has already been pointed out that the posterior root of this nerve may be very small, or even absent altogether. Its posterior ramus is larger than the anterior ramus; it does not divide into medial or lateral branches, and it does not directly supply any cutaneous branch.

Passing backwards, in the space between the occipital bone and the posterior arch of the atlas, the nerve occupies the sub-occipital triangle, and is placed below and behind the vertebral artery, and under cover of the semispinalis capitis muscle. It supplies the following branches:—

(*a*) **Muscular branches** to the semispinalis capitis (O.T. complexus), rectus capitis posterior major and minor, and obliqui capitis, superior and inferior.

(*b*) A **communicating branch** descends to join the second cervical nerve.

The communicating branch may arise in common with the nerve to the obliquus inferior, and reach the second cervical nerve by piercing or passing superficial or deep to that muscle; or it may accompany the nerve to the semispinalis capitis and communicate with the greater occipital nerve, under or over that muscle.

Second Cervical Nerve.—The posterior ramus of this nerve is larger than the corresponding anterior ramus. It passes backwards between the atlas and epistropheus, and in the interval between the obliquus inferior and the semispinalis cervicis muscles, under cover of the semispinalis capitis muscle. In this situation the nerve gives off several small muscular and communicating branches. The main trunk, after piercing the semispinalis capitis and trapezius muscles, accompanies the occipital artery to the scalp as the **greater occipital nerve**. This is the chief cutaneous nerve for the posterior part of the scalp. It enters the superficial fascia at the level of the superior nuchal line of the occipital bone and about an inch from the external occipital protuberance. Ramifying over the surface, it supplies the skin of the scalp as far as the vertex. It *communicates* on the scalp with the following nerves: great auricular, lesser occipital, posterior auricular, and third occipital.

The **muscular branches** of the second cervical nerve are destined for the semispinalis capitis, obliquus inferior, semispinalis cervicis, and multifidus.

Its **communicating branches** form the **posterior cervical plexus**. Descending over the posterior arch of the atlas is a branch from the sub-occipital nerve which forms a loop or network with a branch of the second nerve. From this loop twigs are supplied to the surrounding muscles. A similar loop is formed by a communication between branches of the second and third nerves, from which muscles are also supplied. Occasionally an additional loop is formed between branches of the third and fourth nerves.

Third Cervical Nerve.—This is much smaller than the second nerve. Near its origin it forms a loop of communication with the second, and it may give off a similar communicating branch to the fourth nerve. The main trunk divides into medial cutaneous and lateral muscular branches. The lateral muscular

branch enters contiguous muscles; the medial cutaneous branch passes backwards and medially, and becomes superficial as the **third occipital nerve** (O.T. *n. occipitalis*

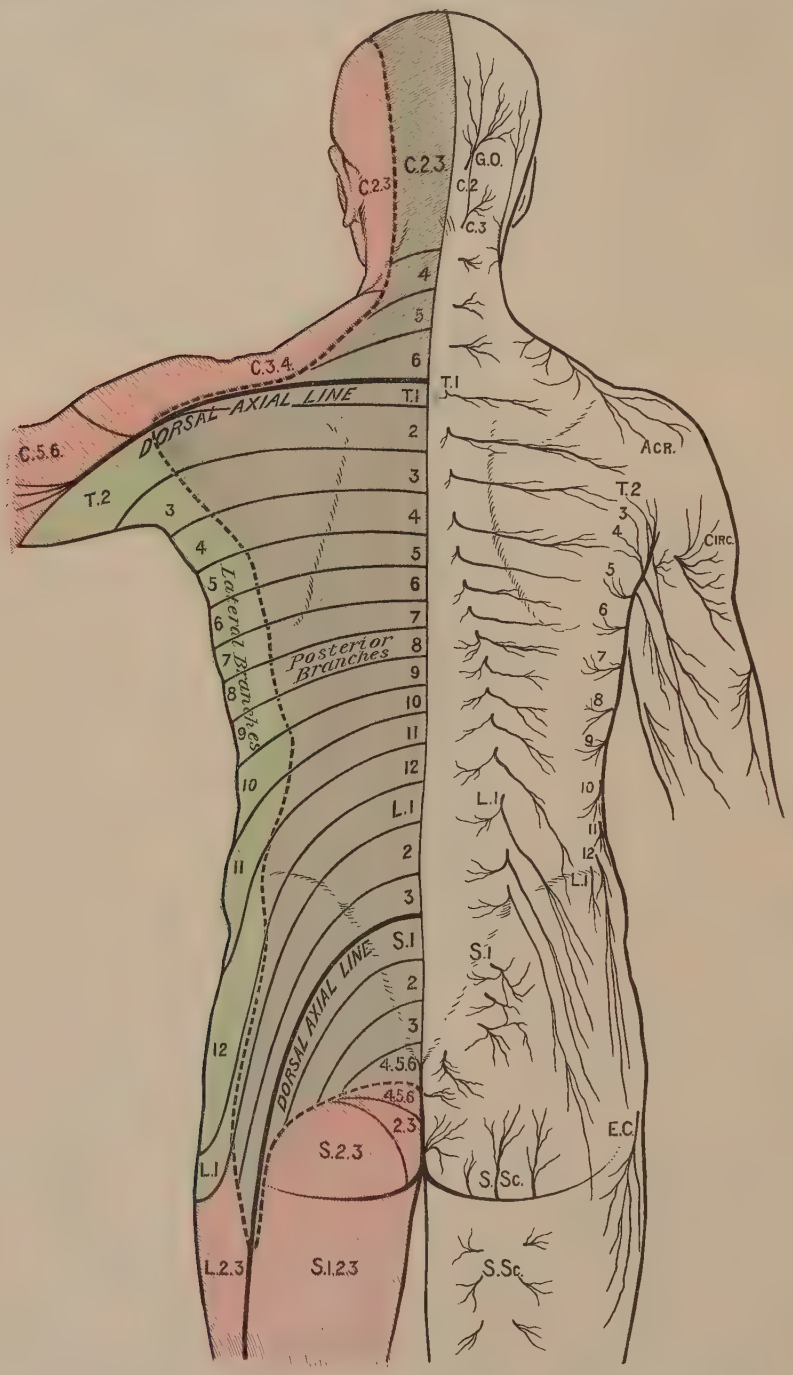

FIG. 598.—THE DISTRIBUTION OF CUTANEOUS NERVES ON THE BACK OF THE TRUNK.

On one side the distribution of the several nerves is represented, the letters indicating their nomenclature.

G.O. (C.2), Greater occipital; C.3, Third occipital; T.1 *et seq.*, Posterior rami of thoracic nerves; L.1 *et seq.*, Posterior rami of first three lumbar nerves; S.1 *et seq.*, Posterior rami of sacral nerves; Acr., Posterior supra-clavicular branches from cervical plexus; T.2-12, Lateral branches of thoracic nerves; Circ., Cutaneous branches of axillary nerve; L.1, Iliac or lateral cutaneous branch of ilio-hypogastric nerve; E.C., Lateral cutaneous nerve of thigh; S.Sc., Posterior cutaneous nerve of thigh.

On the other side a schematic representation is given of the areas supplied by the above nerves, the numerals indicating the spinal origin of the branches of distribution to each area.

minimus), close to the median plane of the neck. It supplies fine branches to the neck and scalp, and communicates with the greater occipital nerve.

The **fourth, fifth, and sixth cervical nerves** are still smaller. Beneath the semispinalis capitis each divides into lateral muscular and medial cutaneous branches. The muscular branches supply neighbouring muscles; the cutaneous branches are small nerves, which, passing backwards, become superficial close to the median plane. They supply the skin of the back of the neck. The sixth is the smallest, and the cutaneous branches of the fifth and sixth nerves may be absent altogether. In certain cases the fourth nerve forms, with the third, a loop of communication from which muscles are supplied.

Seventh and Eighth Cervical Nerves.—These are the smallest of the posterior

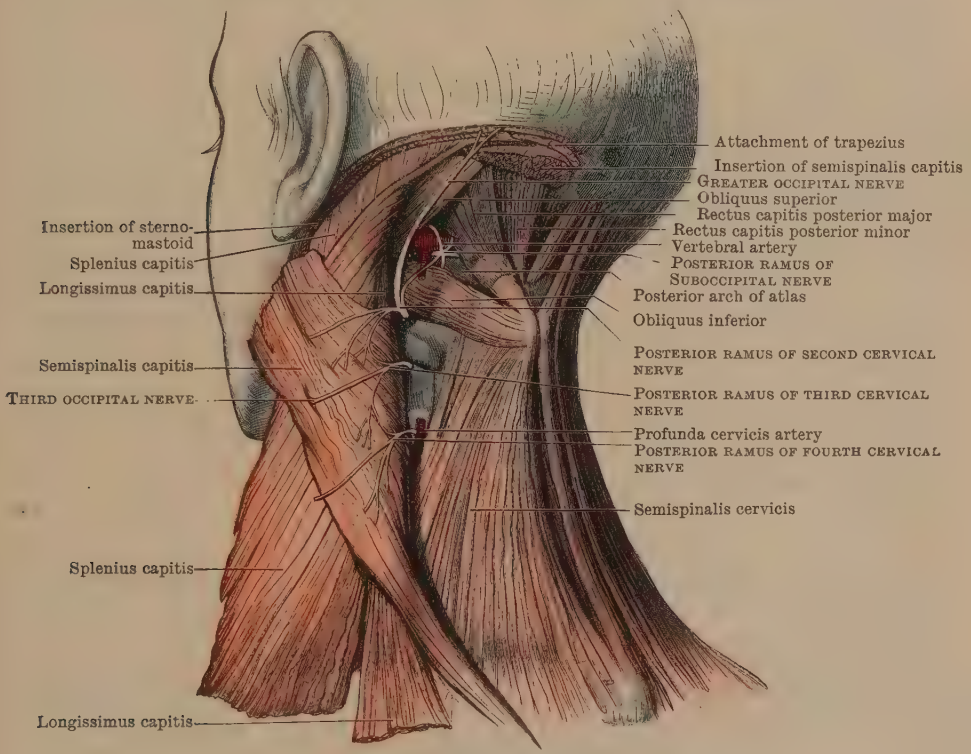

Fig. 599.—Posterior Cervical Plexus.

rami of the cervical nerves. They give off ordinarily no cutaneous branches, and end in the deep muscles of the back. There is occasionally a small cutaneous offset from the eighth nerve.

THORACIC NERVES.

The posterior ramus of each thoracic nerve divides into a **medial** and a **lateral branch.** In the case of the upper six or seven thoracic nerves the medial branches are distributed chiefly as *cutaneous* nerves—only giving off small muscular branches—while the lateral branches are wholly *muscular* in their distribution; in the case of the lower five or six thoracic nerves the opposite is the case. In all cases the muscular branches serve to innervate the longitudinal muscles of the back. The distribution of the cutaneous branches is therefore different in the upper and lower part of the back. The **medial cutaneous branches** of the *upper six* or *seven* thoracic nerves innervate the skin of the scapular region; after a sinuous backward course from their origin, among the dorsal muscles, they reach the surface near the spines of the vertebræ and are directed almost horizontally laterally over the trapezius muscle. The first is small; the second is very large and reaches to the acromion. The rest diminish in size, from above downwards,

and become more and more oblique in direction. The **lateral cutaneous branches** of the *lower five* or *six* thoracic nerves are directed from their origin obliquely downwards and laterally among the parts of the sacro-spinalis muscle. Becoming cutaneous by piercing the latissimus dorsi at some distance from the median plane, they supply the skin of the back in the lower part of the chest and loin, the lowest nerves (eleventh and twelfth) reaching over the iliac crest on to the buttock. The lower nerves often subdivide into two branches before or after their emergence from the latissimus dorsi muscle. Owing to the obliquity of their course, each of these cutaneous branches supplies an area of skin which lies at a lower level than does the posterior ramus from which the branch arises.

LUMBAR NERVES.

First three Lumbar Nerves.—The posterior rami of the first three lumbar nerves subdivide into medial and lateral branches, in the same way as the lower thoracic nerves. The medial branches are muscular and innervate the deep muscles of the back. The lateral branches are chiefly cutaneous. They are directed obliquely downwards and laterally among the fibres of the sacro-spinalis and become superficial by piercing the lumbo-dorsal fascia, just above the iliac crest and a short distance in front of the posterior superior iliac spine. They are then directed downwards in the superficial fascia of the buttock, and supply a lengthy strip of skin, extending from the median plane above the iliac crest to a point distal to and behind the greater trochanter of the femur. There may be only two cutaneous branches, derived from the first two lumbar nerves; in other cases the three nerves are the branches of the twelfth thoracic and first two lumbar nerves.

The **fourth and fifth lumbar nerves** (like the last two cervical nerves) usually supply only muscular branches to the longitudinal muscles of the back. The fifth nerve in many cases sends a branch to form a loop of connexion with the posterior ramus of the first sacral nerve, contributing to the posterior sacral plexus.

SACRAL AND COCCYGEAL NERVES.

The posterior rami of the sacral nerves issue from the posterior sacral foramina. As in the case of the thoracic and lumbar nerves, the upper sacral nerves differ from the lower in their distribution.

The **first three sacral nerves** supply medial muscular branches for the multifidus, and lateral cutaneous branches which pierce the fibres of the sacro-tuberous ligament and the glutæus maximus muscle, and supply the skin over the back of the sacrum and contiguous part of the buttock, giving rise to the posterior sacral plexus.

The **posterior sacral plexus** consists, like the posterior cervical plexus, of loops or plexiform communications over the back of the sacrum between the posterior rami of the first three sacral nerves, to which are frequently joined branches of the last lumbar nerve and fourth and even the fifth sacral nerve. From these loops branches proceed to supply the multifidus muscle; others, piercing the sacro-tuberous ligament, form secondary loops beneath the glutæus maximus muscle. From the secondary loops, two or more cutaneous branches arise, which, after traversing the muscle, supply the skin over the sacrum and medial part of the buttock.

Posterior Ano-coccygeal Nerve.—The posterior rami of the fourth and fifth sacral nerves do not divide into medial and lateral branches. They unite together to form a loop which is joined by the minute posterior ramus of the coccygeal nerve. The union of the three nerves constitutes the **posterior ano-coccygeal nerve**, which, after perforating the sacro-tuberous ligament, is distributed to the skin in the neighbourhood of the coccyx. It supplies no muscles. This nerve is the representative of the **superior caudal trunk** of tailed animals.

Morphology of the Posterior Rami.

1. Muscular Distribution.—In their muscular distribution they are strictly limited to the longitudinal muscles of the back: namely, those associated with the axial skeleton alone.

2. Cutaneous Distribution.—Their cutaneous distribution presents two points of interest.

A. In the first place, while the skin of the back is supplied in a regularly segmental manner by the several nerves, certain of them fail to reach the surface at all. The absence of a cutaneous branch from the sub-occipital nerve may be due either to the absence of a perfect posterior root, or to its communication with the second nerve. The other nerves which do not usually supply the skin are the last two, three, or four cervical, and the fourth and fifth lumbar nerves. These nerves are placed in the centre of regions in which the upper and lower limbs are developed. They are minute nerves, while the corresponding anterior rami are among the largest of the spinal nerves. Thus, opposite the centre of each limb, posteriorly, there is a hiatus in the segmental distribution of the posterior rami of the spinal nerves to the skin of the shoulder and buttock, attributable to the formation of the limbs, and the extension into them of the greater part of the nerves of the region. This gap, in the case of the upper limb, commences at the level of the vertebra prominens; in the case of the lower limb it commences opposite the level of the posterior superior iliac spine. It can be continued on to each limb as a hypothetical area (the **dorsal axial line**), which indicates the area of contact (and overlapping) of cutaneous nerves not in strictly numerical sequence. Thus, in the region of the shoulder, the sixth (or fifth) cervical nerve innervates an area of skin adjoining that supplied by the eighth cervical or first thoracic nerve; in the region of the buttock the third lumbar nerve supplies an area contiguous with that supplied by the fifth lumbar or first sacral nerve.

B. The cutaneous branches of the posterior rami of the spinal nerves differ from the muscular branches in respect of their penetration into regions beyond those supplied by their motor roots. The cutaneous branches, in regions where outgrowths or extensions from the trunk have occurred, follow these extensions; and, in consequence, supply skin covering parts which do not belong to segments represented by the nerves in question. Thus, the second and third cervical nerves (greater and third occipital) are drawn upwards so as to supply the posterior part of the *scalp*; the upper thoracic nerves are drawn laterally over the *scapular region*; the upper lumbar and sacral nerves supply the skin of the *buttock*; and the ano-coccygeal nerve forms a rudimentary *caudal nerve.*

3. Plexuses.—The plexuses formed by the posterior rami of the upper cervical and upper sacral nerves are the simplest met with in the human body. The posterior cervical plexus is one from which muscular branches are supplied; the posterior sacral plexus is mainly concerned in producing cutaneous offsets.

ANTERIOR RAMI OF THE SPINAL NERVES.

The **anterior rami** of the spinal nerves are, with the exception of the first two cervical nerves, much larger than the corresponding posterior rami. Composed of elements of both posterior and anterior roots, each nerve separates from the posterior ramus on emerging from the intervertebral foramen, and, proceeding laterally, is distributed to structures on the lateral and anterior aspects of the body,—including the limbs.

Each nerve is joined near its origin by a **gray ramus communicans** from the corresponding sympathetic gangliated trunk; and in the case of certain thoracic, lumbar, and sacral nerves, the anterior ramus gives off a delicate bundle of fibres, which forms the **white ramus communicans** to the sympathetic trunk. That part of the spinal nerve which is distributed to the body wall and limbs may be termed **somatic**; the small white ramus communicans, innervating structures in the splanchnic area, may be termed the **visceral** or **splanchnic** part of the spinal nerve.

The anterior rami of the spinal nerves are distributed in a regular segmental manner only in certain cases. Except in the case of the thoracic nerves, the anterior rami combine to form the three great **plexuses**—cervical, brachial, and lumbo-sacral—and their arrangement and distribution is rendered exceedingly complex.

A **thoracic nerve,** such as the fifth or sixth, may be regarded as a type to illustrate the mode of distribution of the anterior rami of the spinal nerves (Fig. 595, p. 712). It occupies an intercostal space; near its origin it possesses *gray* and *white rami communicantes*; it courses through the interval between the intercostal muscles; it supplies branches to those muscles and gives off, when it reaches the side of the chest, a *lateral branch,* which, after supplying small muscular branches, pierces the external intercostal muscle, and is distributed to an area of skin over the lateral part of the trunk, contiguous dorsally with a similar area, innervated by the cutaneous branches of the posterior ramus of the same nerve. The lateral branch generally subdivides into a smaller *posterior* and a larger *anterior ramus,* as it pierces the muscles clothing the wall of the chest. The main trunk of the nerve, having given off its lateral branch, then pursues its

course obliquely forwards to the side of the sternum, where, after piercing the pectoral muscles, it appears superficially as the *terminal anterior cutaneous branch.*

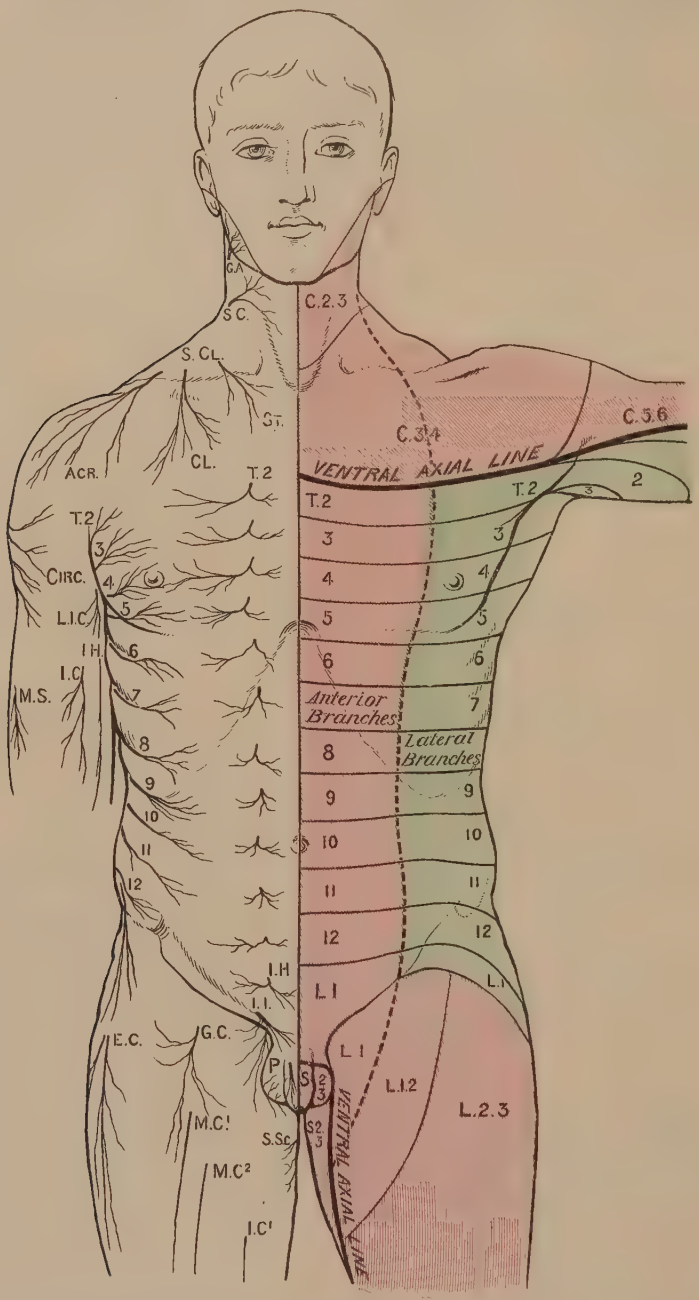

Fig. 600.—The Distribution of Cutaneous Nerves on the Front of the Trunk.

On one side the distribution of the several nerves is represented, the letters indicating their nomenclature.

G.A., Great auricular nerve; S.C., N. cutaneus colli; S.Cl., Supra-clavicular nerves; Acr., Posterior; Cl., Middle; St., Anterior; T.2-12, Lateral and anterior branches of thoracic nerves; I.H. (below) Ilio-hypogastric nerve; I.I., Ilio-inguinal nerve; Circ., Cutaneous branch of axillary nerve; L.I.C., Medial cutaneous nerve of the arm (lesser internal cutaneous nerve); I.H. (above) Intercosto-brachial; I.C., Medial cutaneous nerve of the forearm (internal cutaneous); M.S., Cutaneous branch of radial nerve; E.C., Lateral cutaneous nerves; G.C., Lumbo-inguinal nerve; M.C.$^{1\,2}$, Intermediate cutaneous nerves; I.C.^{1}, Branch of medial cutaneous nerve; P., Branches of pudendal nerve; S.Sc., Branches of posterior cutaneous nerve of the thigh.

On the other side a schematic representation is given of the areas supplied by the above nerves, the numerals indicating the spinal origin of the branches of distribution to each area.

This supplies an area of skin continuous with that supplied by the anterior part of the lateral branch of the same nerve. Such a nerve thus supplies, by means of its lateral and anterior branches, an area of skin which (with the area supplied by the cutaneous branch of its posterior ramus) forms a continuous and uninterrupted belt, extending from the median plane behind to the median plane in front. The lateral and anterior branches of the nerve innervate in their course the intercostal and other muscles, to be afterwards mentioned in detail.

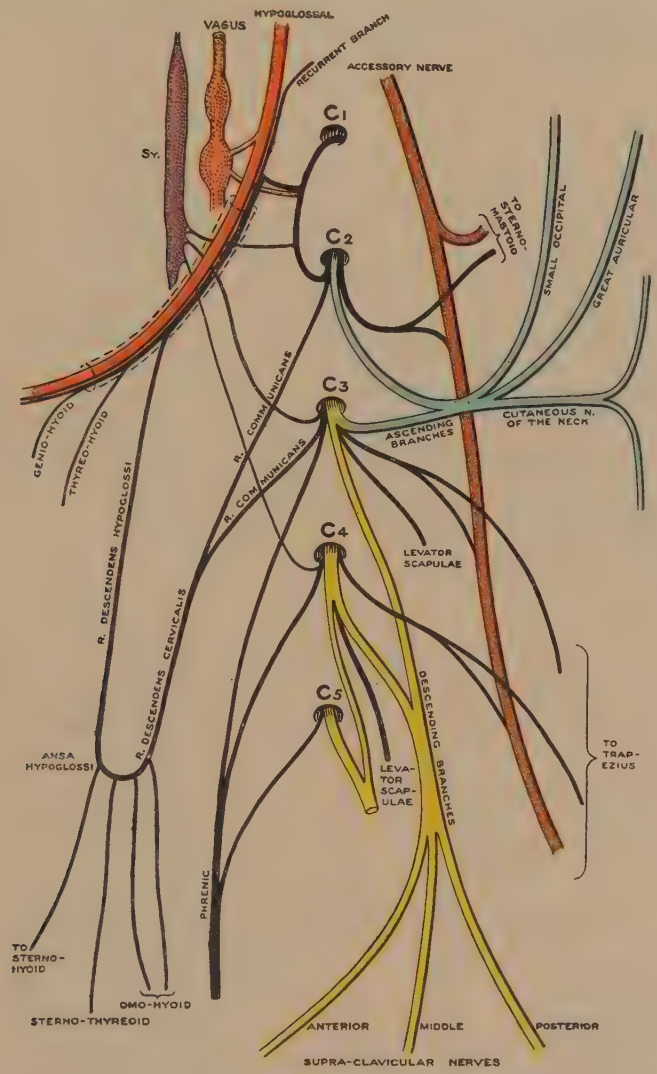

FIG. 601.—THE LEFT CERVICAL PLEXUS.

NERVI CERVICALES.

The anterior rami of the cervical nerves, together with parts of the first and second thoracic nerves, are distributed to the head, neck, and upper extremity. The first four cervical nerves, by means of the **cervical plexus**, innervate the neck; the last four cervical nerves, together with a large part of the first thoracic nerve, through the **brachial plexus**, supply the upper limb. The second thoracic nerve may contribute a trunk to this plexus, and always assists in the innervation of the arm.

The anterior ramus of the **first cervical (sub-occipital) nerve** emerges from the vertebral canal by passing over the posterior arch of the atlas; it curves forwards

round the lateral side of the upper articular process of that vertebra, lying medial to the vertebral artery, and then descends to form a loop with the ascending branch of the second cervical nerve. A large part of its fibres joins the hypoglossal nerve (*vide infra*).

The anterior division of the **second cervical nerve** passes between the neural arches of the first two vertebræ, behind the upper articular process of the epistropheus; curving forwards on the lateral side of the vertebral artery, it divides into an ascending portion, which unites with the first cervical nerve and likewise contributes fibres to the hypoglossal nerve, and a descending part, which joins the third cervical nerve and takes part in the cervical plexus.

PLEXUS CERVICALIS.

The anterior rami of the first four cervical nerves are concerned in forming the **cervical plexus.** Each nerve emerges from the vertebral canal posterior to the vertebral artery. Each is joined on its emergence from the intervertebral foramen at the side of the vertebral column, by a **gray ramus communicans** from the superior cervical ganglion of the sympathetic. In the neck the cervical nerves are concealed at their origins by the sterno-mastoid muscle; in front lies the longus capitis muscle, and behind are the scalenus medius, and (behind the first or suboccipital nerve) the rectus capitis lateralis. The cervical plexus is constituted by the combination of the four nerves in an irregular series of loops under cover of the sterno-mastoid muscle, and overlapped, in part, by the internal jugular vein.

From the loops of the plexus the branches of distribution arise, as (*a*) **cutaneous branches** to the head, neck, and shoulder; (*b*) **muscular branches** to muscles of the neck and to the diaphragm; and (*c*) **communicating branches** to the vagus, accessory, hypoglossal, and sympathetic nerves.

For convenience of description, the nerves derived from the plexus may be classified as follows:—

I. Superficial (cutaneous) Branches—

A. **Ascending Branches** (C. 2, 3).
- N. occipitalis minor (lesser occipital),
- N. auricularis magnus (great auricular),
- N. cutaneus colli (O.T. transverse superficial cervical).

B. **Descending (supra-clavicular) Branches** (C. 3, 4).
- Nn. supraclaviculares anteriores (O.T. supra-sternal),
- Nn. supraclaviculares medii (O.T. supra-clavicular),
- Nn. supraclaviculares posteriores (O.T. supra-acromial).

II. Deep (muscular and communicating) Branches—

A. **Lateral Branches.**
1. Muscular branches to
   - Sterno-mastoid (C. 2),
   - Trapezius (C. 3, 4),
   - Levator scapulæ (C. 3, 4),
   - Scaleni (medius and posterior) (C. 3, 4).
2. Communicating branches to
   - Accessory nerve (C. 2, 3, 4).

B. **Medial Branches.**
1. Muscular to
   - Prevertebral muscles (C. 1, 2, 3, 4),
   - Infra-hyoid muscles (C. 1, 2, 3) (ansa hypoglossi),
   - Diaphragm (C. 3, 4, 5) (phrenic nerve).
2. Communicating branches to
   - Vagus nerve (C. 1, 2),
   - Hypoglossal nerve (C. 1, 2),
   - Ansa hypoglossi (C. 2, 3),
   - Sympathetic (C. 1, 2, 3, 4).

The second, third, and fourth cervical nerves are the chief nerves engaged in forming the plexus. The first cervical nerve only enters into the formation of a small part—the medial portion of the deep part of the plexus.

Superficial Cutaneous Branches.—These nerves, six in number, are entirely cutaneous. They radiate from the plexus, and appear in the posterior triangle of

the neck a little above the mid-point of the posterior border of the sterno-mastoid muscle. They are divisible into two series—the one **ascending**: lesser occipital, great auricular, and nervus cutaneus colli; the other **descending** (supra-clavicular): posterior, middle, and anterior.

Ascending Branches.—The **lesser occipital nerve** is variable in size and is sometimes double. Its origin is from the second and third cervical nerves (more rarely from the second only). It extends backwards under cover of the sterno-mastoid, and then upwards along its posterior border. Piercing the deep fascia near the apex of the posterior triangle, it divides into **auricular, mastoid,** and **occipital branches,** and supplies small **cervical branches** to the upper part of the neck. The auricular branch supplies the skin of the cranial surface of the auricle; the mastoid and occipital branches supply the scalp. The nerve communicates on the scalp with the greater occipital and great auricular nerves, and with the posterior auricular branch of the facial nerve.

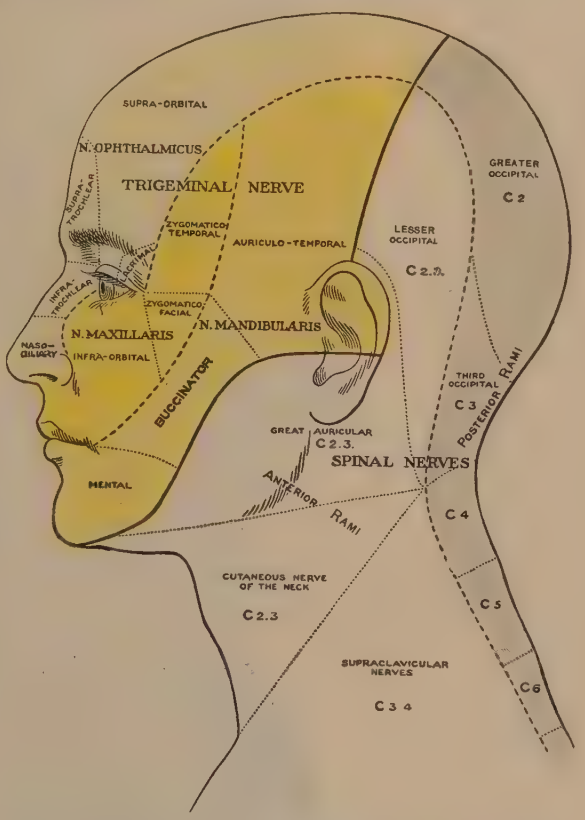

Fig. 602.—Distribution of Cutaneous Nerves to the Head and Neck.

The **great auricular nerve** is the largest of the cutaneous branches. It arises from the second and third cervical nerves (or, more rarely, from the third alone). Winding round the posterior border of the sterno-mastoid muscle, it courses vertically upwards towards the ear. In this course it crosses the sterno-mastoid muscle obliquely and is covered by the platysma muscle. Before arriving at the ear it subdivides into mastoid, auricular, and facial branches. The **mastoid branches** ascend over the mastoid process and supply the skin of the scalp behind the ear, communicating with the lesser occipital and posterior auricular nerves. The **auricular branches** ascend to the ear and supply the lower part of the auricle on both aspects; they communicate with the same nerves. The **facial branches,** passing over the angle of the mandible and through the substance of the parotid gland, supply the skin of the cheek over the inferior part of the masseter muscle and the parotid gland. They communicate with branches of the facial nerve in the parotid gland.

The **nervus cutaneus colli** arises from the second and third cervical nerves. It winds round the posterior border of the sterno-mastoid muscle, and crosses the muscle to reach the anterior triangle, under cover of the platysma muscle and the external jugular vein. It divides near the anterior edge of the sterno-mastoid muscle into superior and inferior branches, which are distributed through the platysma to the skin covering the anterior triangle of the neck. The upper branches communicate freely beneath the platysma with the cervical branch of the facial nerve.

Descending (supra-clavicular) Branches.—By the union of two roots derived from the third and fourth cervical nerves a considerable trunk is formed, which emerges from under cover of the sterno-mastoid muscle and extends obliquely

downwards through the inferior part of the posterior triangle of the neck. It subdivides into radiating branches—**anterior, middle,** and **posterior**—which pierce the deep fascia of the neck above the clavicle, and are distributed to the skin of the inferior part of the side of the neck, to the front of the chest, and the shoulder. The **anterior branches** are the smallest. Passing over the medial end of the clavicle, they supply the skin of the neck and chest as far down as the synchondrosis sternalis. The **middle branches** pass over the intermediate third of the clavicle, beneath the platysma, and can be traced as low as the third rib. The **posterior**

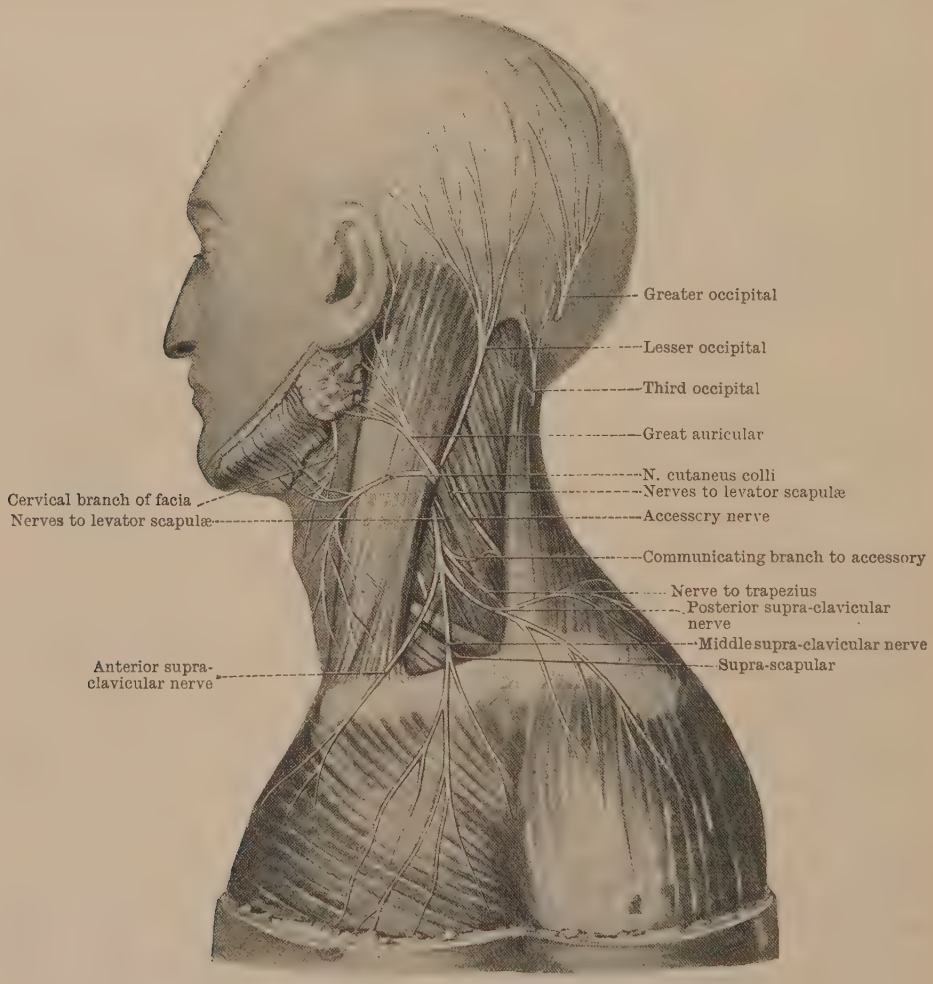

Fig. 603.—The Nerves of the Side of the Neck.

branches pass over or through the insertion of the trapezius muscle, and over the lateral third of the clavicle, to the shoulder, where they supply the skin as far down as the distal third of the deltoid muscle.

Deep Branches.—The deep branches of the cervical plexus are separated into a **lateral** and a **medial set** by their relation to the sterno-mastoid muscle. Beneath the muscle, the lateral branches are directed laterally towards the posterior triangle, and the medial branches pass medially towards the anterior triangle.

The **lateral branches** consist of muscular and communicating nerves, which for the most part occupy the posterior triangle.

The **muscular branches** are the following: (1) To the *sterno-mastoid,* from the second cervical nerve. This enters the muscle on its deep surface and communicates with the accessory nerve. (2) To the *trapezius,* from the third and fourth cervical

nerves. These nerves cross the posterior triangle and end in the trapezius, after having communicated with the accessory nerve, both in the posterior triangle, and under cover of the muscle. (3) To the *levator scapulæ*, from the third and fourth cervical nerves. Two independent branches enter the lateral surface of the muscle in the posterior triangle. (4) To the *scaleni* (medius and posterior), from the third and fourth cervical nerves.

The **communicating branches** are three in number. They join the accessory nerve in three situations: (*a*) A branch from the second cervical nerve to the

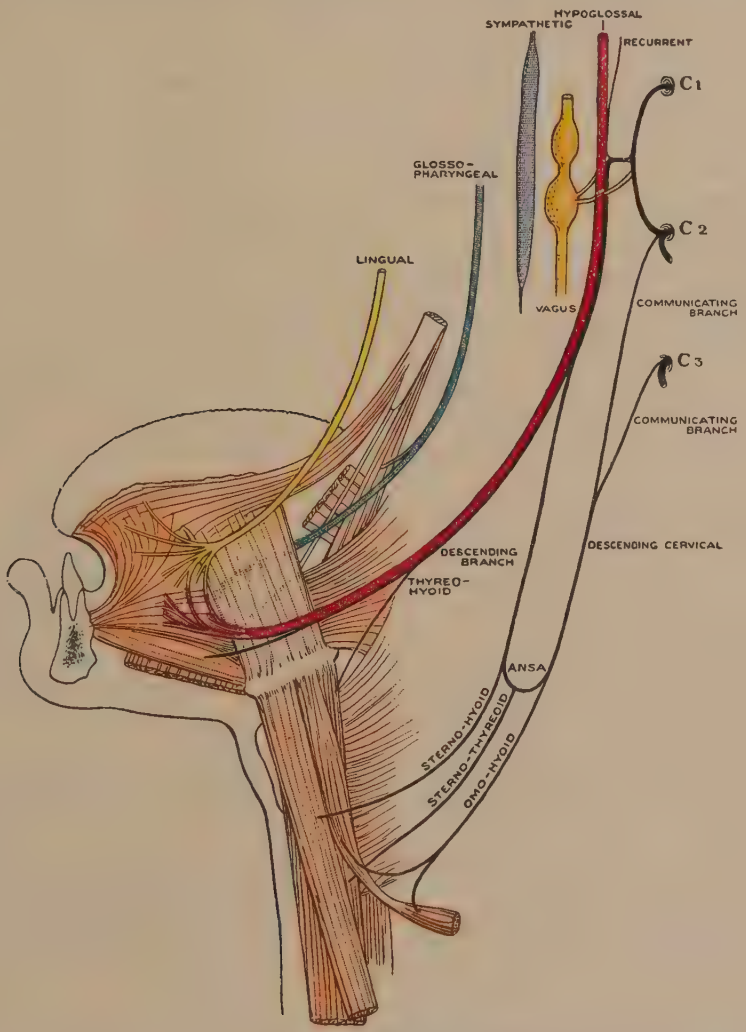

FIG. 604.—THE MUSCLES OF THE HYOID BONE AND STYLOID PROCESS, AND THE EXTRINSIC MUSCLES OF THE TONGUE, WITH THEIR NERVES.

sterno-mastoid joins the accessory nerve *under cover of that muscle.* (*b*) Branches to the trapezius from the third and fourth nerves are connected with the accessory nerve *in the posterior triangle.* (*c*) Branches from the same nerves join the nerve *under cover of the trapezius muscle.*

The **medial branches** of the plexus also comprise muscular and communicating branches. The first cervical nerve assists in the formation of this series of nerves, forming a slender loop with part of the second nerve in front of the transverse process of the atlas.

Communicating Branches.—(*a*) *With the sympathetic.*—Gray rami communicantes pass to each of the first four cervical nerves, near their origins, from the superior cervical ganglion or from the trunk below the ganglion. (*b*) *With the*

vagus nerve.—The ganglion nodosum of the vagus nerve may be connected by a slender nerve with the loop between the first two cervical nerves. This communication is not constant. (*c*) *With the hypoglossal.*—An important communication occurs between the hypoglossal nerve and the loop between the first and second cervical nerves (Fig. 601). A trunk from the loop joins the hypoglossal just beyond its exit from the skull. One fine branch from this trunk passes upwards along the hypoglossal nerve to the cranium (*meningeal branch*). The main part of the trunk accompanies the hypoglossal and separates from it to form successively three nerves—the **descendens hypoglossi**, and the **nerves to the thyreo-hyoid** and **genio-hyoid muscles.** The portion of the nerve which remains accompanies the hypoglossal to the muscles of the tongue. It is probable that no part of the hypoglossal nerve itself is concerned in the formation of these three branches. The descending branch of the hypoglossal descends in front of the internal and common carotid arteries, and is joined in the anterior triangle of the neck by the **descending cervical nerve,** to form the **ansa hypoglossi,** from which the infra-hyoid muscles are innervated. (The descending branch of the hypoglossal, in some cases, arises from the vagus nerve.)

Muscular Branches.—The muscles supplied by the medial branches of the plexus are the prevertebral muscles, the genio-hyoid and the infra-hyoid muscles, and the diaphragm.

(*a*) **Prevertebral Muscles.**—(1) From the loop between the first and second cervical nerves a small branch arises, for the supply of the rectus capitis lateralis, longus capitis, and the rectus capitis anterior. (2) From the second, third, and fourth nerves small branches supply the inter-transverse, longus colli, and longus capitis muscles. (3) From the fourth nerve a branch arises for the upper part of the scalenus anterior.

(*b*) **Genio-hyoid and Infra-hyoid Muscles.**—The **descending cervical nerve** is formed in front of the internal jugular vein by the union of two slender trunks from the second and third cervical nerves (communicantes hypoglossi). It forms a loop of communication in front of the carotid sheath with the descending branch of the hypoglossal nerve (derived ultimately from the first two cervical nerves). This loop of communication is called the **ansa hypoglossi.** It is often plexiform; and from it branches are given to the sterno-hyoid and sterno-thyreoid muscles, and both bellies of the omo-hyoid muscle. The nerve to the sterno-hyoid muscle is often continued behind the sternum, to join, in the thorax, with the phrenic nerve or the cardiac plexus.

The thyreo-hyoid and genio-hyoid muscles are supplied by branches of the hypoglossal nerve, which are also traceable back to the communication between the hypoglossal and the first two cervical nerves.

The anterior muscles in immediate relation to the median plane of the neck, between the chin and the sternum, are thus continuously supplied by the first three cervical nerves. The hypoglossal is the nerve of the muscles of the tongue, and it is not certain that it contributes any fibres to the above-named muscles.

(*c*) **Diaphragm.**—The phrenic nerve supplies the diaphragm.

Nervus Phrenicus.

The **phrenic nerve** is derived mainly from the fourth cervical nerve, reinforced by roots from the third (either directly or through the nerve to the sterno-hyoid) and fifth (either directly or through the nerve to the subclavius muscle). It runs downwards in the neck upon the scalenus anterior muscle; at the root of the neck it passes between the subclavian artery and vein, enters the thorax and traverses the mediastinum to reach the diaphragm, lying in the middle mediastinum between the pericardium and pleura, and anterior to the root of the lung. In its course it presents certain differences on the two sides. In the neck, on the left side, it crosses the first part of the subclavian artery; on the right side it crosses the second part. In the superior mediastinum, on the left side, it lies between the left subclavian and carotid arteries, and crosses the vagus nerve and the aortic arch. On the right side it accompanies the innominate vein and superior

vena cava, and is entirely separate from the vagus nerve. The left nerve is longer than the right, owing to the position of the heart and the left half of the diaphragm. The right nerve sends fibres along the inferior vena cava through the foramen venæ cavæ. Reaching the diaphragm the nerve separates into numerous branches for the supply of the muscle; some enter its thoracic surface (sub-pleural branches), but most of the fibres supply it after piercing the muscle (sub-peritoneal branches). It appears possible, from clinical observations, that the nerve contains some sensory fibres as well as motor.

The **branches of the phrenic nerve** are: (1) Muscular (to the diaphragm); (2) pleural; (3) pericardiac; (4) inferior vena-caval; (5) suprarenal; and (6) hepatic.

The branches to the pleura and pericardium arise as the phrenic nerve traverses the mediastinum. The branches to the inferior vena cava, suprarenal gland, and liver arise after communication of the phrenic nerve with the diaphragmatic plexus of the sympathetic on the abdominal surface of the diaphragm.

Communications of the Phrenic Nerve.—(1) The phrenic nerve may communicate with the nerve to the subclavius muscle. (2) It may communicate with the *ansa hypoglossi*, or a branch from it (the nerve to the sterno-hyoid). (3) It frequently communicates with the cervical part of the sympathetic. (4) It communicates with the cœliac plexus by a junction upon the abdominal surface of the diaphragm with the *diaphragmatic plexus* on the inferior phrenic artery, in which a small *diaphragmatic ganglion* is found on the right side. From this junction branches are given off to the inferior vena cava, suprarenal gland, and hepatic plexus.

Morphology of the Cervical Plexus.

The characteristic feature of the cervical plexus is the combination of parts of adjacent nerves into compound nerve-trunks by the formation of series of loops. The result of the formation of these loops is that parts (particularly cutaneous areas) are supplied by branches of more than one spinal nerve.

A. **Cutaneous Distribution.**—By the combinations of the nerves into loops the discrimination of the elements in the upper cervical nerves, corresponding to the lateral and anterior rami of a typical thoracic nerve, is made a matter of some difficulty. The second, third, and fourth nerves, through the cervical plexus, supply an area of skin extending, laterally, from the side of the head to the shoulder; anteriorly, from the face to the level of the third rib. The higher nerves supply the upper region (second and third); the lower nerves supply the lower region (third and fourth). It is not possible to compare the individual nerves strictly with the lateral and anterior rami of a thoracic nerve. A line drawn from the ear to the middle of the clavicle separates, however, a lateral from an anterior cutaneous area; and certain of the cutaneous nerves fall naturally into one of these two categories. The nerves homologous with anterior rami of intercostal nerves are the n. cutaneus colli and the anterior branches of the supra-clavicular series; those homologous with lateral branches are the smaller occipital and posterior supra-clavicular branches. The great auricular and middle supra-clavicular branches are mixed nerves, comprising elements belonging to both sets.

B. **Muscular Distribution.**—The nerves from the cervical plexus supplying muscles are simpler in their arrangement. They are not generally in the form of loops, and they are easily separated into lateral and anterior series. The lateral nerves comprise the branches to the rectus capitis lateralis, sterno-mastoid, trapezius, levator scapulæ. The nerves in the anterior series are those to the longus capitis, rectus capitis anterior, the hyoid muscles, and the diaphragm.

It is noteworthy that the last-named muscles—genio-hyoid, thyreo-hyoid, sterno-hyoid, omo-hyoid, sterno-thyreoid, and diaphragm—are continuously supplied by branches from the first five cervical nerves: the higher muscles by the higher nerves; the lower muscles by the lower nerves.

PLEXUS BRACHIALIS.

The **Brachial Plexus** is formed by the anterior rami of the fifth, sixth, seventh, and eighth cervical nerves, along with the greater part of the first thoracic nerve. In over half the number of cases a slender branch of the fourth cervical nerve is also engaged; and the second thoracic nerve also, in all cases, contributes to the innervation of the arm, through the intercosto-brachial nerve. In many cases it contributes also directly to the plexus, by an intra-thoracic communication with the first thoracic nerve.

Position of the Plexus.—The nerves forming the brachial plexus appear in

the posterior triangle of the neck between the scalenus anterior and scalenus medius muscles in series with the nerves forming the cervical plexus. Here the plexus is covered by the skin, platysma, supraclavicular nerves, and the deep fascia, and is crossed by the nerve to the subclavius muscle, external jugular vein, posterior belly of the omohyoid muscle, and the transverse cervical artery, which vessel sometimes passes between its branches. At the root of the neck the plexus passes behind the clavicle, subclavius muscle, and transverse scapular vessels; it lies above and behind the third part of the subclavian artery. In the axilla its branches surround the first part of the axillary artery.

Composition of the Brachial Plexus.—Whilst liable to some variation in

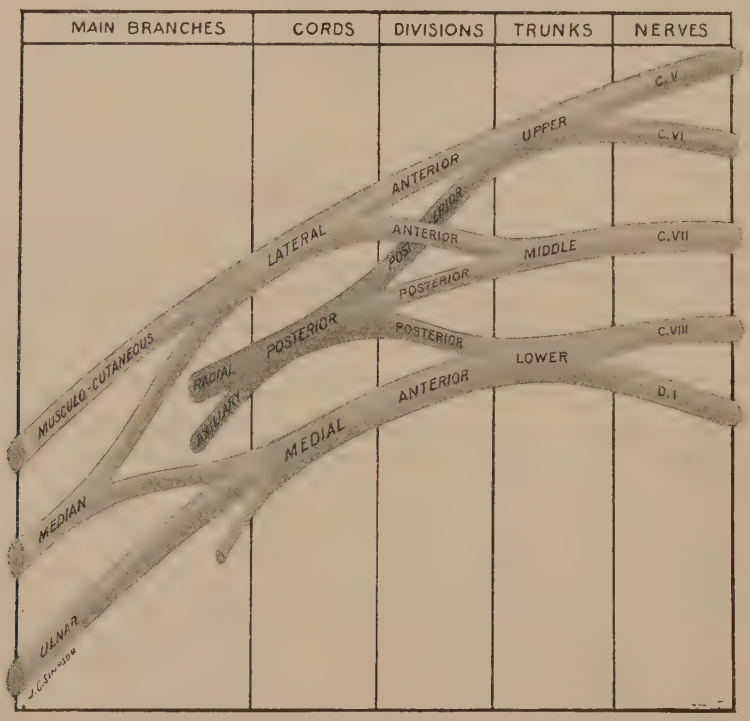

FIG. 605.—SCHEME TO SHOW THE STAGES OF FORMATION OF THE BRACHIAL PLEXUS.

the sequence of separation and junction of its individual parts, in a typical plexus four stages may always be identified:—

(1) The undivided anterior rami of the nerves.
(2) The formation of three trunks.
(3) The separation of each trunk into an anterior and a posterior division.
(4) The union of the divisions to form three cords, from which the nerves of distribution originate.

(1) The undivided **nerves** have only a very short independent course at the side of the neck whilst passing between the scalene muscles.

(2) Immediately after entering the posterior triangle, there are formed three **trunks** in order from above downwards: the upper trunk is formed by the union of the fifth and sixth nerves together; the middle trunk is always formed by the seventh nerve alone; and the lower, by the union of the eighth cervical and first thoracic nerves. This lower trunk grooves the upper surface of the first rib and lies in the sulcus subclaviæ.

(3) Each trunk divides into anterior and posterior **divisions**, which represent corresponding separation of the nerves; sometimes the nerves themselves divide before or during the formation of the trunks, rendering identification of these two stages difficult. The anterior and posterior divisions of the fifth, sixth, and

seventh nerves are nearly equal in size; the posterior division of the eighth cervical nerve is much smaller; and that of the first thoracic nerve is minute and may not be present at all. This division is of morphological significance, since it indicates the separation of the nerve fibres destined for the supply of the ventral parts of the limb from those which supply the dorsal parts.

(4) The **cords** (fasciculi) of the plexus are formed by combinations of the anterior and posterior divisions. They are three in number, and lie in relation to the axillary artery. The lateral cord is formed by union of the anterior divisions of the upper and middle trunks, or of the fifth, sixth, and seventh nerves, and lies on the lateral side of the axillary artery. The medial cord is formed by the anterior division of the lower trunk, comprising the corresponding division of the eighth nerve with the part of the first thoracic nerve engaged in the formation of the plexus; it lies on the medial side of the axillary artery. The posterior cord is made up of the posterior divisions of all three trunks, that is, of the fifth, sixth, seventh, and eighth cervical and first thoracic nerves, and

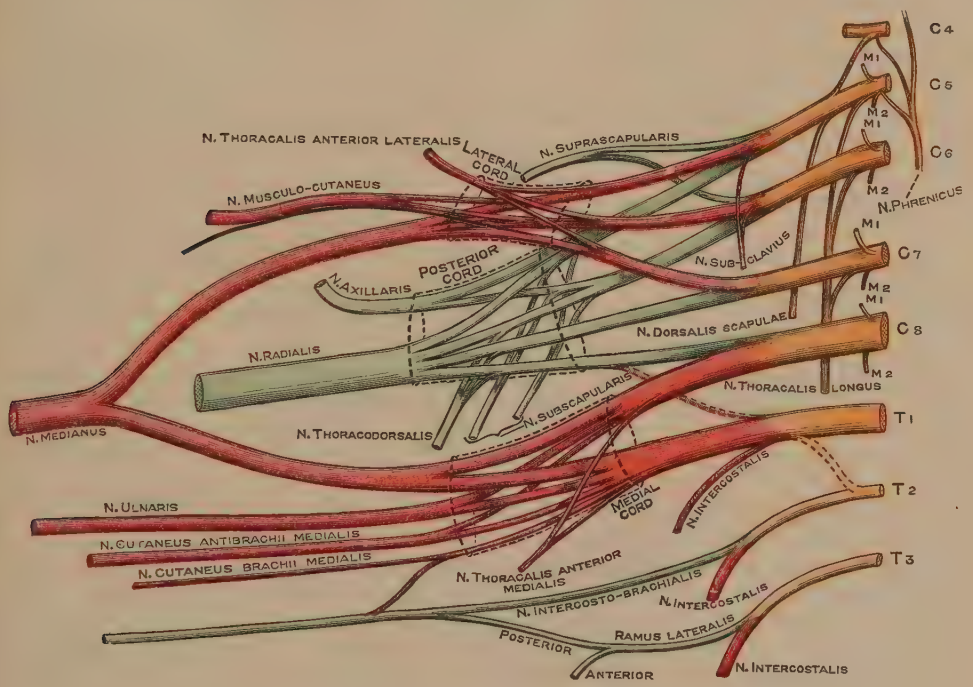

Fig. 606.—The Origins of the Nerves of the Brachial Plexus.

lies behind the axillary artery. The first thoracic nerve may not contribute to the posterior cord, and the branch, when present, is a very small nerve.

The **nerves of distribution** for the shoulder and arm are derived from these cords, and receive in this way various contributions from the constituent spinal nerves. *From the lateral cord* arise the lateral anterior thoracic and musculo-cutaneous nerves, and the lateral head of the median nerve. *From the medial cord* arise the medial head of the median nerve, the ulnar nerve, medial cutaneous nerve of the forearm, medial cutaneous nerve of the arm, and the medial anterior thoracic nerve. *From the posterior cord* arise the axillary nerve, the two sub-scapular nerves, the thoraco-dorsal nerve, and the radial nerve.

It is to be remembered that, although derived from a cord formed by a certain set of spinal nerves, any given nerve does not necessarily contain fibres from all the constituent nerves; *e.g.*, both the musculo-cutaneous and axillary nerves, from the lateral and posterior cords respectively, are ultimately derived only from the fifth and sixth cervical nerves. In other words, the cords are merely collections of nerves of distribution bound together in a common sheath in their passage through the axilla. It may also be pointed out that it is

impossible in nearly all cases to dissect out and trace the fibres of a given spinal nerve through the plexus to their ultimate distribution, owing to the complex manner in which the nerve bundles interlace and join one another.

Communications with the Sympathetic.—The lower four cervical nerves communicate with the cervical portion of the sympathetic by means of **gray rami communicantes.** Two branches arise from the middle cervical ganglion, and join the anterior rami of the fifth and sixth nerves. Two arising from the inferior cervical ganglion join the seventh and eighth nerves. They reach the nerves either by piercing the prevertebral muscles or by passing round the border of the scalenus anterior muscle.

Variations are found (1) in the number of nerves taking part in the formation of the plexus; and (2) in the pattern formed by the union and division of its constituent parts. (1) As regards the former, Kerr, on an examination of 175 plexuses, forms three groups: (*a*) a part of the fourth nerve joins the plexus in nearly two-thirds of cases; (*b*) no contribution is received from the fourth nerve, but all the fifth joins the plexus in one-third of cases; (*c*) a part only of the fifth enters the plexus in about 7 per cent. of cases. At the lower end of the plexus there is an intra-thoracic communication between the second and first thoracic nerves in one-third or more of cases. These figures indicate a higher or lower position of the plexus relative to the spinal column, though it is evidently subject to very slight variation. The presence of a cervical rib may coincide with little or no change in the relation of the nerves. (2) Variations in the pattern of the plexuses are due to (*a*) the stage of either trunk, divisional or even cord formation being absent in one or other part of the plexus, prior to a succeeding stage; in all such cases, however, there is no alteration in the typical nerve source of the ultimate terminal branches; (*b*) in very few cases the lateral or the medial cord may receive fibres from nerves below the seventh or above the eighth, respectively—that is, a new element is introduced into their composition.

The Branches of the Brachial Plexus.

It is customary to separate artificially the nerves of distribution of the brachial plexus into two sets: (1) supra-clavicular and (2) infra-clavicular, a topographical division which is to some extent affected by the alteration in position of the bone in raising or lowering the shoulder.

The point of junction of the three posterior divisions of the trunks to form the posterior cord has been found fairly constantly situated 6·75 cm., or $2\frac{3}{4}$ inches, horizontally lateralwards, from the lateral border of the common carotid artery at the root of the neck, the arm being fully abducted; a vertical line passing through this point separates the trunks from the cords (Linell).

Clinically it is important to realise the position of origin of the nerves relative to the different stages of formation of the plexus. (*a*) The nerves to the prevertebral muscles, the communication with the phrenic, the dorsal scapular, and long thoracic nerves, arise from the *anterior rami* of the nerves involved in the plexus. (*b*) The supra-scapular and the nerve to the subclavius arise at the level of formation of the *trunks*. (*c*) The anterior thoracic, subscapular, and thoraco-dorsal nerves arise from the *cords*, prior to their ultimate subdivision into the nerves of distribution for the upper limb. (*d*) All the rest of the branches of the plexus arise from the *cords* subsequent to this last point.

Pars Supraclavicularis.—The nerves derived from the plexus above the level of the clavicle are, like the main trunks, divisible into two series: **anterior branches**, arising from the front of the plexus; **posterior branches**, arising from the back of the plexus (Fig. 606, p. 729).

(*a*) *Arising from the rami.*

Anterior Branches.	Posterior Branches.
1. Nerves to scalenus anterior and longus colli.	1. Nerves to scalenus medius and scalenus posterior.
2. Communicating nerve to join the phrenic nerve.	2. Dorsal (posterior) scapular nerve.
	3. Long thoracic nerve.

(*b*) *Arising from the trunks.*

3. Nerve to the subclavius muscle.	4. Supra-scapular nerve.

The **muscular twigs** to the anterior scalene and longus colli muscles arise from the lower four cervical nerves, as they emerge from the intervertebral foramina.

The **communicating branch to the phrenic nerve** arises usually from the fifth cervical nerve at the lateral border of the anterior scalene muscle. It is sometimes absent, and occasionally an additional root is present from the sixth cervical nerve. In some instances the nerve is replaced by a branch which springs from the nerve to the subclavius, and passes medially behind the sterno-mastoid muscle to join the phrenic at the inlet of the thorax.

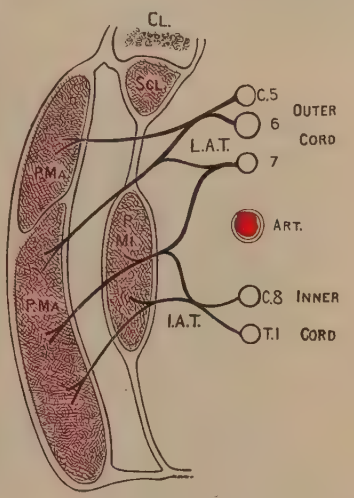

FIG. 607.—DIAGRAM OF THE ORIGIN AND DISTRIBUTION OF THE NERVES TO THE PECTORAL MUSCLES.

L.A.T., Lateral anterior thoracic nerve; I.A.T., Medial anterior thoracic nerve; C.5, 6, 7, C.8, T.1, Nerves of the brachial plexus; ART., Axillary artery; CL., Clavicle; SCL., Subclavius muscle; P.MI., Pectoralis minor, joined to subclavius by costo-coracoid membrane; P.MA., Pectoralis major.

N. Subclavius.—The **nerve to the subclavius** is a slender nerve, which arises from the front of the upper trunk, of the plexus, and usually receives fibres from the fourth, fifth, and sixth cervical nerves. It descends in the posterior triangle of the neck anterior to the third part of the subclavian artery. It often communicates with the phrenic nerve.

The **branches to the scalenus medius and scalenus posterior** are small trunks which arise from the lower four cervical nerves as they emerge from the intervertebral foramina.

N. Dorsalis Scapulæ. — The **dorsal scapular nerve** arises from the back of the fifth cervical nerve, as it emerges from the intervertebral foramen. It appears in the posterior triangle of the neck, after piercing the scalenus medius muscle. It is directed downwards, under cover of the levator scapulæ and rhomboid muscles, and along the vertebral margin of the scapula, to be distributed to the levator scapulæ, rhomboideus minor, and rhomboideus major muscles. It occasionally pierces the levator scapulæ.

N. Thoracalis Longus.—The **long thoracic nerve** arises by three roots, of which the middle one is usually the largest, from the back of the fifth, sixth, and seventh nerves, as they emerge from the intervertebral foramina. The nerve pierces the scalenus medius as two trunks, of which the lower represents the contribution from the seventh cervical nerve, and, descending along the side of the neck behind the cords of the brachial plexus, it enters the axilla between the superior edge of the serratus anterior muscle and the axillary artery. It continues its downward course over the axillary surface of the serratus, to the slips of which it is distributed.

There is a more or less definite relation between the roots of this nerve and the parts of the serratus muscle. The first part of the muscle is innervated by the fifth nerve alone; the second part by the fifth and sixth, or the sixth alone; the third part by the sixth and seventh, or the seventh nerve alone.

N. Suprascapularis.—The **supra-scapular nerve** arises from the back of the upper trunk of the plexus, receiving fibres from the fourth, fifth, and sixth cervical nerves. It occupies a position above the main cords of the brachial plexus, and courses downwards and laterally parallel to them towards the superior margin of the scapula. It passes through the scapular notch to reach the dorsum of the scapula. After supplying the supra-spinatus muscle it winds round the great scapular notch in company with the transverse scapular artery and terminates in the infra-spinatus muscle. It also supplies articular branches to the back of the shoulder-joint.

Pars Infraclavicularis.—The so-called infra-clavicular branches of the brachial plexus all arise from the *cords* of the plexus and are distributed to the chest,

shoulder, arm and forearm. According to their origin they are divisible into two sets—an **anterior set,** derived from the lateral and medial cords, and a **posterior set,** derived from the posterior cord. In their distribution the same arrangement is maintained. The anterior nerves of distribution, springing from the lateral and medial cords, supply the chest and the front of the limb; the posterior nerves, springing from the posterior cord, supply the shoulder and the back of the limb.

(c) and (d) Arising from the cords.

Anterior Branches.

From the Lateral Cord.	**From the Medial Cord.**
Lateral anterior thoracic.	Medial anterior thoracic.
Median (lateral head).	Median (medial head).
Musculo-cutaneous.	Ulnar.
	Medial cutaneous nerve of forearm (O.T. internal cutaneous).
	Medial cutaneous nerve of arm (O.T. lesser internal cutaneous).

Posterior Branches.

Axillary nerve.
Radial nerve.
Two subscapular nerves.
Thoraco-dorsal nerve.

Nervi Thoracales Anteriores.

The **anterior thoracic nerves** are two in number, lateral and medial. The **lateral anterior thoracic nerve** arises from the anterior divisions of the fifth, sixth, and seventh cervical nerves just before they form the lateral cord of the plexus. The **medial anterior thoracic nerve** arises from the medial cord of the plexus, immediately after its formation, receiving fibres from the eighth cervical and first thoracic nerves. They course downwards and forwards, one on each side of the axillary artery, and a loop of communication is formed between them in front of the artery. They are finally distributed to the pectoralis major and minor muscles (Fig. 607).

The nerves are distributed to the pectoral muscles in the following way. Two sets of branches from the lateral anterior thoracic nerve pierce the costo-coracoid membrane. The superior branches supply the *clavicular part* of the pectoralis major; the inferior branches are distributed to the superior fibres of the *sternal portion* of the muscle. The superior branches come from the fifth and sixth cervical nerves; the inferior branches, from the fifth, sixth, and seventh nerves. The *pectoralis minor* is pierced by two sets of nerves—the superior set is derived from the loop of communication between the two anterior thoracic nerves over the axillary artery; the inferior set is derived from the medial anterior thoracic nerve alone. These nerves supply the *pectoralis minor* muscle, and, after piercing it, supply the *sternal part* of the pectoralis major. The inferior nerve, in many cases, sends its branches to the pectoralis major round the inferior border of the pectoralis minor, and on its way it may supply the *axillary arches,* if present. These two branches are derived—the superior from the seventh and eighth cervical, and first thoracic nerves; the inferior from the eighth cervical and first thoracic nerves. The pectoral muscles are thus both supplied by the two anterior thoracic nerves. The clavicular fibres of the pectoralis major are innervated by the fifth and sixth nerves; the sternal fibres, from above downwards, by the fifth, sixth, seventh, and eighth cervical, and first thoracic nerves; and the pectoralis minor is supplied by the seventh and eighth cervical, and first thoracic nerves.

Nervus Musculocutaneus.

The **musculo-cutaneous nerve** takes origin from the lateral cord of the plexus, from the fifth and sixth cervical nerves, and also from the fourth in over half the number of cases (Fig. 606). The **nerve to the coracobrachialis muscle,** arising from

the seventh or sixth and seventh nerves, is usually associated with it. Separating from the lateral head of the median nerve, the musculo-cutaneous nerve lies at first between the coracobrachialis muscle and the axillary artery. It is then directed distally between the two parts of the coracobrachialis, and passes between the biceps and brachialis muscles, to the bend of the elbow. It pierces the deep fascia over the front of the elbow, between the biceps and brachioradialis, and terminates as the lateral cutaneous nerve for the supply of the lateral aspect of the forearm. In its course it may send a branch under the biceps to join the median nerve.

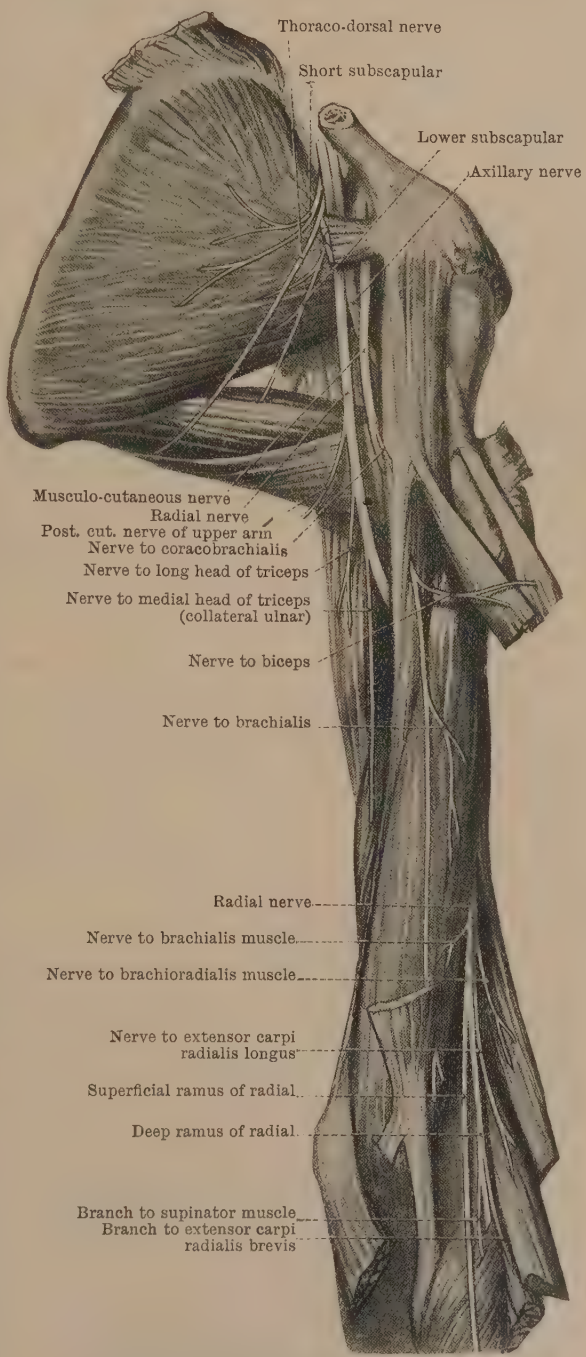

FIG. 608.—THE DEEPER NERVES OF THE ARM.

The branches of the nerve are muscular and cutaneous. The **muscular branches** are supplied to the two heads of the biceps and the brachialis, as the nerve lies between the muscles. The nerve to the coracobrachialis (usually incorporated with the trunk of the musculo-cutaneous nerve) has an independent origin from the seventh or sixth and seventh nerves (possibly the fifth also). It is usually double, one branch entering each portion of the muscle. The **lateral cutaneous nerve of the forearm** divides into volar and dorsal branches (Fig. 616, p. 733). The **volar branch** runs distally along the front of the lateral aspect of the forearm to the wrist, and supplies an area extending medially to the middle line of the forearm anteriorly, and distally so as to include the ball of the thumb. It usually communicates, proximal to the wrist, with the superficial ramus of the radial nerve, and supplies branches to the radial artery. The **dorsal branch** passes backwards and distally over the extensor muscles and supplies the skin on the lateral aspect of the forearm posteriorly in its proximal three-fourths, communicating with the cutaneous branches of the radial nerve. It sometimes extends on to the dorsum of the hand, supplying the skin over the first metacarpal bone.

In addition to the above branches, the musculo-cutaneous nerve supplies in many cases the following small twigs in the arm: (1) a medullary branch to the humerus;

(2) a periosteal branch to the distal end of the humerus on its anterior surface; and (3) a branch to the brachial artery.

Nervus Medianus.

The **median nerve** arises by two heads—one from the lateral cord, the other from the medial cord of the brachial plexus. The lateral head, from the (fifth), sixth, and seventh nerves, descends along the lateral side of the axillary artery; the medial head, from the eighth cervical and first thoracic nerves, crosses the end of the axillary artery or the beginning of the brachial artery, to join the other head in the proximal part of the arm. It therefore receives fibres from all the main nerves forming the plexus. Descending along the lateral aspect of the brachial artery, the nerve crosses over it obliquely in the distal half of the arm. In the hollow of the elbow, it lies on the medial side of the brachial artery, behind the lacertus fibrosus and the median basilic vein. It passes into the forearm between the two heads of the pronator teres muscle, separated from the ulnar artery by the deep origin of that muscle. Extending distally along the middle of the forearm, between the superficial and deep muscles, to the wrist, it enters the palm of the hand on the lateral side of the flexor tendons of the fingers, and deep to the transverse carpal ligament. In the hand, it spreads out at the distal border of the transverse carpal ligament, under cover of the palmar aponeurosis and superficial volar arch, and separates into its six terminal branches. In the forearm a small artery accompanies it—the median branch of the volar interosseous artery. Immediately proximal to the wrist it is comparatively superficial, lying on the lateral side of the superficial flexor tendons and directly behind the tendon of the palmaris longus.

Branches.—The median nerve usually gives off no branches in the (upper) arm.

Branches in the Forearm.—(1) **Articular Branches.**—Minute articular filaments are distributed to the front of the elbow-joint.

(2) **Muscular Branches.**—Just below the elbow a bundle of nerves arises to be distributed to the following muscles: pronator teres, flexor carpi radialis, palmaris longus, flexor digitorum sublimis. Nerves are also generally traceable from this bundle to the upper fibres of the flexor pollicis longus and flexor digitorum profundus. A separate branch to the index belly of the sublimis often arises in the lower half of the forearm. The nerve to the pronator teres, which is the first given off, often arises independently in the hollow of the elbow but seldom proximal to the joint.

(3) The **volar interosseous nerve of the forearm** (O.T. **anterior interosseous**) arises from the posterior surface of the median nerve in the forearm. It passes distally on the volar aspect of the interosseous membrane along with the volar interosseous artery, lies dorsal to the pronator quadratus muscle, and terminates by supplying articular filaments to the radio-carpal articulation. In its course the nerve supplies muscular branches to the flexor pollicis longus, the lateral half of the flexor digitorum profundus, and the pronator quadratus, minute medullary branches to the radius and ulna, and twigs to the periosteum and interosseous membrane.

(4) **Palmar Ramus.**—In the distal third of the forearm a small cutaneous branch arises, which pierces the deep fascia and crosses the transverse carpal ligament to reach the palm of the hand. It supplies the skin of the palm and communicates with a similar branch of the ulnar nerve. This branch is not always present.

Branches in the Hand.—In the hand the median nerve gives off its terminal branches. These are muscular and cutaneous.

The main **muscular branch** arises just distal to the transverse carpal ligament and passes to the base of the thenar eminence; entering the ball of the thumb superficially on the medial side, it supplies branches to the abductor pollicis brevis, opponens pollicis, and the flexor pollicis brevis.

The **cutaneous branches** are five in number. Three separate branches supply each side of the thumb and the lateral side of the index finger. The two remaining branches (*nn. digitales volares communes*) subdivide at the cleft between the

second and third, and the third and fourth fingers respectively, into branches (*nn. digitales volares proprii*) which supply the adjacent sides of the second and third, and the third and fourth fingers. From the nerves which supply respectively the lateral side of the index finger, and the contiguous sides of the index and third fingers, fine muscular branches arise for the first two lumbrical muscles. The cutaneous branches of the median nerve are placed in the palm between the superficial palmar arch and the flexor tendons. They become superficial at the roots of the fingers between the slips of the palmar aponeurosis, or, in

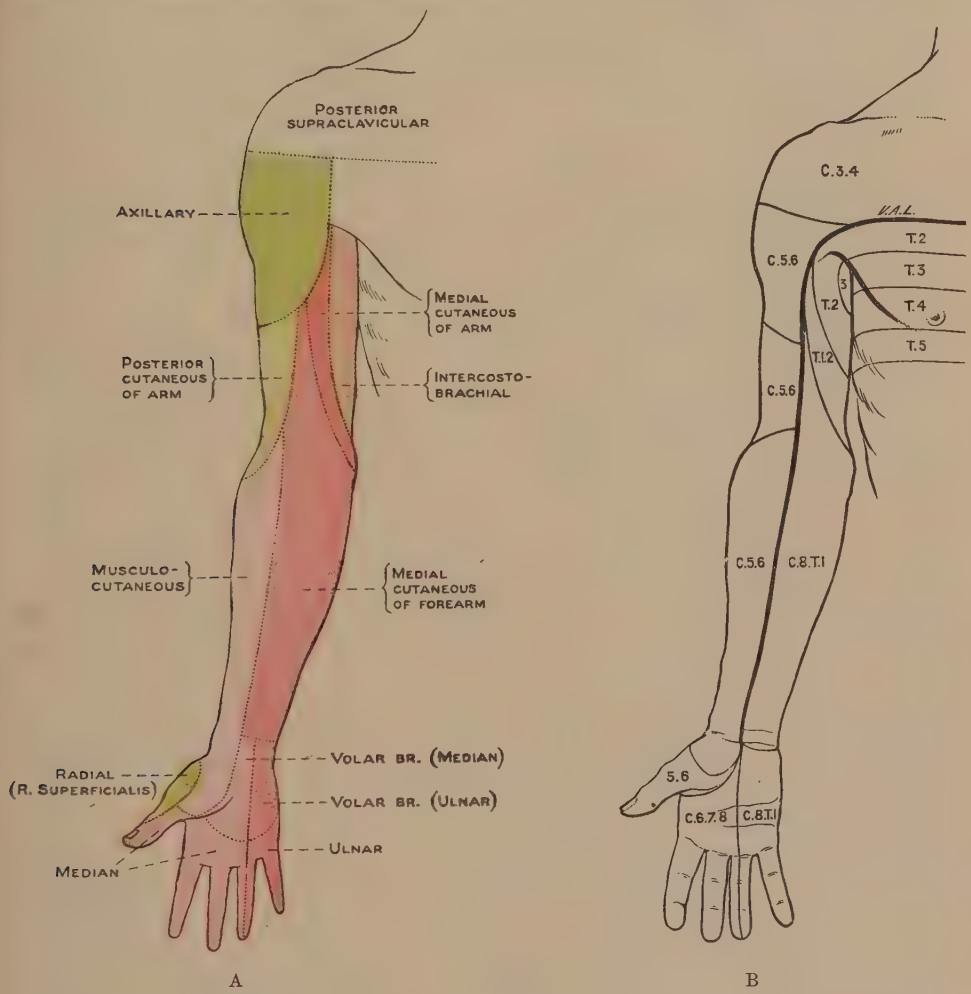

FIG. 609.—THE DISTRIBUTION OF CUTANEOUS NERVES ON THE FRONT OF THE ARM AND HAND.

B is a schematic representation of the areas supplied by the above nerves, the lettering indicating the spinal origin of the branches of distribution to each area. V.A.L., Ventral axial line.

the case of the nerves to the thumb and lateral side of the index finger, at the lateral edge of the central portion of the palmar aponeurosis. In the fingers they are placed superficial to the digital arteries, and are distributed to the sides and volar aspects of the fingers. These volar branches, as in the case of the ulnar nerve, are beset with numerous Pacinian corpuscles. Each nerve supplies one or more *dorsal branches*, distributed to the skin on the dorsal aspect of the terminal phalanx of the thumb and the distal two phalanges of the first two and a half fingers, thus making up for the deficiency of the superficial branch of the radial nerve in those situations.

Communications.—(1) The median nerve, in some cases, receives a communicating branch from the musculo-cutaneous nerve in the arm. (2) It communicates in some

cases, in the proximal part of the forearm, with the ulnar nerve beneath the flexor muscles. (3) It communicates by means of its cutaneous branches with the ulnar nerve in the palm of the hand (*ramus anastomoticus cum nervo ulnari*).

Nervus Ulnaris.

The **ulnar nerve** arises from the medial cord of the brachial plexus, from the eighth cervical and first thoracic nerves. In over half the number of cases

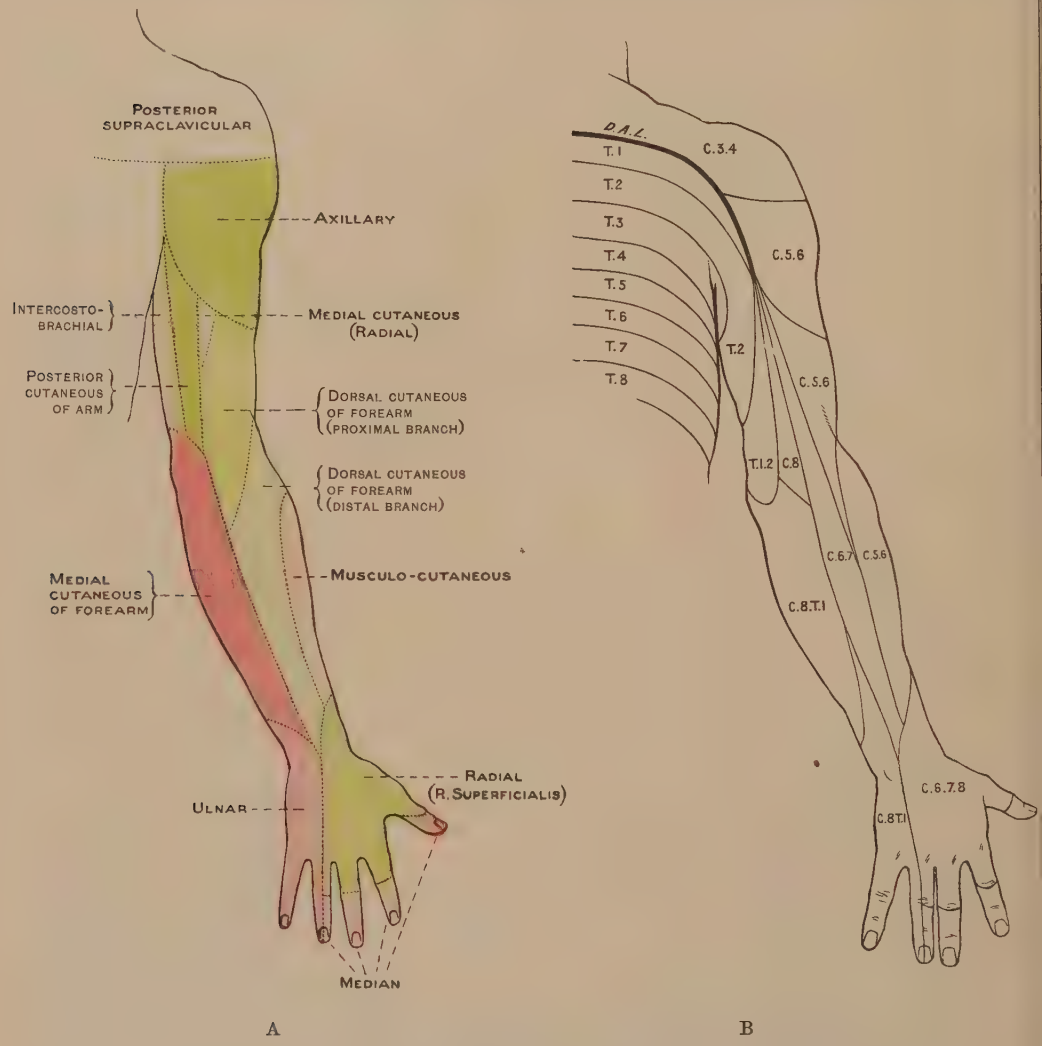

Fig. 610.—The Distribution of Cutaneous Nerves on the back of the Arm and Hand.

B is a schematic representation of the areas supplied by the above nerves, the lettering indicating the spinal origin of the branches of distribution to each area. D.A.L., Dorsal axial line.

it has also a root from the lateral cord of the plexus or from the lateral head of the median nerve (seventh cervical nerve). This *caput laterale nervi ulnaris* is subject to great variation in size. In the axilla the ulnar nerve lies between the axillary artery and vein, and behind the medial cutaneous nerve of the forearm; in the proximal half of the arm it lies on the medial side of the brachial artery anterior to the triceps muscle. In the distal half of the arm it is separated from the brachial artery; and passing behind the intermuscular septum, and in front of the medial head of the triceps in company with the superior ulnar collateral artery, it reaches the interval between the medial epicondyle of the humerus and the

olecranon. It is there protected by an arch of deep fascia stretching between the epicondyle and the olecranon. It enters the forearm between the humeral and ulnar origins of the flexor carpi ulnaris, and courses distally between the flexor carpi ulnaris and flexor digitorum profundus. In the distal half of the forearm it becomes comparatively superficial, lying on the medial side of the ulnar artery (to which it furnishes a supply) overlapped by the tendon of the flexor carpi ulnaris. Just proximal to the transverse carpal ligament, and lateral to the pisiform bone, it pierces the deep fascia, in company with the artery, and passes into the hand over the transverse carpal ligament. Reaching the palm it divides, under cover of the palmaris brevis muscle, into its two terminal branches, superficial and deep.

Branches.—The ulnar nerve gives off no branches till it reaches the forearm.

In **the forearm** it gives off articular, muscular, and cutaneous branches.

The **articular branch** is distributed to the elbow-joint and arises as the nerve passes behind the medial epicondyle of the humerus.

The **muscular branches** arise as soon as the nerve enters the forearm. They are distributed to the muscles between which the ulnar nerve lies—the flexor carpi ulnaris and the medial half of the flexor digitorum profundus. The flexor carpi ulnaris usually receives just below the elbow-joint two branches, one each to its olecranon and condylar heads; the latter may receive a secondary supply at a lower level, and even a fourth branch to the muscle may be found. Only in exceptional cases does one of these branches arise proximal to the elbow-joint (Linell).

The **cutaneous branches** are two in number, palmar and dorsal.

The **palmar cutaneous ramus** is variable in size and position. It pierces the deep fascia in the distal third of the forearm and passes to the hypothenar eminence and palm of the hand, to the skin over which it is distributed. It gives branches to the ulnar artery, and communicates often with the medial cutaneous nerve of the forearm and the palmar branch of the median nerve.

The **dorsal ramus of the hand** is much larger (Fig. 610). It arises from the ulnar nerve at a variable point in the middle third of the forearm; and, directed obliquely distally and backwards, beneath the tendon of the flexor carpi ulnaris, it becomes cutaneous on the medial side of the forearm in its distal fourth. It passes on to the back of the hand, and, after giving off branches to the skin of the wrist and hand which communicate with the superficial ramus of the radial nerve, it terminates in three *dorsal digital nerves*, to supply the little finger, the ring-finger, and half the middle finger in the following way: one branch courses along the medial side of the dorsum of the hand and supplies the little finger as far as the root of the nail; another branch subdivides at the cleft between the little and ring fingers to supply their adjacent sides to the same extent; a third branch bifurcates at the cleft between the ring and middle fingers, and supplies their adjacent sides, but only as far as the level of the proximal interphalangeal joints, the distal part of the surfaces being supplied by branches of the median overlapping from the palmar aspect. This last branch communicates with the superficial ramus of the radial nerve. The ulnar nerve in a less number of cases supplies only the little and half the ring fingers on their dorsal surfaces.

Ramus Volaris Manus.—*In the palm* the ulnar nerve supplies a small muscular branch to the palmaris brevis, and then subdivides into its terminal branches, which are named superficial and deep.

Ramus Superficialis.—The **superficial branch** is purely cutaneous; it passes distally deep to the palmar aponeurosis, and subdivides into a medial and a lateral branch. The medial branch courses along the medial border of the little finger, which it supplies on its palmar aspect. The lateral branch (*common volar digital nerve*) becomes superficial at the cleft between the fourth and fifth fingers, between the slips of the palmar aponeurosis, and subdivides into two branches (*proper volar digital nerves*) which supply the adjacent sides of these fingers on their palmar aspect. It communicates with the adjacent digital branch of the median nerve.

The ulnar nerve, therefore, usually supplies one and a half fingers on their palmar aspects and two and a half fingers on their dorsal aspects, the remaining fingers being supplied by the median nerve on the palmar, and the radial nerve on the dorsal surface. The median nerve further

extends on to the dorsal aspect of the terminal phalanx of the thumb and the distal two phalanges of the first two and a half fingers, so making up for the deficiency of the radial nerve in these regions. Clinical observations show this to be a much more common arrangement than the classical description of the distribution of the ulnar nerve to one and a half fingers on both their surfaces.

Ramus Profundus.—The **deep branch** is purely muscular. It separates from the superficial branch, and passes deeply between the flexor brevis and abductor digiti quinti muscles; it supplies those muscles and the opponens digiti quinti, and, turning laterally along the line of the deep palmar arch and under cover of the deep flexor tendons, it supplies branches to the following muscles: interossei, third and fourth lumbricales (on their deep surfaces), the adductor pollicis (oblique and transverse parts), and the *interosseus primus volaris* (deep part of the flexor pollicis brevis).

Communications.—The ulnar nerve communicates (1), in some cases, with the median nerve in the forearm; (2) with the medial cutaneous nerve of the forearm, and sometimes with the median nerve, by its palmar branch; (3) with the cutaneous part of the median nerve in the palm, by means of its terminal cutaneous branches; (4) with the superficial ramus of the radial nerve on the dorsum of the hand, by means of its dorsal branch.

Nervus Cutaneus Antibrachii Medialis.

The **medial cutaneous nerve of the forearm** (O.T. **internal cutaneous nerve**) arises from the medial cord of the brachial plexus, from the eighth cervical and first thoracic nerves (Figs. 606 and 729). In the axilla and proximal half of the arm it lies superficial to the main artery. It becomes cutaneous by piercing the deep fascia about the middle of the arm on its medial side, and accompanying the basilic vein through the distal half of the arm, it divides at the front of the elbow into its two terminal branches.

Branches.—In the arm, as soon as it becomes superficial, the nerve gives off a branch which supplies the skin of the distal half of the anterior surface of the arm on its medial side. At the elbow it divides into two terminal branches—*volar* and *ulnar*, which, crossing superficial or deep to the median basilic vein, are distributed to the medial side of the forearm.

The **volar branch** can be followed to the wrist and supplies the whole of the volar surface of the forearm in the medial half; the **ulnar branch** is not so large, and, passing obliquely backwards and distally over the origins of the pronator and flexor muscles, it is distributed to the proximal two-thirds or three-fourths of the dorsal aspect of the forearm on the medial side.

Communication.—The medial cutaneous nerve of the forearm communicates with the volar branch of the ulnar nerve in the distal part of the forearm.

Nervus Cutaneus Brachii Medialis.

The **medial cutaneous nerve of the arm** arises from the medial cord of the brachial plexus, and ultimately from the first thoracic nerve (Fig. 606, p. 729). It lies at first between the axillary artery and vein; and after descending over, under, or even, in some cases, through the axillary vein, it perforates the deep fascia and is distributed to the skin of the arm for the proximal half or more on its medial side.

The nerve varies considerably in size. It may be absent, its place being taken by branches of the intercosto-brachial or by branches from the posterior cutaneous branch of the radial nerve. It generally bears a distinct relation in size to the intercosto-brachial, due to the fact that the size of the latter depends upon the size of the part of the second thoracic nerve connected with the first in the thorax. If an intra-thoracic connexion occurs between the first and second thoracic nerves, the intercosto-brachial may be deprived of a certain number of its fibres, which in that case reach the upper limb through the medial cutaneous nerve of the arm. When traced up to the plexus the medial cutaneous nerve of the arm is found to have an origin from the posterior part of the cord formed by the eighth cervical and first thoracic nerves, and usually receives fibres from the first thoracic nerve only. In cases where "*axillary arches*" are present they may be supplied by this nerve.

Nervus Axillaris.

The **axillary nerve** (O.T. **circumflex**) at its origin is just below the suprascapular and comes from the same spinal nerves—the fifth and sixth cervical nerves (Fig. 606, p. 729). Extending distally and laterally behind the axillary artery, it leaves the axilla by passing round the lateral border of the subscapularis muscle, in company with the posterior circumflex artery of the humerus, in a quadrilateral space bounded by the humerus, subscapularis, triceps (long head), and teres major. Winding round the surgical neck of the humerus from medial to lateral side, it terminates by supplying the deltoid muscle (Fig. 611, p. 739).

Branches. — **Muscular branches** are supplied to the teres minor and deltoid muscles. It often gives off the lower subscapular nerve. The nerve to the teres minor enters the lateral aspect of the muscle; it possesses a pseudo-ganglion, a thickening of fibrous tissue, on its trunk.

Articular branches enter the posterior part of the capsule of the shoulder-joint.

A **cutaneous branch** of considerable size — *the lateral cutaneous nerve of the arm*—passes obliquely distally and forwards from beneath the deltoid muscle, becoming superficial at its posterior border. Sometimes branches pierce the muscle. It supplies the skin over the insertion of the deltoid and the proximal half of the arm on its lateral aspect (Figs. 609, p. 735, and 610, p. 736).

Fig. 611.—The Axillary and Radial Nerves.

Nervus Radialis.

The **radial nerve** (O.T. **musculo-spiral**) appears to be the continuation into the upper limb of the posterior cord of the brachial plexus. It usually takes origin from all the nerves which form the posterior cord —the fifth, sixth, seventh, and eighth cervical and first thoracic nerves (Fig. 606,

p. 729). In some cases the first thoracic contributes no fibres, and often the fifth cervical nerve is excluded from it. It extends from the axilla, round the back of the humerus, to the bend of the elbow, where it ends by dividing into its *superficial* and *deep* terminal branches.

In the axilla it lies behind the axillary artery, and in front of the subscapularis, teres major, and latissimus dorsi muscles.

In the arm, in the proximal third, it lies to the medial side of the humerus, behind the brachial artery, and upon the long head of the triceps. In the middle third of the arm it courses obliquely laterally and distally in the radial groove of the humerus, along with the profunda brachii artery, separating the long, lateral, and medial heads of the triceps muscle (Fig. 611, p. 739). In the distal third of the arm, piercing the proximal part of the intermuscular septum at the lateral border of the triceps muscle, it passes to the bend of the elbow in front of the lateral epicondyle of the humerus, in the interval between the brachio-radialis and brachialis muscles. Under cover of the former muscle, usually at the level of the lateral epicondyle of the humerus, it divides into its two terminal branches, the superficial and deep rami.

The **collateral branches** are in three sets, arising (*a*) on the medial side, (*b*) on the back, and (*c*) on the lateral side of the humerus (Fig. 612).

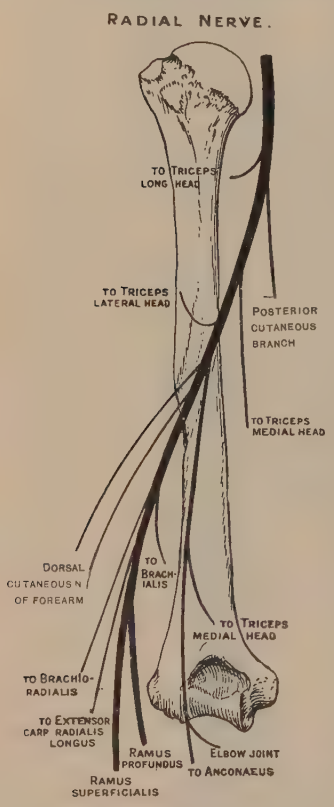

FIG. 612.—DIAGRAMMATIC REPRESENTATION OF THE BRANCHES OF THE RADIAL NERVE.

I. **Branches arising medial to the Humerus.**—1. **N. cutaneus brachii posterior.**—The posterior cutaneous nerve of the arm, arising in common with one of the following, or independently, pierces the fascia on the medial side of the arm near the axilla. It supplies the skin of the posterior surface of the arm in the proximal third, proximal and posterior to the area supplied by the medial nerve of the arm (Fig. 610, p. 736). This nerve varies in size, according to the bulk of the last named and the intercosto-brachial nerves.

2. **Rami Musculares.** — The muscular branches supply the triceps and anconæus. The triceps receives four distinct nerve supplies in the following order: (i.) to the long head, arising from the nerve in the axilla; (ii.) to the distal part of the medial head, arising near the lower border of the teres major, and termed the ulnar collateral nerve since it accompanies the ulnar nerve in the middle third of the arm; (iii.) to the lateral head, arising just distal to the last-mentioned branch; and (iv.) the main supply to the medial head, arising from the nerve just prior to its entry into the radial groove of the humerus. This last branch, after supplying the medial head of the triceps, passes through the muscle and behind the lateral epicondyle of the humerus to terminate in the anconæus muscle. All these branches, therefore, arise from the nerve above or just as it enters the radial groove; the only branch of any consequence arising from it in the groove is the dorsal cutaneous nerve of the forearm.

II. **Branches arising on the Posterior Surface of the Humerus.**—The **dorsal cutaneous nerve of the forearm** consists of two branches, proximal and distal. Arising from the radial nerve before it pierces the lateral intermuscular septum, these branches pierce the deep fascia close together on the lateral side of the arm in its distal half. Passing distally over the back of the lateral epicondyle, the *proximal branch* supplies the skin of the lateral side and posterior surface of the arm in its distal third, and the dorsal surface of the forearm in its proximal half. The *distal branch* supplies an area of skin on the dorsal surface of the forearm in the proximal two-thirds, medial to the area innervated by the musculo-cutaneous nerve (Fig. 610, p. 736).

III. **Branches arising at the Lateral Side of the Humerus.—Muscular Branches.**—The radial nerve, as it lies in the interval between the brachialis and brachio-radialis muscles, supplies nerves to the brachio-radialis (often double) and extensor carpi radialis longus. It may also provide the nerve to the extensor carpi radialis brevis; an inconstant branch is given to the brachialis, which would appear from electrical observations to be an afferent path.

Ramus Superficialis Nervi Radialis.

The **superficial ramus** (O.T. **radial nerve**) is entirely cutaneous in its distribution. Arising in the hollow of the elbow beneath the brachio-radialis, it courses distally under cover of that muscle through the proximal two-thirds of the forearm, and accompanies and supplies the radial artery in the middle third of the forearm. It then passes backwards, under cover of the tendon of the brachio-radialis, and pierces the deep fascia on the lateral aspect of the forearm in the distal third. It is distributed to the skin of the dorsum of the wrist, the lateral side and the dorsum of the hand, and the dorsum of the thumb and lateral two and a half fingers (Fig. 610, p. 736). Its branches communicate, on the ball of the thumb, with the musculo-cutaneous nerve, and, on the dorsum of the hand, with the dorsal branch of the ulnar nerve (*ramus anastomoticus ulnaris*). The **digital nerves** are small, and are five in number. They supply a very variable extent of the dorsum of the hand and fingers. Two pass to the back of the thumb and reach the level of the interphalangeal articulation. One supplies the lateral side of the index finger as far as the second phalanx. The remaining two branches divide at the clefts between the second and third, and third and fourth fingers respectively, and innervate the adjacent sides of those fingers as far as the second phalanx. The rest of the skin of those digits to the tips is supplied by digital branches of the median nerve. The nerve may only supply the thumb and one and a half fingers, being replaced by branches from the ulner nerve. From

clinical observations this last distribution would appear to be the more common, since in about 70 per cent. of cases the radial has been found not to extend medially beyond the second metacarpal bone (Stopford).

Ramus Profundus Nervi Radialis.

The **deep ramus** (O.T. **posterior interosseous nerve**) is entirely muscular and articular in its distribution. It arises, like the superficial ramus, under cover of the brachio-radialis muscle. Directed obliquely distally and backwards, it reaches the back of the forearm, after passing round the lateral aspect of the radius, by piercing the fibres of the supinator muscle (Fig. 613). On the dorsal surface of the forearm it is called the **dorsal interosseous nerve**, and is placed in the proximal part of its course beneath the superficial extensor muscles, and upon the supinator and abductor pollicis longus, along with the dorsal interosseous artery, to which it furnishes twigs. In the distal half of the forearm it passes under cover of the extensor pollicis longus, and lies upon the interosseous membrane. At the wrist it passes deep to the extensor tendons, on to the back of the carpus, where it terminates in a gangliform enlargement of small size, from which branches pass to the inter-carpal articulations. The nerve supplies the following branches:—

(1) Terminal **articular branches** to the carpal joints.

(2) **Muscular branches**, in its course through the forearm. Thus, on the lateral side of the radius, it supplies the extensor carpi radialis brevis and the supinator muscles before it enters the fibres of the last-named muscle. After emerging from the supinator it supplies a large bundle of nerves which enter the extensor digitorum communis, extensor digiti quinti proprius, and extensor carpi ulnaris, near their origins. At a more distal level the nerve gives off branches to the abductor pollicis longus, extensor pollicis longus and extensor pollicis brevis, and extensor indicis proprius.

Nervi Subscapulares.

There are two subscapular nerves (Figs. 606 and 608).

The **first or short subscapular nerve** is often double, and there may be three trunks present. It arises from the posterior cord of the plexus behind the axillary nerve, and comes from the fifth and sixth cervical nerves (often from the fourth and seventh in addition). It passes downwards behind the axillary artery and enters the subscapularis muscle.

The **second, lower, or axillary subscapular nerve** also arises behind the axillary nerve from the posterior cord of the plexus (from the fifth and sixth cervical nerves). Its origin is distal and lateral to that of the first nerve; and it often arises in common with the axillary nerve. It courses downwards behind the axillary artery and the axillary and radial nerves, to the teres major muscle. It supplies branches to the lateral part of the subscapularis muscle and ends in the teres major.

Nervus Thoracodorsalis.

The **thoraco-dorsal nerve** arises from the back of the posterior cord of the plexus, behind the radial nerve, and from the sixth, seventh, and eighth cervical nerves, or from the seventh and eighth nerves only. It is directed distally and laterally between the two preceding nerves, behind the axillary artery and over the posterior wall of the axilla, in company with the subscapular artery, to the latissimus dorsi muscle, which it supplies on its anterior (deep) surface.

NERVI THORACALES.

The anterior rami of the **thoracic nerves** are twelve in number, each nerve emerging below the corresponding vertebra and rib. Eleven of the series are intercostal, the twelfth lying below the last rib. The first, second, third, and twelfth nerves present peculiarities in their course and distribution. The other

thoracic nerves, as already stated, are simple, and may be regarded as types both in course and distribution.

The anterior ramus of the **first thoracic nerve** is the largest of the series. It emerges from the vertebral canal below the neck of the first rib, and divides in the first intercostal space into two very unequal, superior and inferior parts. The *superior* and larger part ascends obliquely over the neck of the first rib, lying lateral to the arteria intercostalis suprema, and enters the neck behind the subclavian artery and the pleura. It proceeds laterally upon the scalenus medius muscle and enters into the formation of the brachial plexus, as already described.

The *inferior, intercostal part* of the nerve is much smaller in size. It courses

FIG. 614.—DIAGRAM OF THE ORIGIN AND DISTRIBUTION OF A TYPICAL SPINAL NERVE.

Note that the medial division of the posterior ramus is represented as distributed to skin, whilst the lateral division terminates at a deeper level in muscle; in some situations the reverse condition occurs. The medial and lateral divisions of all posterior rami supply muscles.

forwards in the first intercostal space and supplies the intercostal muscles. It usually gives off no anterior branch to the skin of the chest and no lateral cutaneous branch.

In some cases a lateral cutaneous branch emerges from the side of the first intercostal space. This may be derived from the first nerve, or it may be the **intercosto-brachial nerve**, *i.e.* the lateral branch of the second thoracic nerve. In many cases an anterior cutaneous branch perforates the first intercostal space and supplies the skin on the front of the chest. This branch, similarly, is sometimes traceable to the second thoracic nerve.

Communications.—Besides its junction with the eighth cervical to form the brachial plexus, the first thoracic nerve effects the following communications: (*a*) The last cervical or first thoracic ganglion of the sympathetic sends a *gray ramus communicans* to join the nerve on its appearance in the thorax. (*b*) The second thoracic nerve in a majority of cases communicates with the first. This communication varies considerably in size and distribution. It may reinforce the intercostal branch of the nerve, it may send one branch to the intercostal portion and another to the part of the nerve joining the brachial plexus, or it may consist of a nerve proceeding solely to join the brachial plexus by

a junction in the first intercostal space with the part of the first thoracic nerve, which is engaged in forming the plexus. (*c*) The first *white ramus communicans* in the thoracic region connects the first thoracic nerve with, as a rule, the stellate ganglion of the sympathetic trunk.

The anterior ramus of the **second thoracic nerve** is of large size, though much smaller than the first. It passes forwards in the second intercostal space, lying at first in the costal groove, between the external and internal intercostal muscles. At the level of the mid-axillary line it gives off a large lateral branch; continuing its course, it pierces the internal intercostal muscle and lies upon the pleura; finally, at the lateral border of the sternum, it passes forwards in front of the internal mammary artery and through the internal intercostal muscle, and the aponeurosis of the external intercostal muscle and pectoralis major, and ends by supplying the skin of the front of the chest over the second intercostal space.

The nerve supplies the following branches:—

1. **Muscular branches** to the muscles of the second intercostal space.
2. **Cutaneous branches.** (*a*) **Anterior terminal branches** to the skin over the second intercostal space (Fig. 615). (*b*) A large lateral cutaneous branch, the **intercosto-brachial** (O.T. **intercosto-humeral**) **nerve** (Fig. 609, p. 735). This nerve pierces the intercostal and serratus anterior muscles, and, crossing the axilla, extends to the arm. It pierces the deep fascia just beyond the posterior fold of the axilla, and can be traced as far as the interval between the medial epicondyle of the humerus and the olecranon. It supplies an area of skin stretching across the axilla and along the posterior surface of the arm on the medial side as far as the elbow (Fig. 609, p. 735). It may supply the axillary arches, when present.

The intercosto-brachial nerve varies in size. It may pierce the first intercostal space, and it is often divisible into anterior and posterior branches, like the lateral branch of an ordinary intercostal nerve.

Communications.—(1) The intercosto-brachial nerve communicates with two adjacent nerves. Either before or after piercing the fascia of the axilla it is joined by the medial cutaneous nerve of the arm. It also communicates with the posterior part of the lateral branch of the third intercostal nerve by means of the branches distributed to the floor and boundaries of the axilla. (2) Besides the branches referred to, the second thoracic nerve in many cases transmits a nerve to the brachial plexus, which becomes incorporated with the first thoracic nerve after passing over the neck of the second rib. This branch is inconstant. As already mentioned, it may join only the intercostal part of the first thoracic nerve, it may join the brachial plexus only, or it may send branches to both parts of the first thoracic nerve. (3) Besides the communications effected by branches of the second thoracic nerve in its course, it also receives a *gray ramus communicans* from the second thoracic ganglion of the sympathetic trunk in the thorax. It also sends to the sympathetic a *white ramus communicans*, probably the first, though this is not known with certainty.

The anterior ramus of the **third thoracic nerve** differs from a typical thoracic nerve only in one respect. Its **lateral branch** divides in the usual way into anterior and posterior parts, of which the latter is carried to the arm and supplies an area of skin on the medial side near the root of the limb. It effects a junction with the intercosto-brachial nerve (Fig. 615, p. 745).

The anterior rami of the **fourth, fifth, and sixth thoracic nerves** have a course and distribution which are simple and typical. Except for the peculiarities above mentioned, the second and third thoracic nerves have a similar distribution.

The nerves lie on the posterior wall of the thorax, in the costal groove of the corresponding rib. They extend forwards between the intercostal muscles as far as the middle of the chest wall, lying at a lower level than the intercostal vessels. At the side of the chest each nerve passes obliquely through the internal intercostal muscle, and comes to lie upon the pleura, transversus thoracis muscle, and internal mammary artery. Thereafter, piercing the fibres of the internal intercostal muscle, the aponeurosis of the external muscle, and the pectoralis major, each nerve ends by supplying the skin of the front of the chest, over an area

corresponding to the medial or anterior part of the intercostal space to which it belongs.

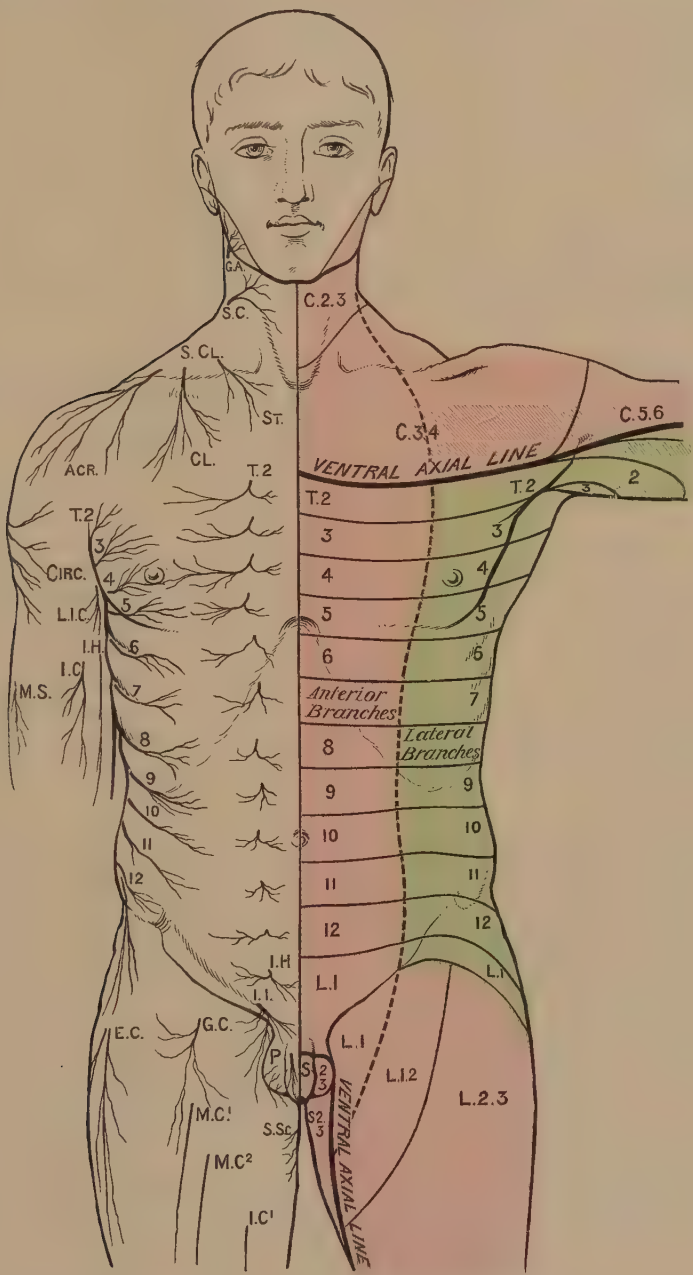

FIG. 615.—THE DISTRIBUTION OF CUTANEOUS NERVES ON THE FRONT OF THE TRUNK.

On one side the distribution of the several nerves is represented, the letters indicating their nomenclature.

G.A., Great auricular nerve; S.C., N. cutaneus colli; S.CL., Supra-clavicular nerves; ACR., Posterior; CL., Middle; ST., Anterior; T.2-12, Lateral and anterior branches of thoracic nerves; I.H., (below) Ilio-hypogastric nerve; I.I., Ilio-inguinal nerve; CIRC., Cutaneous branch of axillary nerve; L.I.C., Medial cutaneous nerve of the arm (O.T. lesser internal cutaneous nerve); I.H., (above) Intercosto-brachial; I.C., Medial cutaneous nerve of the forearm (O.T. internal cutaneous); M.S., Cutaneous branch of radial nerve; E.C., Lateral cutaneous nerves; G.C., Lumbo-inguinal nerve; M.C.$^{1\,2}$, Intermediate cutaneous nerves; I.C.^{1}, Branch of medial cutaneous nerve; P., Branches of pudendal nerve; S.SC., Branches of posterior cutaneous nerve of the thigh.

On the other side a schematic representation is given of the areas supplied by the above nerves, the numerals indicating the spinal origin of the branches of distribution to each area.

Branches.—Each intercostal nerve supplies, in addition to the anterior terminal cutaneous branches, *muscular branches* to the intercostal muscles and a **lateral cutaneous ramus,** which, piercing the intercostal and serratus anterior muscles, divides into anterior and posterior branches for the innervation of the skin over the side of the chest. Each area of skin thus innervated is continuous anteriorly with the area innervated by the anterior rami of the same nerves, and posteriorly with the areas supplied by their posterior rami.

The upper six intercostal nerves supply the muscles of the first six intercostal spaces and the transversus thoracis (3, 4, 5, 6). The second, third, fourth, fifth, and sixth nerves supply the skin of the front of the chest: the second, opposite the sternal synchondrosis; the sixth, opposite the base of the xiphoid process. Their lateral branches supply branches to the intercostal muscles and the skin of the side of the chest, the second (intercosto-brachial) and the third, in part, being drawn out to the arm. The fourth supplies the nipple (Fig. 615).

Communications.—Each of these intercostal nerves communicates with the sympathetic trunk and ganglia by two branches—a *white ramus communicans* to the corresponding sympathetic ganglion or the adjacent part of the sympathetic trunk; and a *gray ramus communicans,* which passes to each nerve from the corresponding ganglion.

The anterior rami of the **seventh, eighth, ninth, tenth, and eleventh thoracic nerves** differ from the preceding nerves only in regard to a part of their course and distribution. Each has the same course and communications as the preceding nerves in the thoracic wall. In addition, these nerves have a further course and distribution in the abdominal wall. Each nerve traverses an intercostal space in the way described. At the anterior end of the space, the nerve passes between the attachments of the diaphragm and the transversus abdominis muscle to the costal cartilages, and courses forwards in the abdominal wall between the transversus and obliquus internus muscles. The nerve then passes between the rectus abdominis muscle and the posterior layer of its sheath, and eventually reaches the anterior abdominal wall and becomes cutaneous by piercing the rectus abdominis itself and the anterior layer of its sheath.

Muscular Branches.—The lower intercostal nerves supply the intercostal muscles of the spaces in which they lie; and in the abdominal wall they innervate the transversus, obliquus externus and internus, and rectus abdominis. The branches arise from the main trunk as well as from its lateral and anterior branches. (The ninth, tenth, and eleventh nerves are described as assisting in the innervation of the diaphragm by communications with the phrenic nerve.)

Cutaneous Branches.—These are lateral and anterior. The **lateral branches** divide into anterior and posterior parts, and, becoming superficial along the line of inter-digitation of the obliquus externus muscle with the serratus anterior and latissimus dorsi, they are directed more obliquely downwards than the lateral branches of the higher intercostal nerves, and are distributed to the skin of the loin as low down as the buttock. The lateral branch of the eleventh nerve can be traced over the iliac crest.

The **anterior branches** are small. That of the seventh nerve innervates the skin at the level of the xiphoid process. The eighth and ninth appear between the xiphoid process and the umbilicus; the tenth nerve supplies the region of the umbilicus; and the eleventh, the area immediately below the umbilicus.

The cutaneous branches of these nerves, including those of the posterior rami, thus supply continuous belts of skin, which can be mapped out on the body from the vertebral column behind to the median plane in front. These areas are not placed horizontally, but tend to be drawn more downwards anteriorly as the series is followed from the upper to the lower nerves.

The anterior ramus of the **twelfth thoracic nerve** is peculiar in its course and distribution. It emerges below the last rib (Fig. 617), and passes laterally and downwards in the posterior abdominal wall under cover of the psoas muscle; it appears in the abdomen beneath the lateral lumbo-costal arch, and crosses over the quadratus lumborum muscle, lying behind the kidney and colon. It then pierces the transversus abdominis muscle, and courses forwards in the interval between it and the obliquus internus as far as the sheath of the rectus muscle.

After piercing the posterior layer of the sheath, the rectus muscle, and the anterior layer of the sheath, it terminates by supplying the skin of the anterior abdominal wall midway between the umbilicus and the os pubis. The branches of the nerve are **muscular** to the transversus, obliqui, rectus, and pyramidalis muscles of the abdominal wall; and **cutaneous branches**, two in number—an *anterior terminal branch*, which supplies the skin of the anterior abdominal wall midway between the umbilicus and the pubis, and a large *lateral cutaneous branch*, which, passing obliquely downwards through the lateral muscles of the abdominal wall, becomes superficial above the iliac crest, a couple of inches behind the anterior superior spine. It supplies the skin of the buttock as far down as a point below and anterior to the greater trochanter of the femur (Fig. 615, p. 745).

The twelfth thoracic nerve, in many cases, receives a **communicating branch** from the eleventh, near its origin, and still more frequently sends a fine branch to join the origin of the first lumbar nerve in the psoas muscle. It may communicate also with the ilio-hypogastric nerve, as they lie together in the abdominal wall.

Intercommunications of the Thoracic Nerves.—It has been noted already that the belts or areas of skin supplied by the branches of the thoracic nerves are also innervated by adjacent nerves on either side which invade the area supplied by a given nerve. Communications also take place between the branches of the nerves supplying the intercostal muscles, whereby the muscles of a given space derive their innervation from more than one intercostal nerve.

PLEXUS LUMBOSACRALIS.

The **lumbo-sacral plexus** is formed by the union of the anterior rami of the remaining spinal nerves—five lumbar, five sacral, and one coccygeal. Frequently a fine communicating branch of the twelfth thoracic nerve joins the first lumbar nerve near its origin.

Of the nerves in question the first sacral is generally the largest in size, the nerves diminishing gradually above and rapidly below this nerve. The plexus, for the most part, forms the nerves destined for the supply of the lower limb. In addition, however, nerves arise at its superior limit which are distributed to the trunk above the level of the limb, and at the inferior end of the plexus nerves arise for the supply of the perineum.

Partly for convenience of description, and partly on account of the differences in position and course of some of the nerves emanating from it, the plexus is subdivided into three subordinate parts — lumbar, sacral, and pudendal plexuses. There is, however, no strict line of demarcation between the three parts.

Plexus Lumbalis.—The **lumbar plexus** is formed by the first four lumbar nerves, and is often joined by a branch from the twelfth thoracic nerve as well. It is limited below by the fourth lumbar nerve (*n. furcalis*), which enters also into the composition of the sacral plexus. The nerves of the lumbar plexus are formed in the loin, and supply that region as well as part of the lower limb. They are separated from the nerves of the sacral portion of the plexus by the articulation of the hip bone with the sacrum.

Plexus Sacralis.—The **sacral plexus** is formed by the fourth and fifth lumbar, and the first two or three sacral nerves. It is generally limited below by the third sacral nerve (*n. bigeminus*), which assists also in forming the pudendal plexus. The nerves of the sacral plexus are placed on the posterior wall of the pelvis, and are destined almost entirely for the lower limb.

Plexus Pudendus.—The **pudendal plexus** is formed by the second, third, fourth, and fifth sacral nerves, and the minute coccygeal nerve. It is placed on the posterior wall of the pelvis and supplies branches mainly to the perineum.

Communications with the Sympathetic.—Each of these nerves has communications with the gangliated trunk of the sympathetic in the abdomen and pelvis by means of **rami communicantes.**

From the lumbar and sacral ganglia long slender *gray rami communicantes* are directed backwards and laterally over the bodies of the vertebræ, and (in the lumbar region) beneath the origins of the psoas muscle, to reach the spinal nerves. These branches are irregular in their arrangement. A given nerve may receive branches from two ganglia, or one ganglion may send branches to two nerves. The rami are longer in the

loin than in the pelvis, owing to the projection of the lumbar portion of the vertebral column.

Certain lumbar and sacral nerves are also connected with the sympathetic by means of *white rami communicantes*. From the first two, and possibly in some cases also the

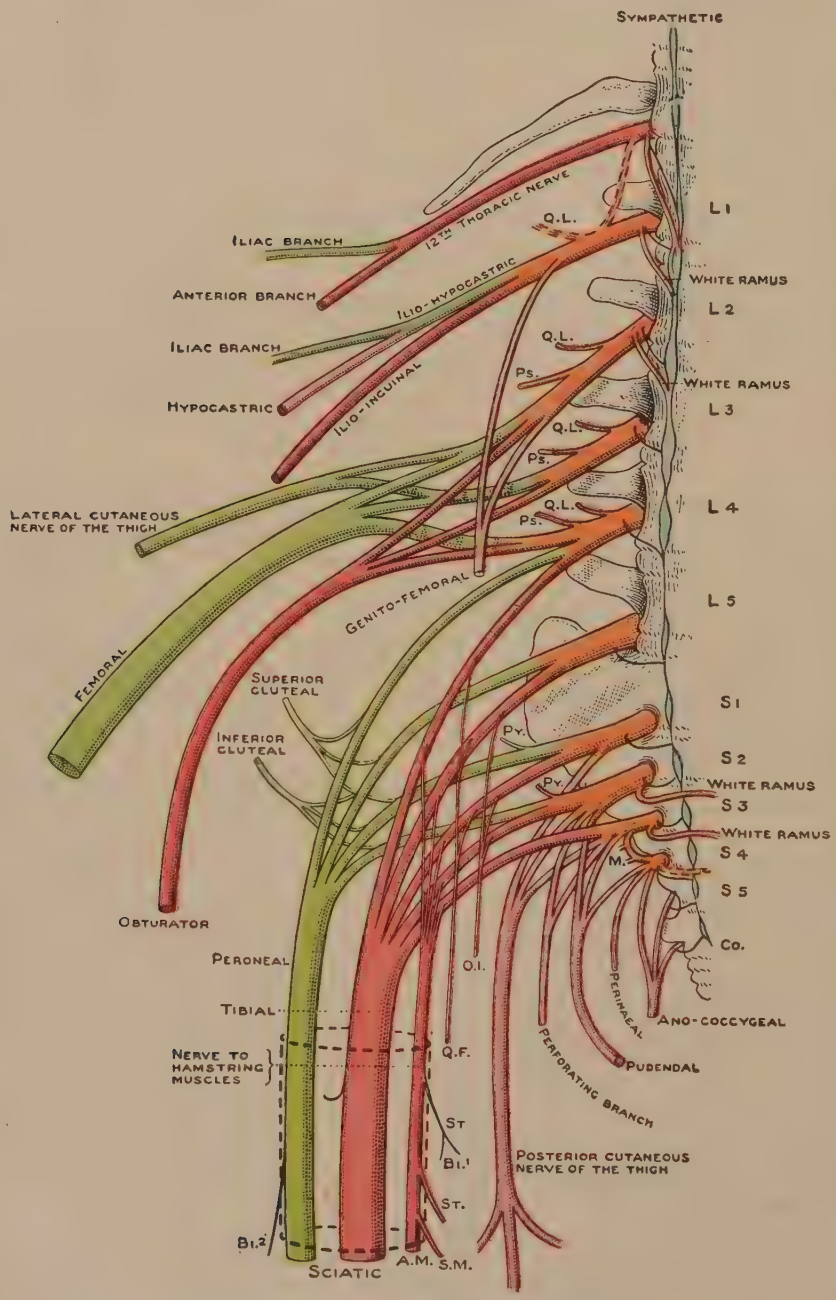

FIG. 616.—NERVES OF THE LUMBO-SACRAL PLEXUS.

third and fourth lumbar nerves, white rami are directed forwards, either independently or incorporated with the corresponding gray rami, to join the upper part of the lumbar sympathetic trunk. The fifth lumbar nerve and the first sacral nerves are unprovided with white rami. From the anterior rami of the second and third, or third and fourth sacral nerves, white rami (visceral or splanchnic branches) pass medially, and, crossing over (without joining) the sympathetic trunk, enter the pelvic plexus of the sympathetic. The fifth sacral and coccygeal nerves possess no white rami communicantes.

Variations in the Position of the Lumbo-Sacral Plexus.

The **lumbo-sacral plexus** shows a very considerable variability in position and constitution. Eisler records concomitant variations in the plexus in 18 per cent. of the cases examined by him. The variations occur within wide limits. The plexus may begin at the eleventh or twelfth thoracic or first lumbar nerve. The last nerve in the sciatic cord may be the second, third, or fourth sacral nerve. The position of the n. furcalis is a guide to the arrangement of the plexus. It may be formed by the third, third and fourth, fourth and fifth, or fifth lumbar nerves. The resulting variations are illustrated by the following extreme cases :—

	(1) *Prefixed Variety.*	(2) *Normal.*	(3) *Postfixed Variety.*
Nervus furcalis . .	L. 3 and 4 (double).	L. 4.	L. 5.
Obturator . . .	L. 1, 2, 3.	L. 2, 3, 4.	L. 2, 3, 4, 5.
Femoral . . .	T. 12, L. 1, 2, 3, 4.	L. 2, 3, 4.	L. 2, 3, 4, 5.
Tibial	L. 3, 4, 5, S. 1, 2.	L. 4, 5, S. 1, 2, 3.	L. 5, S. 1, 2, 3, 4.
Common peroneal .	L. 3, 4, 5, S. 1.	L. 4, 5, S. 1, 2.	L. 5, S. 1, 2, 3.

Those variations in the constitution of the lumbo-sacral plexus are most numerous which are due to the inclusion of nerves more caudally placed. Thus, out of twenty-two variations in the position of the *n. furcalis*, in nineteen Eisler found it formed by the fifth lumbar nerve; in two cases only, by the third lumbar nerve. There is further evidence that variations in the position of the plexus are accompanied by variations in the vertebral column itself. Out of the twenty-two abnormal plexuses examined by Eisler, sixteen were coincident with abnormal arrangement of the associated vertebræ.

PLEXUS LUMBALIS.

The **lumbar plexus** is formed by the anterior rami of the first three and a part of the fourth lumbar nerves, with the addition, in half the number of cases, of a small branch from the twelfth thoracic nerve. The nerves increase in size from above downwards (Fig. 616).

Position and Constitution.—The plexus is formed in the substance of the psoas muscle, in front of the transverse processes of the lumbar vertebræ. The nerves, on emerging from the intervertebral foramina, are connected as above described with the sympathetic system, and then divide in the following manner in the substance of the psoas major muscle. The first and second nerves divide into superior and inferior branches. The superior branch of the first nerve (which may be joined by the branch from the twelfth thoracic nerve) forms two nerves, the **ilio-hypogastric** and **ilio-inguinal**. The inferior branch of the first joins the superior branch of the second nerve, to produce the **genito-femoral nerve**. The inferior branch of the second nerve, the whole of the third, and that part of the fourth nerve engaged in the constitution of the plexus divide each into two unequal parts—smaller *anterior* and larger *posterior parts*. The smaller anterior portions combine together to form the **obturator nerve**, which is thus formed by the second, third, and fourth lumbar nerves. The root from the second nerve is not always present. The larger posterior portions of the same nerves combine together to form the **femoral nerve**. From the posterior aspect of the posterior parts of the second and third nerves the **lateral cutaneous nerve of the thigh** arises. The nerves also provide, near their origins, irregular **muscular branches** for the psoas and quadratus lumborum muscles. The following is a list of the nerves which spring from the lumbar plexus together with their origins.

(1) Muscular branches to the quadratus lumborum (L. 1-4) and psoas muscles (L. 2, 3).
(2) Ilio-hypogastric (? T. 12, L. 1).
(3) Ilio-inguinal (? T. 12, L. 1).
(4) Genito-femoral (L. 1, 2).
(5) Lateral cutaneous (L. 2, 3).
(6) Obturator (L. 2, 3, 4).
(7) Femoral (L. 2, 3, 4).

Muscular Branches.—The nerves to the **quadratus lumborum muscle** arise independently from the first three or four lumbar nerves (and sometimes also from the twelfth thoracic nerve). The nerves to the **psoas muscles** arise from the second and third lumbar nerves, with additions, in some cases, from the first or fourth. They are often associated in their origin with the nerve to the iliacus from the

femoral nerve. The **psoas minor**, when present, is innervated by the first or second lumbar nerve.

The ilio-hypogastric and ilio-inguinal nerves closely resemble, in their course and distribution, the lower thoracic nerves, with which they are in series.

The **ilio-hypogastric nerve** is the highest branch of the first lumbar nerve.

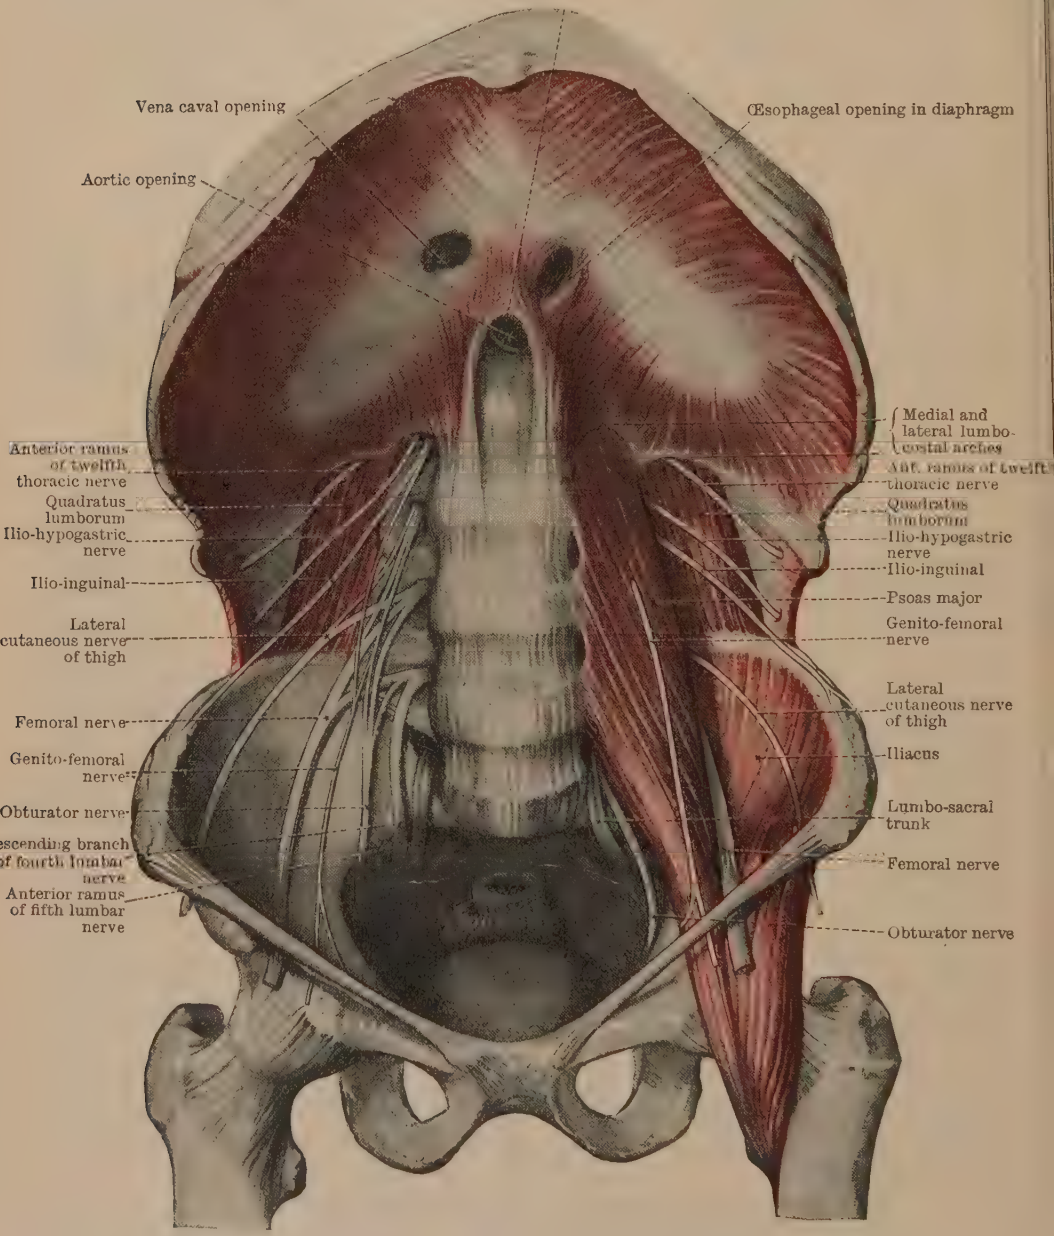

FIG. 617.—THE MUSCLES AND NERVES ON THE POSTERIOR ABDOMINAL WALL.

It receives fibres also from the twelfth thoracic, when that nerve communicates with the first lumbar nerve. After traversing the psoas muscle obliquely, it appears at its lateral border, on the surface of the quadratus lumborum and behind the kidney. It courses through the loin, lying between the transversus and obliquus abdominis internus muscles, above the crest of the ilium. About an inch in front of the anterior superior spine it pierces the obliquus internus, and continues its course in the groin beneath the aponeurosis of the obliquus ex-

ternus. It finally becomes cutaneous in the anterior abdominal wall, by piercing the aponeurosis of the obliquus externus about an inch and a half above the subcutaneous inguinal ring (Fig. 615, p. 745).

Its **branches** are—(1) *muscular* to the muscles of the abdominal wall; and (2) *cutaneous branches*, two in number. The **lateral cutaneous branch** corresponds with the lateral branch of an intercostal nerve, and, after piercing the obliquus internus and obliquus externus, becomes cutaneous just above the iliac crest, below and behind the iliac branch of the last thoracic nerve. It is small, and may be absent. It is distributed to the skin over the superior part of the lateral side of the buttock, in continuity with the cutaneous branch of the posterior ramus of the first lumbar nerve. The **anterior cutaneous branch** is the anterior terminal branch of the nerve. It supplies the skin of the anterior abdominal wall below the level of the last thoracic nerve and above the os pubis.

The **ilio-inguinal nerve** is the second branch given off from the first lumbar nerve. It also may receive fibres from the last thoracic nerve. Not infrequently the ilio-hypogastric and ilio-inguinal nerves are represented for a longer or shorter part of their course by a single trunk. When separate the nerve takes a course similar to that of the ilio-hypogastric nerve, but at a lower level, as far as the anterior abdominal wall. It then pierces the obliquus internus farther forward and lower down than the ilio-hypogastric; and coursing forwards beneath the aponeurosis of the obliquus externus, just above the inguinal ligament, it becomes superficial after passing through the subcutaneous inguinal ring and external spermatic fascia (Fig. 615, p. 745).

Its branches are *muscular* to the muscles of the abdominal wall, among which it passes, and *cutaneous branches* (*anterior scrotal*, or *labial* nerves), which innervate the skin (1) of the anterior abdominal wall over the symphysis pubis, (2) of the thigh over the proximal and medial part of the femoral triangle, and (3) of the superior part of the scrotum, and root and dorsum of the penis (of the mons Veneris and labium majus in the female). These last-named branches are contiguous to branches of the perineal and pudendal nerves. No lateral cutaneous branch arises from the ilio-inguinal nerve. It thus corresponds, like the anterior cutaneous part of the ilio-hypogastric nerve, to the anterior trunk of a typical thoracic nerve.

The **genito-femoral nerve** usually arises by two independent roots from the front of the first and second lumbar nerves, which unite in the substance of the psoas major to form a slender trunk. It appears on the posterior abdominal wall, lying on the psoas major, medial to the psoas minor, and, piercing the psoas fascia, it extends downwards on the lateral aspect of the common and external iliac vessels and behind the ureter, to the inguinal ligament (Fig. 617, p. 750). At a variable point above that ligament it divides into two branches. 1. The **external spermatic branch** is a small nerve. It crosses the terminations of the external iliac vessels, and, along with the ductus deferens and testicular and external spermatic vessels, enters the inguinal canal through the abdominal inguinal ring. It terminates by supplying small branches to the skin of the scrotum and adjacent part of the thigh. In the female it accompanies the round ligament to the labium majus. This nerve gives off in its course the following small branches: (1) to the external iliac artery; (2) to the cremaster muscle; (3) to communicate with the spermatic plexus of the sympathetic. 2. The **lumbo-inguinal branch** continues the course of the parent nerve into the thigh, lying on the lateral aspect of the femoral artery. It becomes cutaneous by passing through the fossa ovalis or through the iliac portion of the fascia lata, and supplies an area of skin over the femoral triangle, lateral to that supplied by the ilio-inguinal nerve (Fig. 615, p. 745). It communicates in the thigh with the intermediate cutaneous branch of the femoral nerve. Before piercing the deep fascia it gives a minute branch to the femoral artery.

The **lateral cutaneous nerve of the thigh** is distributed only to the skin (Fig. 615). It arises from the back of the lumbar plexus, and usually from the second and third lumbar nerves. Emerging from the lateral border of the psoas major muscle, the nerve crosses the iliacus muscle, beneath the fascia iliaca, to reach the anterior superior iliac spine. It enters the thigh beneath the lateral end of the

inguinal ligament, and either over, under, or through the origin of the sartorius muscle. It extends distally along the front of the thigh for a few inches, lying at first beneath the fascia lata, and afterwards in a tubular investment of the fascia. It gives off small branches in this part of its course, and finally, piercing the fascia about four inches distal to the anterior superior iliac spine, it separates into anterior and posterior terminal branches. The **anterior branch** is the larger, and is distributed on the lateral aspect of the front of the thigh almost to the knee. The smaller **posterior branch** supplies the skin of the lateral side of the buttock, distal to the greater trochanter, and the skin of the proximal two-thirds of the lateral aspect of the thigh (Fig. 619, p. 755).

Nervus Obturatorius.

The **obturator nerve** supplies the muscles and skin on the medial side of the thigh. It arises in the substance of the psoas major muscle by three roots

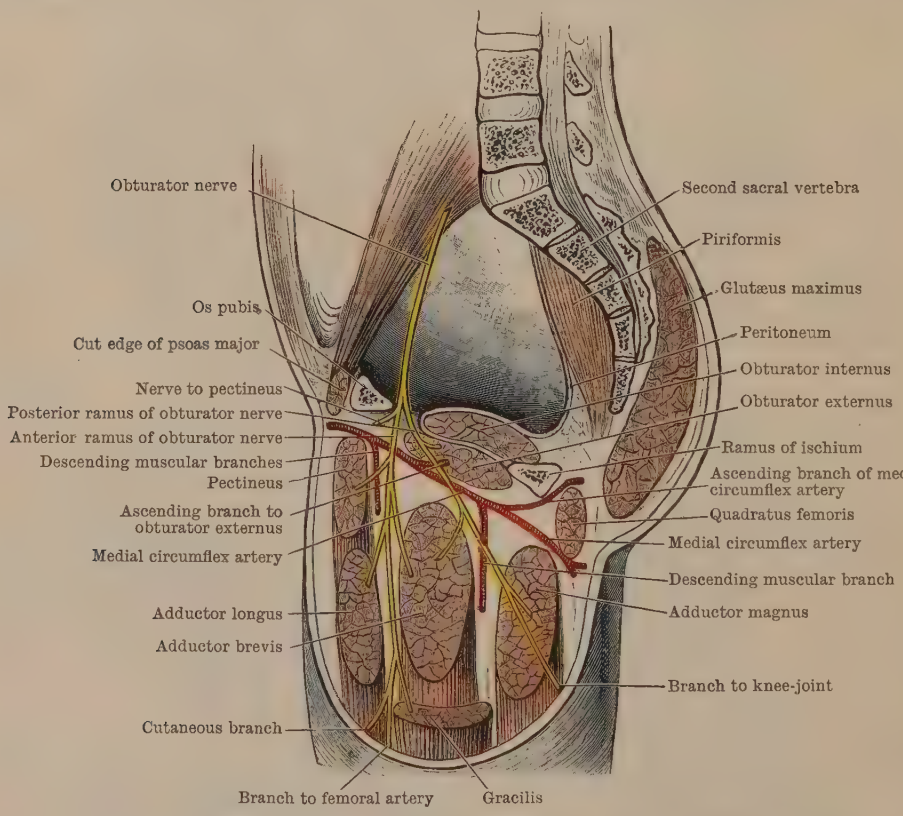

Fig. 618.—Scheme of the Course and Distribution of the Obturator Nerve.

placed in front of those of the femoral nerve, and derived from the second, third, and fourth lumbar nerves (Fig. 616, p. 748). Sometimes the root from the second nerve is absent. Passing vertically downwards, the nerve emerges from the psoas major at its medial border, behind the common iliac, and on the lateral side of the hypogastric vessels. It passes forwards below the pelvic brim in company with the obturator artery to the obturator groove of the obturator foramen, through which it reaches the thigh. While in the obturator groove it separates into its two main branches, named anterior and posterior (Fig. 618).

The **anterior branch** enters the thigh in front of the obturator externus and adductor brevis muscles, and behind the pectineus and adductor longus. In the middle third of the thigh it is found coursing along the medial border of the adductor longus anterior to the gracilis; and it finally divides into two slender terminal filaments, of which one enters the adductor canal and ends on the femoral

artery, while the other supplies the skin for a variable distance on the medial side of the thigh and joins in the obturator plexus.

The branches of the anterior part of the nerve are:—

1. An **articular branch** to the hip-joint, which arises from the nerve as soon as it enters the thigh, and supplies the joint through the acetabular notch.

2. **Muscular branches** to the adductor longus, gracilis, adductor brevis (usually), pectineus (occasionally). The last-named muscle is not usually supplied from the obturator nerve.

3. A **cutaneous branch** of very variable size forms one of the terminal branches (Fig. 618). It becomes superficial between the gracilis and adductor longus, in the middle third of the thigh, and may supply the skin of the distal two-thirds of the thigh on its medial side. It is generally of small size, and is connected with branches of the medial cutaneous and saphenous nerves behind the sartorius muscle to form the **obturator** (O.T. **sub-sartorial**) **plexus.** The branch from the saphenous nerve to the plexus passes medially behind the sartorius after piercing the aponeurotic covering of the adductor canal. The branch from the medial cutaneous nerve is generally superficial at the point of formation of the plexus.

4. The **branch to the femoral artery** is the other terminal branch of the nerve. It enters the adductor canal along the medial border of the adductor longus, and ramifies over the distal part of the artery.

5. A fine **communicating branch** sometimes joins the femoral nerve in front of the hip-joint.

The **posterior branch of the obturator nerve** reaches the thigh by piercing the obturator externus muscle. It passes distally between the adductor brevis and adductor magnus muscles. After passing obliquely through the adductor magnus, it appears in the popliteal fossa on the popliteal artery, to which it furnishes twigs, and terminates by piercing the oblique ligament of the knee and supplying the knee-joint.

Its branches are: (1) **muscular branches** to the obturator externus, adductor magnus, and (when the muscle is not supplied by the superficial part of the nerve) the adductor brevis. The branch to the obturator externus arises before the nerve enters the muscle, in the obturator groove. The nerve to the adductor magnus is given off as the obturator nerve passes through the substance of the muscle. (2) An **articular terminal branch** is supplied to the posterior aspect of the knee-joint.

Nervus Femoralis.

The **femoral nerve** is the large nerve for the muscles and skin of the front of the thigh. It arises in the substance of the psoas major muscle, from the back of the second, third, and fourth lumbar nerves, posterior to the obturator nerve. Passing obliquely through the psoas major muscle, it emerges from its lateral border in the pelvis major (Fig. 617, p. 750). Passing downwards in the groove between the psoas and iliacus, it enters the thigh beneath the inguinal ligament, lateral to the femoral sheath and femoral vessels. In the femoral triangle it breaks up into a large number of branches, among which the lateral circumflex artery of the thigh passes in a lateral direction.

The **branches** of the femoral nerve, which are (1) muscular, (2) articular, (3) cutaneous, and (4) vascular, arise in the following way:—

In the abdomen a muscular branch arises from the lateral aspect of the nerve and enters the iliacus muscle, and a vascular branch descends to supply the femoral artery, which vessel also receives branches lower down in the thigh.

In the femoral triangle the terminal muscular, articular, and cutaneous branches arise in the form of a large bundle of nerves.

1. The **muscular branches** supply the pectineus, sartorius, and quadriceps. The nerve to the *pectineus* arises close to the inguinal ligament, and, coursing obliquely distally and medially behind the femoral vessels, enters the muscle at its lateral border. It is not infrequently double. It sometimes gives off a fine communicating branch to the anterior part of the obturator nerve. The nerves to the *sartorius* are in two sets: a lateral, short set of nerves, associated with the

lateral part of the intermediate cutaneous nerve, which supply the proximal part of the muscle; and a medial, longer set, which are associated with the medial part of the intermediate cutaneous nerve, and enter the middle of the muscle. The parts of the *quadriceps* are supplied by several branches. The vastus lateralis and rectus femoris are supplied on their deep surface by separate nerves which are accompanied by branches of the lateral circumflex artery of the thigh. The vastus intermedius muscle is supplied superficially by a nerve which passes through the muscle, and innervates also the muscle of the knee-joint (subcrureus). It also receives fibres from one of the nerves to the vastus medialis. The vastus medialis muscle is supplied by two nerves: a proximal trunk, which supplies the proximal part of the muscle, and sends fibres to the vastus intermedius as well; and a distal trunk, which descends on the lateral side of the femoral artery along with the saphenous nerve, and passing beneath the sartorius, over or under the aponeurotic covering of the adductor canal, enters the medial side of the muscle. This nerve gives off a small branch which enters the medullary canal of the femur.

2. The **articular branches** supply the hip and knee-joints. The articular branch to the hip-joint arises from the nerve to the rectus femoris, and is accompanied by branches from the lateral circumflex artery of the thigh. The articular branches to the knee-joint are four in number. Three of them arise from the nerves to the vastus lateralis, vastus intermedius, and vastus medialis, which, after the muscular nerves are given off, are continued downwards to the knee-joint along the front of the femur. A fourth articular branch arises (sometimes) from the saphenous nerve.

3. The **cutaneous branches** are the intermediate and medial cutaneous, and the saphenous nerves (Fig. 619).

The **intermediate cutaneous nerve** arises in two parts, a *lateral* and a *medial branch*, in the proximal part of the femoral triangle. The two branches descend vertically and become cutaneous by piercing the fascia lata over the proximal third of the sartorius muscle. They carry muscular branches to the sartorius, and the lateral branch in many cases pierces the muscle. These two nerves supply the skin of the distal three-fourths of the front of the thigh, between the lateral cutaneous nerve of the thigh laterally and the medial cutaneous on the medial side. They reach to the front of the patella, and there assist in the formation of the patellar plexus. The lateral branch communicates, in the proximal third of the thigh, with twigs from the lumbo-inguinal branch of the genito-femoral nerve.

The **medial cutaneous nerve** lies at first in the femoral triangle on the lateral side of the femoral vessels. At the apex of the triangle it crosses over the femoral vessels, and is directed distally over or through the sartorius muscle, and beneath the fascia lata, to the distal third of the thigh. It is distributed to the skin of the distal two-thirds of the thigh on the medial side by means of three branches —proximal, middle, and distal.

The *proximal branch* may be represented by two or more twigs. It arises from the main nerve near its origin, and pierces the fascia lata near the apex of the femoral triangle. It is distributed to the skin of the proximal part of the thigh, along the line of the great saphenous vein. The *middle* or *anterior branch* is a larger nerve. It separates from the distal branch at the apex of the femoral triangle, and passing over the sartorius muscle becomes cutaneous in the middle third of the thigh on the medial side. It supplies the skin of the distal half of the thigh, extending as far as the knee, where it joins in the formation of the patellar plexus.

The *distal branch* represents the termination of the nerve. It passes along the medial side of the thigh over the sartorius muscle, and communicates in the middle third of the thigh with the saphenous and obturator nerves to form the obturator plexus. Piercing the fascia lata on the medial side of the thigh in the distal third, it ramifies over the side of the knee, and assists in the formation of the patellar plexus.

The size of the medial cutaneous nerve varies with the size of the cutaneous part of the obturator, and of the saphenous nerve.

The **saphenous nerve** may be regarded as the terminal branch of the femoral nerve. It is destined for the skin of the leg and foot. From its origin in the

femoral triangle it extends distally alongside the femoral vessels to the adductor canal. In the canal it crosses obliquely over the femoral sheath from lateral to medial side. At the distal end of the canal, accompanied by the saphenous branch of the arteria genu suprema, it passes over the tendon of the adductor magnus, and opposite the medial side of the knee-joint becomes cutaneous by passing between the sartorius and gracilis muscles. The nerve then extends distally in the

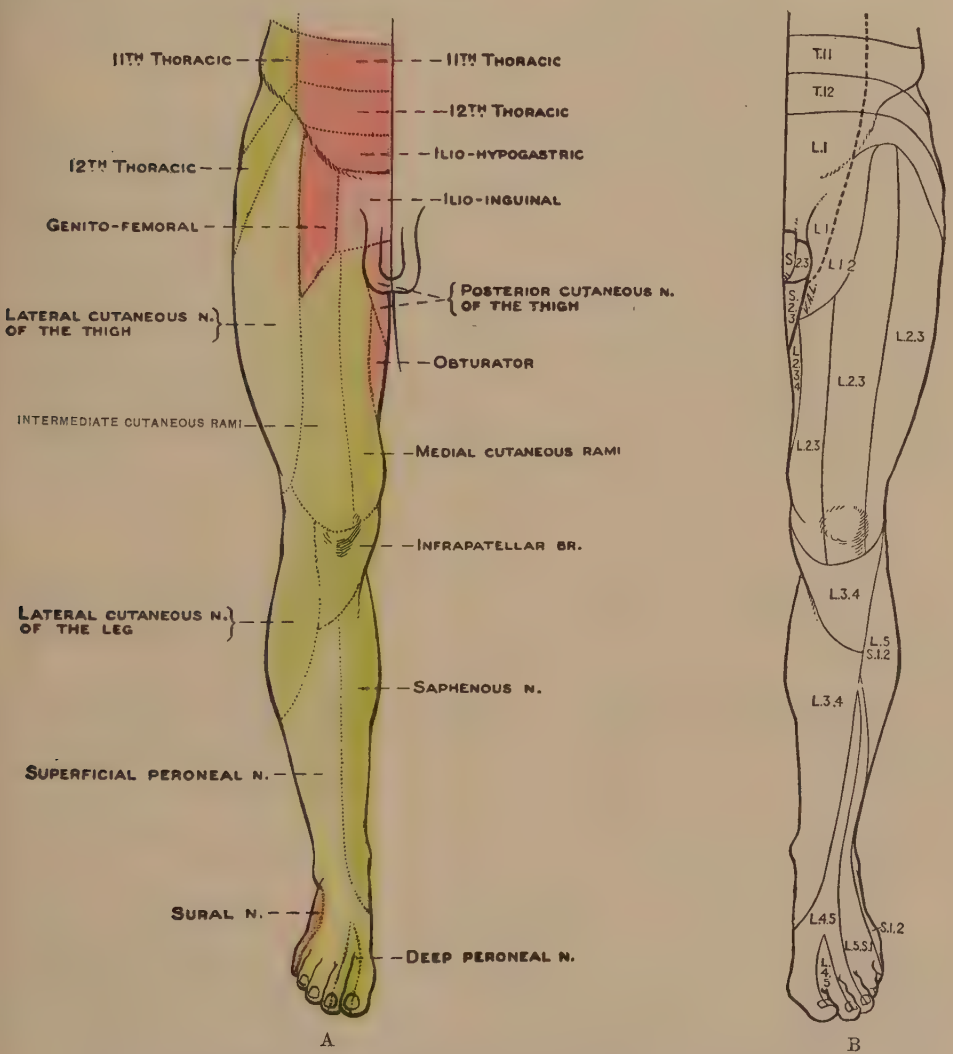

FIG. 619.—DISTRIBUTION OF CUTANEOUS NERVES ON THE FRONT OF THE LOWER LIMB.

On the left side the distribution of the several nerves is represented in colour.

On the right side a schematic representation is given of the areas supplied by the above nerves, the figures indicating the spinal origin of the branches of distribution to each area.

leg along with the great saphenous vein, and coursing over the front of the medial malleolus it terminates at the middle of the medial border of the foot.

Branches.—1. A **communicating branch** arises in the adductor canal, and, passing medially behind the sartorius, joins with branches of the obturator nerve in forming the obturator plexus.

2. The **infra-patellar branch** arises at the distal end of the adductor canal, and piercing the sartorius muscle is directed distally and forwards below the patella, and over the medial condyle of the tibia to the front of the knee and proximal part of the leg. It enters into the formation of the patellar plexus.

3. An **articular branch** sometimes arises from the nerve at the medial side of the knee.

4. The **terminal branches** of the saphenous nerve (**rami cutanei cruris mediales**) are distributed to the skin of the front and medial side of the leg and the posterior half of the dorsum and medial side of the foot.

The **patellar plexus** consists of fine communications beneath the skin in front of the knee, between the branches of the cutaneous nerves supplying that region. The nerves which enter into its formation are the infra-patellar branch of the saphenous, medial, and intermediate cutaneous nerves, and sometimes the lateral cutaneous nerve of the thigh.

The **accessory obturator nerve** is only occasionally present (29 per cent., Eisler). It arises from the third, or third and fourth lumbar nerves, between the roots of the obturator and femoral nerves. Associating itself with the obturator, from which, however, it is quite separable, it appears in the abdomen at the medial side of the psoas muscle, and coursing over the pelvic brim behind the external iliac vessels, it leaves the obturator nerve, and enters the thigh in front of the os pubis.

In the thigh, behind the femoral vessels, it usually ends in three branches: a nerve which replaces the branch from the femoral nerve to the pectineus, a nerve to the hip-joint, and a nerve which communicates with the superficial part of the obturator nerve. In some cases it only supplies the nerve to the pectineus; more rarely it is of considerable size, and reinforces the obturator nerve in the innervation of the adductor muscles.

It is more closely associated with the femoral than with the obturator. Its origin is behind the roots of the obturator: it is separated, like the femoral, from the obturator by the pubic bone, and its chief branch, to the pectineus muscle, replaces the normal branch from the femoral nerve. On the other hand, for a part of its course it accompanies the obturator, and in rare cases it may replace branches of that nerve.

PLEXUS SACRALIS.

The sacral portion of the lumbo-sacral plexus is destined almost entirely for the lower limb. It is usually formed by the anterior rami of a part of the fourth lumbar nerve (n. furcalis), the fifth lumbar, the first, and parts of the second, and third sacral nerves (n. bigeminus).

Communications with the Sympathetic.—Each of the nerves named is connected to the lumbar or pelvic sympathetic by *gray rami communicantes*, as already described; and *white rami communicantes* pass from the third and usually also from the second or fourth sacral nerves to join the pelvic plexus of the sympathetic.

Position and Constitution.—The plexus is placed on the posterior wall of the pelvis between the parietal pelvic fascia and the piriformis muscle. In front of it are the pelvic colon, the hypogastric vessels, and the ureter.

The plexus is constituted by the convergence of the nerves concerned towards the inferior part of the greater sciatic foramen, and their union to form a broad triangular band, the apex of which is continued through the greater sciatic foramen below the piriformis muscle into the buttock, as the **sciatic nerve.** From the anterior and posterior surfaces of this triangular band numerous small branches arise, which are distributed to the parts in the neighbourhood of the origin of the nerve.

The sciatic nerve ends in the thigh by dividing into two large nerves, the **tibial** (O.T. **internal popliteal**) and **common peroneal** (O.T. **external popliteal**). In many cases these two nerves are distinct at their origin, and are separated sometimes by fibres of the piriformis muscle. In all cases, on removal of the sheath investing the sciatic nerve, the tibial and peroneal nerves can be traced up to the plexus, from which they invariably take origin by distinct and separate roots.

Formation.—The descending branch of the fourth lumbar nerve (n. furcalis), after emerging from the border of the psoas major muscle, medial to the obturator nerve, divides behind the iliac vessels into anterior and posterior (ventral and dorsal) parts, each of which joins a corresponding part of the fifth lumbar nerve. The anterior ramus of the fifth lumbar nerve descends over the ala of the sacrum, and divides into anterior and posterior parts, which are joined by the corresponding parts of the fourth lumbar nerve. The two resulting trunks are sometimes called the

truncus lumbosacralis or **lumbo-sacral trunk**. The first and second sacral nerves pass almost horizontally laterally from the anterior sacral foramina, and divide in front of the piriformis into similar anterior and posterior parts. The third sacral nerve (n. bigeminus) divides into superior and inferior parts. The inferior part is concerned in forming the pudendal plexus. The superior part is directed laterally, and slightly upwards, towards the second nerve, and does not separate into two parts, but remains undivided.

The nerves mentioned combine to form the sacral plexus, and its main subdivisions, in the following way. Lying in apposition, and converging to the lower part of the greater sciatic foramen, the *posterior* (dorsal) *trunks* of the fourth and fifth lumbar nerves (lumbo-sacral trunk), and of the first and second sacral nerves, combine to form the **common peroneal nerve** and the subordinate nerves which arise from the posterior aspect of the plexus. The *anterior* (ventral) *trunks* of the fourth and fifth lumbar nerves (lumbo-sacral trunk), and of the first and second sacral nerves, together with that part of the third sacral nerve which is contributed to the plexus, unite to form the **tibial nerve** and the subordinate nerves arising from the front of the plexus.

Of these nerves the fifth lumbar and first sacral are the largest; the others diminishing in size as they are traced upwards and downwards. There is no distinct demarcation between the sacral and pudendal plexuses. The second and third sacral nerves (and in some cases the first sacral also) are concerned in the formation of both plexuses.

Branches.—The nerves of distribution derived from the sacral plexus are divided according to their origin into an *anterior* (ventral) and a *posterior* (dorsal) *series*. Each set comprises one of the two essential terminal parts of the sciatic—peroneal and tibial nerves—and numerous smaller collateral branches.

Anterior (Ventral) Branches.	Posterior (Dorsal) Branches.
Tibial nerve (L. 4, 5, S. 1, 2, 3)	Common peroneal nerve (L. 4, 5, S. 1, 2)
Muscular branches—	*Muscular branches*—
Nerves to hamstring muscles (L. 4, 5, S. 1, 2, 3)	Nerves to short head of biceps (L. 5, S. 1, 2)
Nerves to quadratus femoris (L. 4, 5, S. 1)	Nerves to piriformis (S. 2)
Nerves to gemelli	Superior gluteal nerve (L. 4, 5, S. 1)
Nerves to obturator internus (L. 5, S. 1, 2)	Inferior gluteal nerve (L. 5, S. 1, 2)
Articular branches (to hip-joint)	*Articular branches* (to knee-joint)

Nervus Ischiadicus.

The **sciatic nerve** is the largest nerve in the body. It consists of two nerves, the tibial and the common peroneal, bound together by an investing sheath, which contains, in addition to these nerves, a branch from each: the nerve to the hamstring muscles, from the tibial nerve, and the nerve to the short head of the biceps femoris, from the common peroneal nerve. From the account given of the origin of the fibres of the tibial and common peroneal nerves, it follows that the fibres of the sciatic nerve are derived from the fourth and fifth lumbar and first, second, and third sacral nerves. A thick band about half an inch in breadth is formed, consisting, from the medial to the lateral side, of (1) the nerve to the hamstring muscles, (2) the tibial nerve, (3) the common peroneal nerve, (4) the nerve to the short head of the biceps femoris.

The sciatic nerve leaves the pelvis and enters the gluteal region through the greater sciatic foramen between the piriformis and the superior gemellus. It runs laterally and then downward through the gluteal region, in the hollow between the great trochanter of the femur and the tuberosity of the ischium, accompanied by the inferior gluteal artery and the arteria comitans nervi ischiadici. It is covered posteriorly by the glutæus maximus, and is in relation anteriorly with the following structures, from above downwards: (1) the posterior aspect of the

ischium, (2) the nerve to the quadratus femoris, (3) the superior gemellus, (4) the obturator internus, (5) the inferior gemellus, (6) the quadratus femoris.

The nerve enters the thigh by emerging below the inferior border of the glutæus maximus, lying in the angle between the lower border of this muscle above and laterally, and the origin of the hamstring muscles medially. It runs down the back of the thigh, on the posterior surface of the adductor magnus, and is covered by the long head of the biceps femoris, which crosses posterior to the nerve from the medial to the lateral side.

It usually terminates at the proximal angle of the popliteal fossa by dividing into the tibial and common peroneal nerves; but the separation may occur at any higher level, and, as already noted, these two nerves may even be distinct at their origin, in which case the common peroneal usually pierces the piriformis.

The Nerves of Distribution from the Sacral Plexus.

These are divisible into two series—**collateral** and **terminal branches**. Each subdivision consists of a series of *anterior* and *posterior trunks*.

1. Collateral Branches.—The *anterior branches* are (*a*) muscular branches (to the quadratus femoris, gemelli, obturator internus, and hamstring muscles); and (*b*) articular branches (to the hip-joint). These nerves all arise from the anterior aspect of the sacral plexus.

The **nerve to the quadratus femoris** (and **inferior gemellus**) arises from the front of the fourth and fifth lumbar and first sacral nerves. It passes downwards over the back of the capsule of the hip-joint (to which it sends a fine branch) beneath the sacral plexus, gemelli, and obturator internus muscles. It supplies a nerve to the inferior gemellus, and terminates in the deep surface of the quadratus femoris.

The **nerve to the obturator internus** (and **superior gemellus**) arises from the anterior aspect of the fifth lumbar and first two sacral nerves. In the buttock it lies medial to the sciatic nerve on the lateral side of the pudendal vessels; crossing the ischial spine, it enters the ischio-rectal fossa through the lesser sciatic foramen. The nerve supplies, in the buttock, a branch to the superior gemellus, and terminates by entering the pelvic surface of the obturator internus.

The **nerve to the hamstring muscles** forms the most medial part of the sciatic trunk in the lower part of the buttock. It arises from all the roots of the tibial nerve on their anterior aspect, viz., from the fourth and fifth lumbar and the first three sacral nerves. These roots unite to form a cord which is closely associated with the tibial nerve and is placed in front of it and afterwards on its medial side. Extending into the thigh, the trunk is distributed to the hamstring muscles by means of two sets of branches. Just distal to the ischial tuberosity a proximal set of nerves enters the proximal part of the semitendinosus and the ischial head of the biceps. More distally in the thigh the remaining portion of the nerve separates off from the tibial part of the sciatic trunk and supplies branches to the semimembranosus, the distal part of the semitendinosus, and the adductor magnus.

Articular branches for the hip-joint arise from the nerve to the quadratus femoris, and often directly from the anterior surface of the tibial part of the sciatic nerve near its origin. They enter the back of the capsule of the joint in the region of the buttock.

The *posterior branches* are: (*a*) muscular branches—a nerve to the piriformis, the superior gluteal nerve, the inferior gluteal nerve, and a nerve to the short head of the biceps; (*b*) articular branches (to the knee-joint).

These nerves all arise from the posterior aspect of those roots of the sacral plexus, which are associated with the origin of the common peroneal nerve.

The **nerve to the piriformis muscle** may be double. It arises from the back of the second, or first and second sacral nerves, and at once enters the anterior surface of the muscle.

N. Glutæus Superior.—The **superior gluteal nerve** arises from the posterior surface of the fourth and fifth lumbar and first sacral nerves, and is directed backwards and laterally into the buttock, above the piriformis muscle, along with

the superior gluteal artery. Under cover of the glutæus maximus and glutæus medius, it passes over the glutæus minimus, along with the inferior branch of the deep division of the superior gluteal artery, to the deep surface of the tensor fasciæ latæ, in which it ends. On its way it supplies branches to the glutæus medius and glutæus minimus muscles.

N. Glutæus Inferior.—The **inferior gluteal nerve** arises from the posterior surface of the fifth lumbar and first two sacral nerves. It appears in the buttock at the lower border of the piriformis muscle, superficial to the sciatic nerve, and at once breaks up into a number of branches for the supply of the glutæus maximus. In its course in the buttock it is closely associated with the posterior cutaneous nerve of the thigh. Its origin is sometimes combined with that of the following nerve.

The **nerve to the short head of the biceps** springs from the lateral side of the common peroneal trunk in the proximal part of the thigh. When traced to its origin, it is found to arise (sometimes in combination with the inferior gluteal nerve) from the fifth lumbar and first two sacral nerves. In its course it is closely applied to the common peroneal nerve, from which it separates in the middle third of the thigh, usually in combination with the articular branches of that nerve for the knee-joint. In some cases it has an independent course in the thigh, and it may be associated in the buttock with the inferior gluteal nerve.

An **articular branch** for the lateral and anterior aspects of the knee-joint generally arises from the common peroneal nerve in common with the nerve to the short head of the biceps. When traced up to the plexus, it is found to arise from the posterior surface of the fourth and fifth lumbar and first sacral nerves. It passes through the proximal part of the popliteal fossa concealed by the biceps muscle, and separates into proximal and distal branches, which accompany the superior and inferior lateral articular arteries to the knee-joint.

2. Terminal Branches.—The **common peroneal** (O.T. **external popliteal**) and **tibial** (O.T. **internal popliteal**) **nerves** are the two main trunks resulting from the combination of the posterior and anterior cords of the sacral plexus respectively. The common peroneal nerve is homologous with the radial nerve of the upper limb; the tibial nerve represents a medio-ulnar trunk; and, as already stated, the two nerves, constituting the sciatic nerve, are enveloped in a common sheath for a variable distance before pursuing an independent course in the leg.

Nervus Peronæus Communis.

The **common peroneal nerve** arises from the posterior part of the sacral plexus from the fourth and fifth lumbar and first two sacral nerves. Incorporated with the sciatic nerve in the buttock and proximal part of the thigh, it passes distally from the bifurcation of that nerve through the popliteal fossa, to its termination at a point about an inch distal to the head of the fibula. It is concealed at first by the biceps muscle. Following the tendon of that muscle, it passes obliquely through the proximal and lateral part of the popliteal fossa and over the lateral head of the gastrocnemius muscle to the posterior aspect of the head of the fibula. In the distal part of its course it is quite superficial, but at its termination it is covered by the peronæus longus muscle lying between the muscle and the neck of the fibula, round which it winds.

Collateral Branches.—These are divided into two sets: (*a*) Nerves arising from the roots or trunk of the nerve while it is in combination with the tibial nerve in the sciatic trunk. These have been already described, as a **muscular branch** to the short head of the biceps, and an **articular branch** to the knee-joint. (*b*) Nerves arising in the popliteal fossa. These are **cutaneous branches**, viz., the lateral sural nerve or lateral cutaneous nerve of the calf and the peroneal anastomotic ramus.

The **lateral sural branch** is irregular in size and distribution, and may be represented by two or more branches (Fig. 620, p. 761). Arising from the common peroneal nerve in the popliteal fossa, often in common with the succeeding nerve, it pierces the deep fascia over the lateral head of the gastrocnemius, and is distributed to the skin on the lateral aspect of the back of the leg in the proximal

two-thirds. The extent of its distribution varies with that of the posterior cutaneous nerve of the thigh and the nervus suralis.

The **peroneal anastomotic nerve** (O.T. **communicans fibularis**), arising in the popliteal fossa, passes over the lateral head of the gastrocnemius beneath the deep fascia to the middle third of the leg, where it assists in forming the nervus suralis by its union with an anastomotic (communicating) branch of the tibial nerve called the medial sural nerve or medial cutaneous nerve of the calf. In many cases the two branches do not unite. In such cases the peroneal anastomotic nerve may be limited in its distribution to the skin of the lateral side of the leg, heel, and ankle, or it may be distributed to the area usually supplied by the nervus suralis.

Terminal Branches.—The terminal branches of the common peroneal nerve are three in number: recurrent tibial, deep peroneal (O.T. anterior tibial), and superficial peroneal (O.T. musculo-cutaneous). They arise just distal to the head of the fibula, and are directed forwards, diverging in their course, beneath the peronæus longus muscle.

The **recurrent tibial nerve** is the smallest branch. Passing forwards under cover of the origin of the peronæus longus and the extensor digitorum longus muscles, it divides, distal to the lateral condyle of the tibia, into branches which supply the proximal fibres of the tibialis anterior muscle, the proximal tibio-fibular articulation, and the knee-joint.

Nervus Peronæus Profundus.

The **deep peroneal nerve** (O.T. **anterior tibial**) passes obliquely distally, under cover of the peronæus longus, extensor digitorum longus, and extensor hallucis longus muscles, to the front of the leg. In its course it is deeply placed upon the interosseous membrane and the distal part of the tibia, in company with the anterior tibial artery lying first lateral, then anterior, and then lateral again, to the vessel. At the ankle it lies under cover of the transverse ligament of the leg and the tendon of the extensor hallucis longus, and, crossing the ankle-joint, it divides on the dorsum of the foot into its terminal branches.

1. **Collateral Branches** (in the leg).—These are given off to the muscles between which the deep peroneal nerve passes, namely: tibialis anterior, extensor hallucis longus, extensor digitorum longus, and peronæus tertius. A fine articular branch supplies the ankle-joint.

2. **Terminal Branches** (on the foot).—The terminal branches are medial and lateral. The **medial branch** passes along the dorsum of the foot, on the lateral side of the dorsalis pedis artery, to the first interosseous space, where it divides into two dorsal digital branches for the supply of the skin of the lateral side of the great toe and the medial side of the second toe (**nervi digitales dorsales, hallucis lateralis et digiti secundi medialis**). Each of these branches communicates with branches of the superficial peroneal (O.T. musculo-cutaneous) nerve. It gives off one or two *dorsal interosseous branches*, which supply the medial tarso-metatarsal and metatarso-phalangeal articulations, and enter the first dorsal interosseous muscle.

The **lateral branch** passes obliquely over the tarsus under cover of the extensor digitorum brevis, and ends in a gangliform enlargement (similar to the gangliform enlargement on the dorsal interosseous nerve of the forearm at the back of the wrist). From this enlargement muscular branches arise for the supply of the extensor digitorum brevis, along with branches for the tarsal, tarso-metatarsal, and metatarso-phalangeal articulations. Its *dorsal interosseous branches* may be as many as four in number. Of these the lateral two, extremely small, may only reach the tarso-metatarsal articulations. The medial two are fine branches, which, besides supplying the articulations, may give branches to the second and third dorsal interosseous muscles.

The branches from the nerve to the interosseous muscles are probably sensory, the motor supply of these muscles being certainly derived from the lateral plantar nerve.

Nervus Peronæus Superficialis.

The **superficial peroneal nerve** (O.T. **musculo-cutaneous**), the last of the branches of the common peroneal nerve, passes distal to the head of the fibula and under cover of the proximal fibres of the peronæus longus muscle. Lying in a sheath in the intermuscular septum, between the peronæi and the extensor digitorum longus, it proceeds distally in front of the fibula to the distal third of the leg, where it pierces the deep fascia in two branches, medial and lateral.

Its branches are: (1) *collateral* muscular branches distributed to the peronæus longus and peronæus brevis, as the nerve lies in relation to these muscles; (2) *terminal* cutaneous branches, medial and lateral.

Nn. Cutanei Dorsales Medialis et Intermedius.—The **medial terminal branch (n. cutaneus dorsalis medialis)** courses distally over the transverse ligament of the leg, and after supplying offsets to the distal third of the leg and to the dorsum of the foot, divides into three branches. (1) The most medial branch supplies the skin of the dorsum of the foot and the medial side of the great toe, and communicates with the saphenous nerve. (2) The intermediate branch passes to the interval between the great toe and the second, and divides into two branches which communicate with the medial branch of the deep peroneal nerve. (3) The lateral branch passes to the interval between the second and third toes, and divides into dorsal digital branches to supply the adjacent sides of these toes.

The **lateral terminal branch (n. cutaneus dorsalis intermedius)** of the nerve passes over the transverse ligament of the leg, and after supplying branches to the distal part of the leg and to the dorsum of the foot, divides into two parts, which, passing to the intervals between the third and fourth, and fourth and fifth toes respectively, divide into dorsal digital branches for the adjacent sides of these toes. These branches communicate with offsets of the nervus suralis (nerve of the calf).

The arrangement of the cutaneous branches of the superficial peroneal nerve is liable to considerable variation. The lateral division of the nerve may be increased in size, and may supply the nerve to the adjacent sides of the second and third toes; or it may be reduced in size, in which case the nervus suralis takes its place on the dorsum of the foot, often supplying as many as two and a half toes on the lateral side.

The cutaneous nerves on the dorsum of the toes are much smaller than the corresponding plantar digital nerves. They are reinforced on the dorsum of the terminal phalanges by twigs from the plantar nerves, which supply the tips of the toes and the nails.

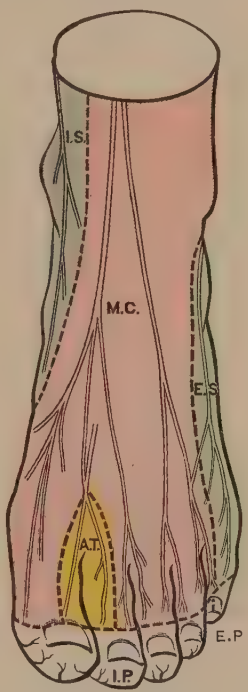

Fig. 620.—Distribution of Cutaneous Nerves on the Dorsum of the Foot.

I.S., Saphenous nerve; M.C., Superficial peroneal nerve; A.T., Deep peroneal nerve; E.S., Nervus suralis. The extremities of the toes are supplied by the medial and lateral plantar nerves (I.P., E.P.).

Nervus Tibialis.

The **tibial nerve** (O.T. **internal popliteal**) arises from the anterior surface of the sacral plexus, usually from the fourth and fifth lumbar and first three sacral nerves (Fig. 616, p. 748). It is incorporated in the sciatic trunk in the buttock and proximal part of the thigh. At the bifurcation of the sciatic nerve it passes onwards through the popliteal fossa and the back of the leg. The part of the nerve from its origin from the plexus or the bifurcation of the sciatic nerve to the distal border of the popliteus muscle, was formerly called **internal popliteal**; the part of the nerve in the back of the leg being then designated **posterior tibial.** The course of the nerve through the buttock and thigh has already been described (p. 757). In the popliteal fossa it is concealed at first by the semimembranosus and the other hamstring muscles. It passes to the medial side of the popliteal vessels, and is thereafter found upon the popliteus muscle, under cover of the gastrocnemius and plantaris. In the back

of the leg, from the distal border of the popliteus muscle to the ankle, the tibial (O.T. posterior tibial) nerve lies on the tibialis posterior muscle and the tibia, and, along with the posterior tibial vessels, occupies a sheath in the intermuscular septum separating the superficial and deep muscles of the back of the leg. In the proximal part of the leg the nerve is medial to the vessels, but, crossing behind them, it lies on their lateral side in the distal portion of its course. It terminates under cover of the ligamentum laciniatum by dividing into the lateral and medial plantar nerves.

The **collateral branches** may be divided into three series, arising respectively in the region of the thigh, the popliteal fossa, and the back of the leg:—

(*a*) *Branches arising from the Roots or Trunk of the Nerve while it is incorporated with the Sciatic Nerve.*—These have been already described as **muscular branches** to the quadratus femoris, gemelli, obturator internus, and the hamstring muscles, and an **articular branch** to the hip-joint (Fig. 623, p. 766).

(*b*) *Branches arising in the Popliteal Fossa proximal to the Knee-Joint.*—These are in three sets—articular, muscular, cutaneous. Vascular branches to the popliteal artery are also described.

1. The **articular branches** are slender nerves, variable in number. There are usually two, an *azygos* branch which pierces the oblique ligament of the knee-joint, and a *medial* branch, a long fine nerve which, crossing the popliteal vessels, runs distally on the medial side of the fossa to accompany the distal medial articular artery to the knee-joint. In its course it gives off a branch, often absent, which accompanies the proximal medial articular artery.

2. The **muscular branches** are five in number. Nerves for the two heads of the *gastrocnemius*, and for the *plantaris* enter those muscles at the borders of the popliteal fossa. A nerve for the *soleus* enters the superficial surface of the muscle. A nerve for the *popliteus* muscle passes over the surface of that muscle, and after winding round its distal border, supplies it on its deep (anterior) surface. As this nerve passes below the popliteus it supplies branches to the *tibialis posterior*, an *interosseous* branch for the interosseous membrane, which can be traced as far as the tibio-fibular syndesmosis, an *articular* branch for the proximal tibio-fibular joint, and a *medullary* branch for the shaft of the tibia.

3. **The Medial Sural Nerve** (O.T. **N. Communicans Tibialis**).—The **cutaneous branch** is the **medial cutaneous nerve of the leg.** This nerve passes from the popliteal fossa in the groove between the two heads of the gastrocnemius muscle, and afterwards lies upon the tendo calcaneus. It pierces the deep fascia in the middle third of the back of the leg, and is joined immediately afterwards by the peroneal anastomotic ramus from the common peroneal nerve. From their union the nervus suralis results, which reaches the foot, winding round the back of the lateral malleolus, along with the small saphenous vein. The nervus suralis supplies cutaneous branches to the lateral side and back of the distal third of the leg, the ankle and heel, and the side of the foot and little toe, as well as articular branches to the ankle and tarsal joints.

The nervus suralis communicates on the foot with the superficial peroneal nerve, and its size varies with the size of that nerve. It may extend on to the dorsum of the foot for a considerable distance, and may either reinforce or replace the branches of the above-named nerve to the intervals between the fourth and fifth and the third and fourth toes. The mode of formation of the nervus suralis is very variable. The usual arrangement is that described. Frequently the peroneal anastomotic nerve and the medial sural nerve (medial cutaneous nerve of the leg) do not unite, and in such cases the more usual arrangement is for the tibial trunk alone to form the nervus suralis (nerve of the calf), the peroneal anastomotic ramus extending only to the ankle and heel. It is less usual for the peroneal anastomotic ramus alone to form the nervus suralis, the medial sural nerve in these cases ending at the heel.

(*c*) *Branches arising in the Back of the Leg distal to the Knee-Joint.*—These branches are mainly muscular and cutaneous.

The **muscular branches** are four in number, comprising nerves to the soleus (entering its deep surface) and tibialis posterior, often arising by a common trunk, and nerves to the flexor digitorum longus and flexor hallucis longus, the latter

generally accompanying (and supplying) the peroneal artery for some distance. The nerve to the tibialis posterior supplies twigs to the posterior tibial artery.

The **cutaneous branches** are the **medial calcanean rami**, which pierce the ligamentum laciniatum, and are distributed to the skin of the heel and posterior part of the sole of the foot.

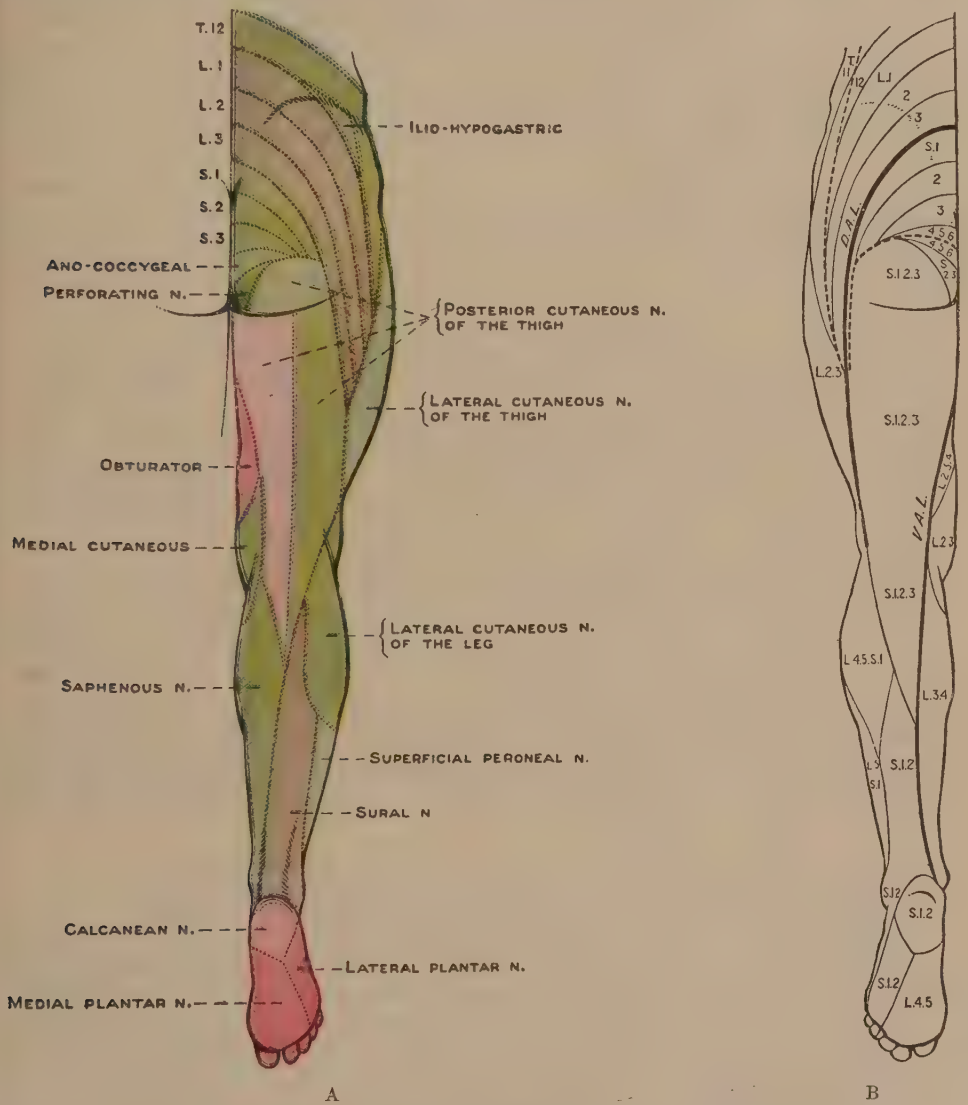

FIG. 621.—DISTRIBUTION OF CUTANEOUS NERVES ON THE BACK OF THE LOWER LIMB.

In A the distribution of the several nerves is represented, their names being given.

In B a schematic representation is given of the areas supplied by the above nerves, the figures indicating the spinal origin of the branches of distribution to each centre.

In addition, a *medullary nerve* to the fibula, and a small *articular branch* to the ankle-joint, are supplied by the tibial nerve.

The **terminal branches of the tibial nerve** are the *medial* and *lateral plantar nerves.*

NERVUS PLANTARIS MEDIALIS.

The **medial plantar nerve** is homologous with the median nerve in the hand (Fig. 621, p. 763). It is rather larger than the lateral plantar. It courses

forwards in the sole of the foot, under cover of the ligamentum laciniatum and abductor hallucis, to the interval between that muscle and the flexor digitorum brevis, in company with the medial plantar artery.

The **collateral branches** are muscular, cutaneous, and articular. The *muscular* branches supply the abductor hallucis and the flexor digitorum brevis. The plantar *cutaneous* branches are small twigs which pierce the plantar aponeurosis in the interval between these muscles to supply the medial part of the sole of the foot. The *articular* branches are minute twigs which supply the tarsal and tarso-metatarsal articulations.

The **terminal branches** are four in number, the *common plantar digital nerves*, and may be designated first, second, third, and fourth, from medial to lateral side.

The **first** (most medial) branch separates from the nerve before the others, and pierces the plantar aponeurosis behind the ball of the great toe. It supplies a muscular branch to the flexor hallucis brevis, and cutaneous branches to the medial side of the foot and ball of the great toe. It terminates as the plantar proper digital nerve for the medial side of the great toe.

The **second branch** arises along with the third and fourth; after supplying a branch to the first lumbrical muscle, it becomes superficial in the interval between the first and second toes, and terminates by dividing into two *proper digital nerves* for the supply of the adjacent sides of these toes.

The **third** and **fourth branches** are entirely cutaneous in their distribution. They become superficial in the intervals between the second and third and the third and fourth toes, respectively, and there divide into proper digital branches for the supply of the adjacent sides of these toes.

FIG. 622.—SCHEME OF DISTRIBUTION OF THE PLANTAR NERVES.

In brown, medial plantar nerve, and its cutaneous and muscular branches; F.B.D., Flexor digitorum brevis; A.H., Abductor hallucis; F.B.H., Flexor hallucis brevis; L.I., First lumbrical. *In green*, lateral plantar nerve, and its cutaneous and muscular branches; Quad. P., Quadratus plantæ; A.D.Q., Abductor digiti quinti; F.B.D.Q., Flexor brevis digiti quinti.

The **plantar proper digital nerves** supply the whole length of the toes on the plantar aspect, and, in relation to the terminal phalanges, furnish minute dorsal offsets for the supply of the nails and tips of the toes on their dorsal surface.

The medial plantar nerve thus supplies the skin of the three and a half medial toes in the sole of the foot, and four muscles: the abductor hallucis and flexor digitorum brevis, the flexor hallucis brevis, and the first lumbrical muscle.

NERVUS PLANTARIS LATERALIS.

The **lateral plantar nerve** is homologous with the ulnar nerve in the hand. From its origin, under cover of the ligamentum laciniatum, it extends forwards and laterally in the sole, in company with the lateral plantar artery, between the flexor digitorum brevis and the quadratus plantæ, towards the base of the fifth metatarsal bone. There it terminates by dividing into superficial and deep branches.

Collateral Branches.—*Muscular branches* are given off from the undivided nerve to the quadratus plantæ and abductor digiti quinti muscles. *Cutaneous branches* pierce the plantar fascia at intervals along the line of the intermuscular septum, between the flexor digitorum brevis and abductor digiti quinti.

Terminal Branches—Ramus Superficialis.—The **superficial branch** is mainly cutaneous. Passing forwards between the flexor digitorum brevis and abductor digiti quinti, it divides into lateral and medial parts.

The *lateral branch*, after supplying the flexor quinti digiti brevis muscle, and sometimes one or both interossei of the fourth space, becomes superficial behind the ball of the little toe, and supplies cutaneous twigs

to the sole of the foot and ball of the toe. It terminates as the proper digital branch for the lateral side of the little toe.

The *medial branch* passes forwards to the interval between the fourth and fifth toes, where it becomes cutaneous, and divides into two proper digital branches for the supply of the adjacent sides of these toes. It communicates with the fourth terminal branch of the medial plantar nerve.

Ramus Profundus.—The **deep branch** of the lateral plantar nerve, passing deeply along with the lateral plantar artery, extends medially towards the great toe, under cover of (*i.e.* dorsal to) the quadratus plantæ and oblique head of the adductor hallucis. It gives off *articular branches* to the tarsal and tarso-metatarsal joints, and *muscular branches* to the interossei of each space (except in some cases the muscles of the fourth space): to the adductor hallucis, and the lateral three lumbrical muscles. These nerves enter the deep surface of the muscles, that to the second lumbrical reaching its muscle after passing forwards dorsal to the transverse head of the adductor hallucis.

PLEXUS PUDENDUS.

The **pudendal plexus** constitutes the third and last subdivision of the lumbo-sacral plexus. It is composed, for the most part, of the spinal nerves below those which form the sacral plexus; but, as already stated, there is no distinct point of separation between the two plexuses. On the contrary, there is considerable overlapping, so that two and sometimes three of the principal nerves derived from the pudendal plexus have their origin in common with nerves of the sacral plexus.

The plexus is formed by fibres from the anterior rami of the first three sacral nerves, and by the whole of the anterior rami of the fourth and fifth sacral and coccygeal nerves. The size of the nerves diminishes rapidly from the first sacral to the coccygeal, which is extremely slender.

Position and Constitution.—The plexus is formed on the posterior wall of the pelvis. Of the nerves forming it, the upper ones emerge from the anterior sacral foramina; the fifth sacral nerve appears between the last sacral and first coccygeal vertebra; and the coccygeal nerve appears below the transverse process of that vertebra. The nerves of distribution derived from the plexus are the following:—

1. Visceral branches.
2. Posterior cutaneous nerve of the thigh.
3. Perforating cutaneous nerve.
4. Pudendal nerve.
5. Muscular branches.
6. Ano-coccygeal nerve.

All the nerves, except the visceral branches, are distributed to the perineum. Only two, the posterior cutaneous nerve of the thigh and the perforating cutaneous nerve, send branches to the lower limb.

Visceral Branches.—Like the other spinal nerves, the fourth and fifth sacral and coccygeal nerves are provided with fine *gray rami communicantes* from the sacral sympathetic trunk, which join them after a short course on the front of the sacrum. The third (along with the second or fourth) sacral nerve, in addition, sends a considerable *white ramus communicans* or **visceral branch** direct to the pelvic plexus and viscera.

The Posterior Cutaneous Nerve of the Thigh (O.T. **Small Sciatic**).—This nerve is complex both in origin and distribution (Fig. 623, p. 766). Springing from the junction of the sacral and pudendal plexuses, it is derived from the first three or second and third sacral nerves. It is distributed to the lower limb and perineum, and is associated with other nerves belonging to both regions. It arises from the back of the roots of the sacral plexus in the pelvis. Its higher roots from the first and second sacral nerves are intimately associated with the origin of the inferior gluteal nerve; its lowest root from the third sacral nerve is associated with the origins of the perforating cutaneous or of the pudendal nerve. It enters the buttock through the greater sciatic notch, below the piriformis, along with the

inferior gluteal artery and nerve. Proceeding distally, posterior to the sciatic nerve, it enters the thigh at the lower border of the glutæus maximus muscle, where it gives off considerable branches. Becoming gradually smaller as it courses distally over the hamstring muscles to the popliteal fossa, it finally pierces the

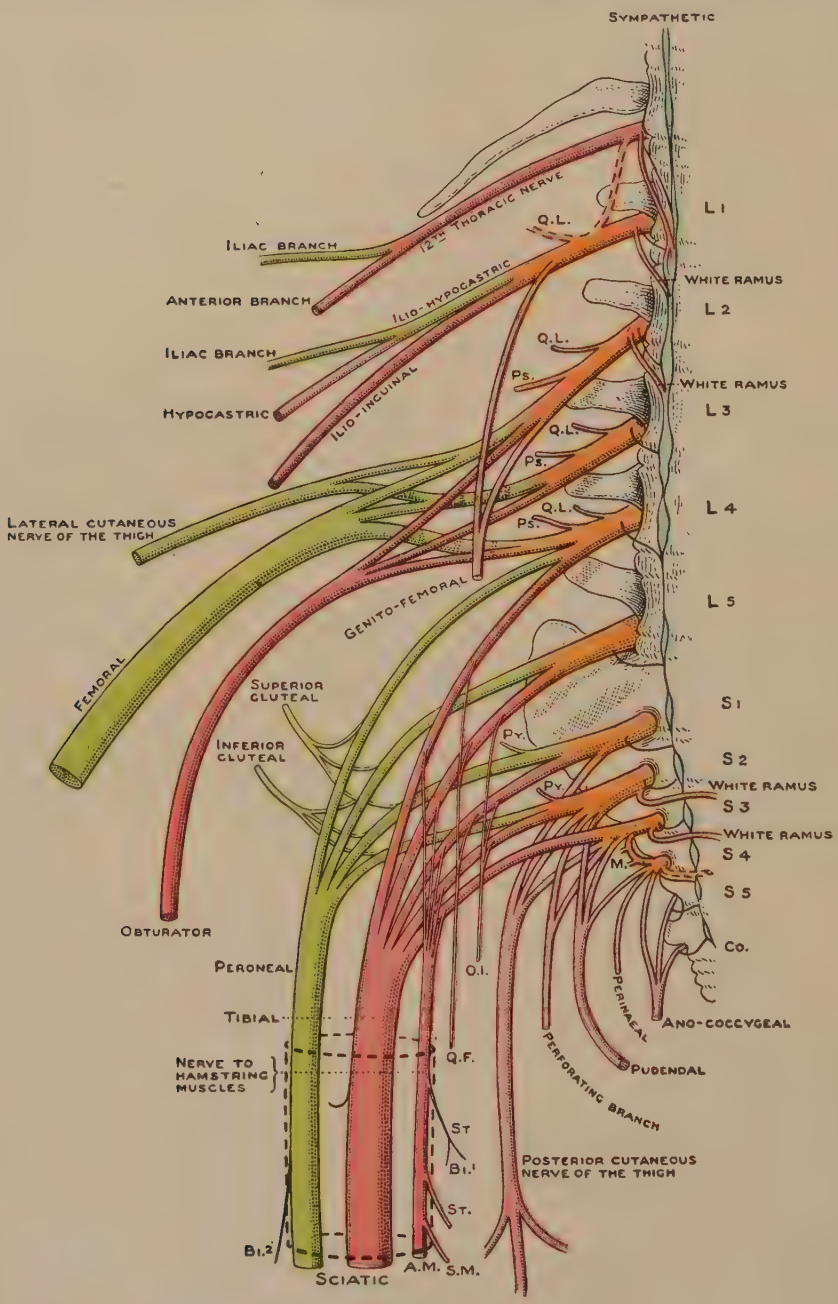

Fig. 623.—Nerves of the Lumbo-Sacral Plexus.

popliteal fascia in one or more cutaneous branches, which supply the skin over the calf of the leg for a variable distance (Fig. 621, p. 763).

Branches.—The nerve is purely cutaneous. It supplies branches to the perineum, buttock, thigh, and leg.

The **perineal branch** arises at the lower border of the glutæus maximus muscle (Fig. 625, p. 769). It sweeps in a medial direction to the perineum, lying on the

origin of the hamstring muscles, distal to the ischial tuberosity; and becoming subcutaneous after passing over the pubic arch, its terminal branches supply the skin of the scrotum and root of the penis, or, in the female, the labium majus and clitoris, some of them being directed backwards towards the anus and central point of the perineum. They communicate with the inferior hæmorrhoidal and perineal branches of the pudendal nerve, and with the ilio-inguinal nerve. In its course to the perineum the nerve gives off *collateral branches* to the skin of the proximal and medial part of the thigh.

The **inferior gluteal branches** are large and numerous (Fig. 623, p. 766). They arise from the nerve beneath the glutæus maximus, and become subcutaneous by piercing the fascia lata at different points along its lower border. They supply the skin of the lower half of the buttock. The most lateral branches, reaching to the back of the greater trochanter, overlap the terminal filaments of the gluteal branches of the lateral cutaneous nerve of the thigh, and the posterior rami of the first three lumbar nerves. The most medial branches, which may pierce the sacro-tuberous ligament, reach nearly to the coccyx, and are co-extensive in their distribution with the branches of the perforating cutaneous nerve, which they reinforce and not infrequently replace.

The **femoral branches** are divisible into two sets—*medial* and *lateral*. They pierce the fascia lata of the thigh at intervals, and supply the skin of the back of the thigh.

The **sural branches** are two or more slender nerves which pierce the fascia over the popliteal fossa, and are distributed for a variable extent to the skin of the back of the leg. They may stop short over the popliteal fossa, or may extend as far as the ankle. Usually they innervate the skin as far as the middle of the calf. They communicate with the nervus suralis.

In cases where the sciatic nerve is naturally divided at its origin into tibial and common peroneal nerves (*e.g.* by the piriformis muscle), the posterior cutaneous nerve also is separated into two parts: a **posterior part**, associated with the common peroneal nerve and arising in common with the lower roots of the inferior gluteal nerve (usually from the first and second sacral nerves), and comprising the gluteal and lateral femoral branches; and an **anterior part**, associated with the tibial nerve and arising usually from the second and third sacral nerves, along with the perforating cutaneous and pudendal nerves, and comprising the perineal and medial femoral branches.

Perforating Cutaneous Nerve (n. perforans ligamenti tuberoso-sacri (Schwalbe), n. cutaneus clunium inferior medialis (Eisler)).—This nerve arises from the back of the second and third sacral nerves (Fig. 623, p. 766). At its origin it is associated with the lower roots of the posterior cutaneous nerve of the thigh. Passing distally it pierces the sacro-tuberous ligament, along with the coccygeal branch of the inferior gluteal artery; and after winding round the lower border of the glutæus maximus muscle, or in some cases piercing its lower fibres, it becomes cutaneous a little distance from the coccyx, and supplies the skin over the lower part of the buttock and the medial part of the fold of the nates.

The perforating cutaneous nerve is not always present. In a minority of cases it is associated at its origin with the pudendal nerve. When absent as a separate nerve, its place is taken by (1) gluteal branches of the posterior cutaneous nerve of the thigh, or (2) a branch from the pudendal nerve, or (3) a small nerve (n. perforans coccygeus major, Eisler), arising separately from the posterior part of the third and fourth sacral nerves.

Muscular Branches.—Between the third and fourth sacral nerves (occasionally reinforced by the second, Eisler) a plexiform loop is formed, from which muscular nerves are given off to the levator ani (supplying the muscle on its pelvic surface), coccygeus, and external sphincter. The nerve to the external sphincter (*perineal branch of fourth sacral*) pierces the sacro-tuberous ligament and the coccygeus muscle, to which it gives offsets, and appears in the ischio-rectal fossa between the glutæus maximus and the external sphincter. Besides supplying the posterior fibres of the external sphincter, it distributes cutaneous offsets to the skin of the ischio-rectal fossa and the fold of the nates behind the anus. This nerve, in some instances, replaces the perforating cutaneous nerve.

Ano-coccygeal Nerve.—By the union of the remaining part of the fourth with the fifth sacral and coccygeal nerves, the so-called **plexus coccygeus (coccygeal plexus)** is formed. A fine descending branch of the fourth sacral nerve passes over or through the sacro-tuberous ligament, to join the fifth sacral nerve. This fifth sacral nerve, joined by the descending branch of the fourth, descends alongside the coccyx and is again joined by the coccygeal nerve, so that a plexiform cord, the *ano-coccygeal nerve*, results, homologous with the inferior caudal trunk of tailed animals. Fine twigs arise from it, which pierce the sacro-tuberous ligament and

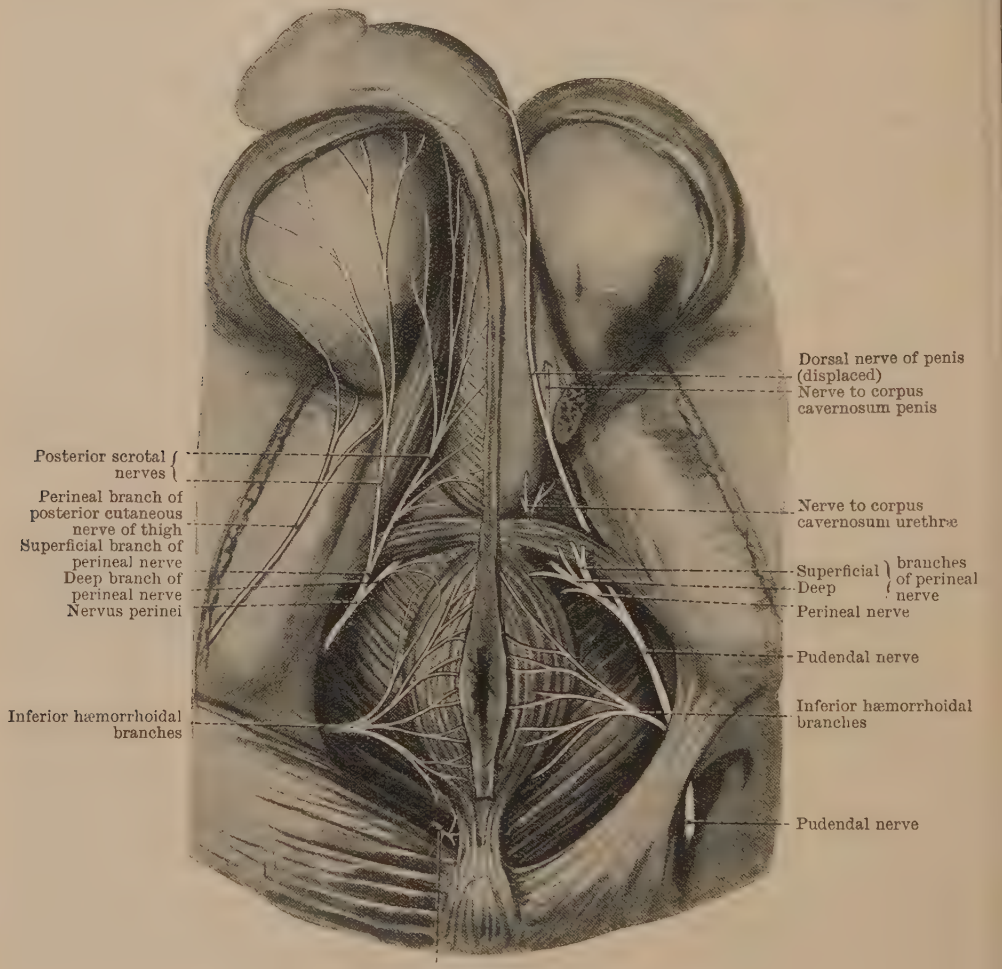

Fig. 624.—Distribution of the Pudendal Nerve.

supply the skin in the neighbourhood of the coccyx, medial to the branches of the perforating cutaneous nerve and behind the anus.

Nervus Pudendus.

The **pudendal nerve** (O.T. **pudic**) is the principal nerve for the supply of the perineum. It arises in the pelvis usually by three roots from the second, third, and fourth sacral nerves (Fig. 623, p. 766). (Frequently one of its branches, the inferior hæmorrhoidal nerve, arises independently from the third and fourth sacral nerves.) The nerve passes to the buttock through the greater sciatic foramen, below the sciatic nerve, and lies on the sacro-spinous ligament, or the spine of the ischium, medial to the internal pudendal artery. It enters the perineum along with the artery through the lesser sciatic foramen. In the perineum it is deeply placed in the lateral wall of the ischio-rectal fossa, enclosed in a special sheath derived

from the parietal pelvic fascia covering the medial surface of the obturator internus muscle. At the anterior limit of the ischio-rectal fossa, the nerve approaches the surface and divides at the base of the urogenital diaphragm into its terminal branches, the perineal nerve and the dorsal nerve of the penis.

The branches of the nerve are essentially the same in the two sexes. As a rule no branches are given off till it enters the perineum, but sometimes the inferior hæmorrhoidal nerve has an independent origin from the plexus, merely accompanying the pudendal nerve in the first part of its course; and in exceptional cases the perforating cutaneous nerve of the buttock is a branch of the pudendal nerve.

The **inferior hæmorrhoidal nerve** arises from the pudendal nerve under cover of the glutæus maximus, at the posterior part of the ischio-rectal fossa. In cases in which it has an independent origin from the plexus, it arises from the third and fourth sacral nerves. It crosses the ischio-rectal fossa in company with the inferior hæmorrhoidal vessels, and separates into numerous branches—muscular, cutaneous, and communicating.

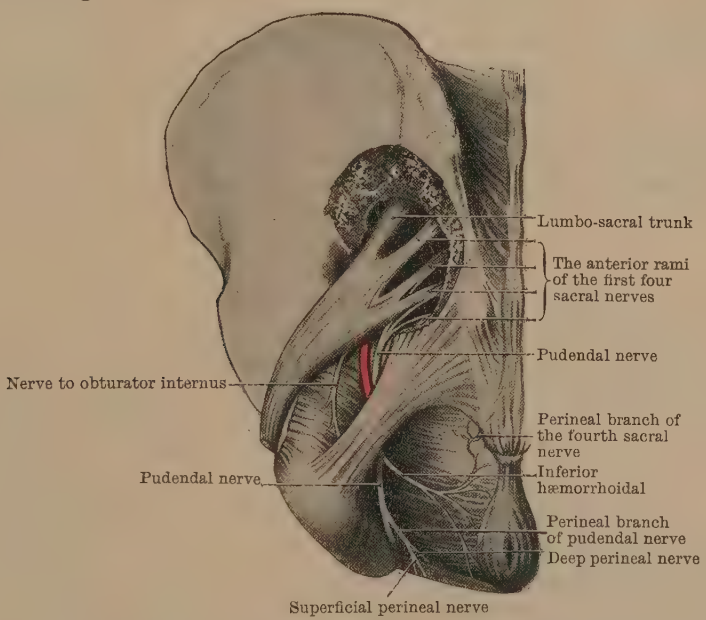

FIG. 625.—THE ORIGIN AND COURSE OF THE PUDENDAL NERVE.

The **muscular branches** end in the external sphincter ani muscle. The **cutaneous branches** supply the skin around the anus. The **communicating branches** connect the inferior hæmorrhoidal with three other nerves—the perineal branches of the posterior cutaneous nerve of the thigh, pudendal, and fourth sacral nerves.

The **perineal nerve**, one of the two terminal branches of the pudendal nerve, arises near the base of the urogenital diaphragm. It almost immediately divides into two parts, superficial and deep.

The **superficial part** is purely cutaneous and consists of two nerves, the posterior or lateral and the anterior or medial superficial perineal nerves (nn. scrotales posteriores or nn. labiales posteriores), which pass, along with the superficial perineal vessels, to the anterior part of the perineum. The **posterior or lateral superficial perineal nerve**, at the anterior limit of the ischio-rectal fossa, usually passes over the base of the urogenital diaphragm and over the (superficial) transversus perinei muscle. The **anterior or medial superficial perineal nerve**, lying more deeply, pierces the base of the fascia inferior of the urogenital diaphragm and goes underneath or through the transversus perinei muscle. Becoming superficial in the anterior (urethral) triangle of the perineum, they are distributed to the skin of the scrotum (or labium majus), and communicate with the perineal rami of the posterior cutaneous nerve of the thigh and with the inferior hæmorrhoidal nerve.

The **deep part** of the perineal nerve is mainly but not entirely muscular. Coursing forwards through the anterior part of the ischio-rectal fossa, it passes between the two layers of fascia of the urogenital diaphragm towards the urethra. It supplies muscular branches to the anterior parts of the levator ani and external sphincter, to the transversus perinei superficialis and profundus, ischio-cavernosus, bulbo-cavernosus (or sphincter vaginæ), and sphincter urethræ membranaceæ. It terminates as the nerve to the bulb, which, piercing the urogenital diaphragm, enters the bulb of the urethra and supplies the erectile tissue of the bulb and corpus cavernosum urethræ, as well as the mucous membrane of the urethra as far as the glans penis.

The **dorsal nerve of the penis or clitoris**, the other terminal branch of the pudendal nerve, accompanies the internal pudendal artery above the fascia inferior of the urogenital diaphragm. It passes forward close to the pubic arch, lying under cover of the crus and ischio-cavernosus and fascia inferior of the urogenital diaphragm, and upon the sphincter urethræ membranaceæ muscle; piercing the fascia inferior of the urogenital diaphragm near its apex, at the lateral side of the dorsal artery of the penis (or clitoris), it passes on to the dorsum of the penis or clitoris, to which it is distributed in its distal two-thirds, sending branches round the sides of the organ to reach its under surface. In the female the nerve is much smaller than in the male. The dorsal nerve of the penis supplies one branch, the **nerve to the corpus cavernosum penis**, as it lies between the fasciæ of the urogenital diaphragm. This is a slender nerve, which, piercing the fascia inferior of the urogenital diaphragm, supplies the erectile tissue of the crus and corpus cavernosum penis.

Morphology of the Pudendal Plexus.

The structures occupying the perineum are placed in the ventral axis of the body, and comprise, from before backwards, the penis and scrotum, or mons Veneris and vulva, the central point of the perineum, the anus and ischio-rectal fossa, and the coccyx. They are placed on the medial side of the attachment of the lower limbs—the penis or mons Veneris in relation to the preaxial border; the coccyx in relation to the postaxial border of the limb.

The nerves of the perineum, thus reaching the ventral axis of the trunk, are homologous with the anterior (ventral) terminations of other nerves. They are separable into two series. The perineum is supplied mainly through the pudendal plexus by the last four sacral and the coccygeal nerves, but it is also innervated to a minor extent by the first lumbar nerve through the ilio-inguinal nerve, which reaches the root of the penis and the scrotum. The region is thus supplied by two series of widely separated nerves, which have their meeting-place on the dorsum and side of the penis and scrotum. This junction of the ilio-inguinal and pudendal nerves constitutes the beginning of the **ventral axial line** (Fig. 626, p. 770), which extends peripherally along the medial side of the lower limb. Apart from this break in their distribution, a definite numerical order may be followed in the arrangement of the perineal nerves. The higher parts of the perineum are innervated by the higher spinal nerves; the lower parts, by the lower nerves. This is best exemplified in the distribution of the cutaneous nerves. The base of the penis and scrotum (or mons Veneris) is supplied by the first lumbar nerve (ilio-inguinal). The dorsal nerve of the penis (or clitoris), when traced back to the pudendal plexus, is found to come from the second, and to a less extent from the third sacral nerves; the scrotal nerves (perineal branches of the pudendal and posterior cutaneous nerve of the thigh) similarly arise from the third, and to a less extent from the second sacral nerves; the skin of the ischio-rectal fossa and anus is innervated by the inferior hæmorrhoidal (third and fourth sacral nerves), and the perineal branch of the fourth sacral

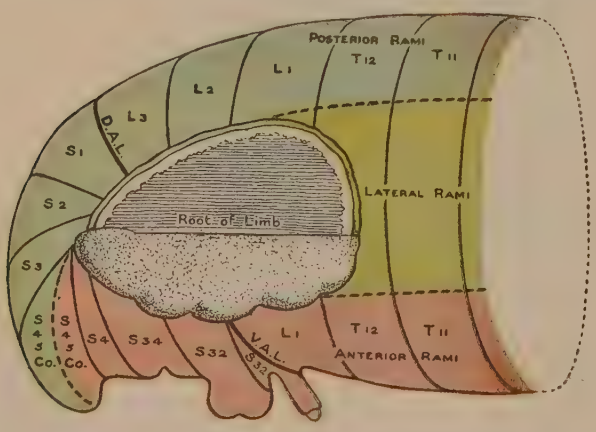

Fig. 626.—Scheme of the innervation of the hinder portion of the trunk and of the perineum, and the interruption of the segmental arrangement of the nerves associated with the formation of the limb.

nerve. The ano-coccygeal nerve (coccygeal plexus), lastly, supplies the skin round the coccyx (fourth and fifth sacral and coccygeal nerves).

Judged from its nerve supply the perineum is to be regarded as occupying, for the most part, a position behind or more caudal than that of the lower limb in relation to the trunk. There is here a remarkable gap in the numerical sequence of the nerves supplying the ventral axis of the body. All the nerves between the first lumbar and the second sacral fail to reach the mid-ventral line of the trunk and are wholly concerned in the innervation of the lower limb.

At the preaxial border of the limb (groin) the first lumbar nerve, the highest nerve supplying the perineum, is concerned also in innervating the skin of the limb. At the postaxial border of the limb (fold of the nates and back of the thigh), the nerves which are the highest of those constituting the pudendal plexus (the second and third sacral nerves) are also implicated in innervating that border of the limb. The fourth sacral nerve is concerned only to a very slight extent in the innervation of the limb by means of the perineal branch, which reaches the beginning of its postaxial border; the last two spinal nerves are wholly unrepresented in the limb proper and end entirely in the trunk behind the limb.

The Distribution of the Spinal Nerves to the Muscles and Skin of the Limbs.

By dissection, experiment, and clinical observation, it is conclusively proved that, as a rule, each nerve of distribution in the limb, whether to muscle or skin, is made up of fibres derived from more than one spinal nerve; and, further, that in cutaneous distribution a considerable overlapping occurs in the course of the several peripheral nerves. Moreover, the arrangement of the distribution of the nerves to skin and to muscles is not identical. In the case of the skin of the limbs, by the covering of the limb being drawn on to it from adjacent parts in the process of growth, cutaneous nerves are engaged which are derived from sources not represented in the muscular innervation of the limbs. Again, among the muscles, some have undergone fusion, others have become rudimentary, and others again have altered their position in the limb.

Innervation of the Skin of the Limbs.

While the scheme of cutaneous innervation of the limbs is fundamentally segmental, yet the arrangement is confused and complicated by various causes. The growth of the limb from the trunk has caused the skin to be drawn out over it like a stretched sheet of india-rubber (Herringham), and at the same time the extent of the dorsal area of the limb is increased at the expense of the ventral area. The central nerves of the plexus remain buried deeply in the substance of the limb, only coming to the surface towards the periphery. The proximal parts of both surfaces of the limb thus become innervated by cutaneous nerves otherwise not necessarily concerned in the innervation of the limbs. Herringham has shown that—(A) *Of two spots on the skin, that nearer the preaxial border tends to be supplied by the higher nerve.* (B) *Of two spots in the preaxial area, the lower tends to be supplied by the lower nerve; and of two spots in the postaxial area, the lower tends to be supplied by the higher nerve.* In other words, from the root of the limb along the preaxial border to its distal extremity, and along the postaxial border to the root of the limb again, there is a definite numerical sequence of spinal nerves supplying skin areas through nerves of the limb plexuses, as is illustrated, for example, in Fig. 609, p. 735. A similar numerical sequence in the arrangement of the nerves is also found extending over the dorsal and ventral surfaces of the limbs from preaxial to postaxial border, except in certain situations.

On the dorsal and ventral surfaces of both upper and lower limbs there is a hiatus, for a certain distance, in the numerical sequence of the spinal nerves in their cutaneous distribution, explicable on the ground that the central nerves of the plexus, which fail to reach the surface in these situations, are replaced by cutaneous branches from neighbouring nerves. This hiatus has been named the *axial area or line.*

In the upper limb, *the dorsal axial area or line* extends from the median line of the back, opposite the vertebra prominens, to the insertion of the deltoid. *The ventral axial area or line* extends anteriorly from the median plane of the trunk, at the sternal synchondrosis, across the chest, distally along the front of the arm and forearm to the wrist.

In the lower limb, *the dorsal axial area or line* may be traced from the median plane of the back over the posterior superior iliac spine, across the buttock and thigh, to the head of the fibula. *A ventral axial area or line* can also be traced from the root of the penis along the medial side of the thigh and knee, and along the back of the leg to the heel.

These areas or lines represent the meeting-place and overlapping of nerves, which are not in numerical sequence; and it is only at the peripheral parts of the limbs, on the dorsal and ventral surfaces, that the nerves appear in numerical sequence from the preaxial to the postaxial border. In the case of the upper limb the hiatus is caused, in both surfaces of the limb, by the absence of cutaneous branches of the seventh cervical nerve; in the case of the lower limb the hiatus is due to the absence of branches from the fifth lumbar nerve on both surfaces of the limb, and the absence of branches from the fourth lumbar nerve, in addition, on the dorsal surface.

These points in the innervation of the skin of the limbs are illustrated by Figs. 609, 610, pp. 735, 736, and by Fig. 598, p. 716, and Fig. 626, p. 770.

Innervation of the Muscles of the Limbs.

The following laws appear to be applicable to the upper and lower limbs alike :—

1. *No limb-muscle receives its nerve-supply from posterior rami.*

2. *The dorsal and ventral strata of muscles are always supplied by the corresponding dorsal and ventral branches of the nerves concerned. The ventral muscular stratum is more extensive than the dorsal; the ventral nerves are the more numerous, and the additional nerves are postaxially placed.* The spinal nerves supplying muscles of the upper limb are C. 5, 6, 7, 8 (dorsal), and C. 5, 6, 7, 8, T. 1 (ventral); the nerves for the muscles of the lower limb are L. 2, 3, 4, 5, S. 1, 2 (dorsal), and L. 2, 3, 4, 5, S. 1, 2, 3 (ventral).

3. *The dorsal and ventral trunks of the nerves are distributed in the limb in a continuous, segmental manner*; so that, "of two muscles, that nearer the head end of the body tends to be supplied by the higher nerve, and that nearer the tail end by the lower nerve" (Herringham).

4. *The nerves placed most centrally in the plexus extend furthest into the limb, and the more preaxial nerves terminate sooner in the limb than the more postaxial nerves.*

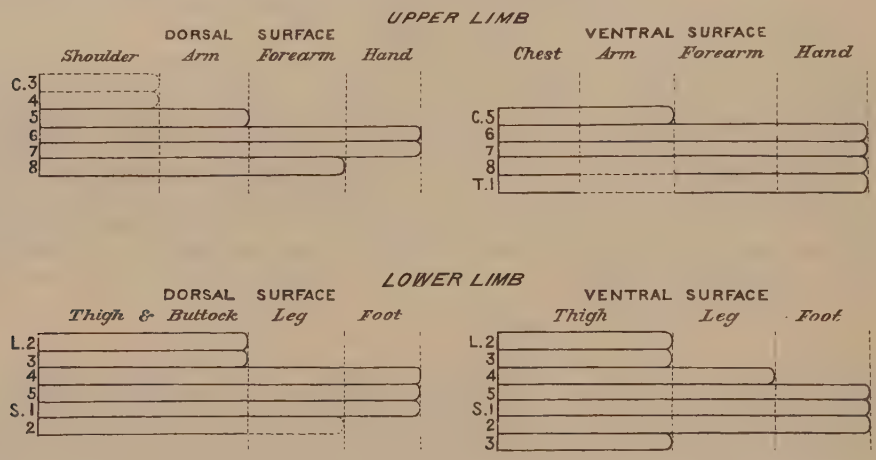

Diagram of the segmental distribution of the muscular nerves of the upper and lower limbs.

The only exception to this rule is on the ventral (anterior) surface of the arm, where a suppression of the muscle elements leads to an absence of the regular series of segmental nerves (C. 8, T. 1) on its postaxial border. These nerves reappear in the forearm, and the occasional "axillary arches" may be regarded as the muscular elements usually suppressed, and, when present, supplied by these nerves.

Muscles with a Double Nerve Supply.—The existence of more than one nerve to a muscle indicates usually that the muscle is composite and is the representative of originally separate elements, belonging to more than one segment or to both surfaces of the limb. In the case of the pectoralis major, subscapularis and flexor digitorum profundus, adductor magnus, and soleus, parts of the same (ventral or dorsal) stratum have fused, to form muscles innervated from the corresponding ventral or dorsal nerves. The other muscles having a double nerve-supply—brachialis, biceps femoris, and (sometimes) pectineus—are examples of fusion at the preaxial or postaxial border of muscular elements derived from the dorsal and ventral surfaces of the limb, which are correspondingly innervated by branches from both dorsal and ventral series: *e.g.*, the brachialis is innervated by the musculo-cutaneous and radial nerves; the biceps femoris by the peroneal (short head) and tibial nerves (long head); and the pectineus, by the femoral and (sometimes) obturator nerves.

THE LIMB PLEXUSES.

Composition of the Limb Plexuses.

In all mammals the same definite plan underlies the constitution of the limb plexuses. The nerves concerned are the anterior rami of certain segmental spinal nerves, which (with certain exceptions at the preaxial and postaxial borders) are destined wholly and solely for the innervation of the limb. Each of the anterior rami engaged divides into a pair of **secondary trunks**, named **dorsal** or posterior, **ventral** or anterior. The dorsal and ventral trunks again subdivide into **tertiary trunks**, which combine with the corresponding subdivisions of neighbouring dorsal and ventral trunks to form the **nerves of distribution**. The combinations of *dorsal trunks* provide a series of nerves for the supply of that part of the limb which is derived from the *dorsal surface* of the embryonic limb bud (coloured green in Fig. 626, p. 770, for the upper limb, and green and pink in Fig. 626, p. 770, for the lower limb); the combinations of *ventral trunks* give

rise to nerves of distribution to the regions corresponding to its *ventral surface* (coloured red in both the above-noted diagrams for the upper and lower limbs respectively).

In the regions of the limbs no anterior cutaneous branches, derived from the limb nerves, supply the trunk. The whole of the nerve is carried into the limb and is absorbed in its innervation, and the dorsal and ventral trunks forming the limb plexuses are to be looked upon as homologous with the lateral and anterior trunks of an intercostal nerve.

Significance of the Limb Plexuses.

It is obvious that something more than convenience of transit for the spinal nerves to skin and muscles is secured by the formation of the limb plexuses. It has been shown that by their combinations in the plexuses, every spot or area of skin in the limbs is innervated by more than one spinal nerve; and generally, also, each limb-muscle is supplied by more than one spinal nerve. Each cutaneous area and each limb muscle is thus brought into relationship with a wider area of the spinal medulla than would occur if the plexuses were non-existent. A simultaneous record of sensation is thus transmitted from any given point on the surface of the limb through more than one posterior root; and a more ready co-ordination of muscular movement is brought about by the transmission of motor impulses from the anterior root of a given spinal nerve to more than one muscle at the same time. Whilst segmentation becomes less obvious, increased co-ordination is effected both of movement and sensation. In a word, a plexus exists to supply the whole limb and the limb as a whole, as an organ which has its different active parts connected with the central nervous system by means of the limb plexus.

DEVELOPMENT OF THE SPINAL NERVES.

I. **Origin of the Spinal Nerve Roots.**—Whilst both the posterior and anterior roots are developed from cells of the neural plate, they differ as regards their exact site of origin.

The **posterior roots** are derived entirely from the neural crest, the origin of which from the cells of the lateral margin of the neural plate is described in the section on Human Embryology (p. 36). At the time when they first appear, the neural crest is a flattened cellular band which extends from the auditory vesicle along the lateral border of the neural tube to its caudal extremity. In the spinal region the crest shows segmental ganglionic enlargements along its ventral border, whilst its dorsal border shows a continuous cellular bridge throughout its length. Central processes are developed from the cells (neuroblasts) of the ganglionic enlargements, and, travelling upward through the crest, leave it along its dorsal border in segmental bundles to grow into the alar lamina of the neural tube. With the establishment of these dorsal root fibres the cellular bridge of the neural crest disappears, and the ganglionic enlargements thus become separated into individual spinal ganglia; these grow ventrally and come into relation with the anterior roots. Peripheral processes are developed from the ganglionic neuroblasts and emerge from the ventral border of the ganglia to join the fibres of the anterior root, with which they course as the posterior root fibres of the spinal nerves.

The **anterior roots**, on the contrary, are developed from the neural tube, which is a derivative of the medial portion of the neural plate. Processes from the neuroblasts situated in the mantle zone of the basal lamina grow out in small bundles which pierce the external limiting membrane and emerge in a continuous longitudinal series of rootlets from the ventro-lateral wall of the tube. Outside the tube these rootlets are grouped into segmental bundles, the anterior roots, which join the dorsal roots just peripheral to the spinal ganglia.

II. **Formation of the Spinal Nerve.**—The fibres of the posterior root ganglion and the anterior root grow by extension from the cells with which they are respectively connected, and meet in the space between the myotome and the side of the medullary tube to form the **spinal nerve**. In the adult there is a fundamental division of the spinal nerve into posterior and anterior rami In the process of development this separation is even more obvious. As the fibres of the posterior and anterior roots approximate, they separate at the same time each into two unequal portions: the smaller parts of the two roots unite together to form the **posterior ramus**, and the larger parts unite to form the **anterior ramus** of the spinal nerve.

The **posterior ramus**, curving laterally and dorsally, passes through the myotome and is connected with it. In the substance of the myotome it separates into branches as it proceeds towards the dorsal wall of the embryo. At a later stage, the branches are definitely arranged into a lateral and a medial series.

The **anterior ramus** grows gradually in a ventral direction to reach the somato-splanchnopleuric angle, under cover of the growing myotome. It spreads out at its distal end and eventually separates into two portions: a smaller, splanchnic, or visceral; and a larger, somatic, or parietal portion. (1) The smaller, **splanchnic**, or **visceral portion** grows inwards, dorsal to the Wolffian ridge, to be connected through the sympathetic trunk with the innervation of organs in the splanchnic area. This branch of the spinal nerve becomes the **white ramus communicans** of the sympathetic. It is not present in the case of all the spinal nerves, but only in relation to the thoracic and upper lumbar and the third and second or fourth sacral nerves. It will be referred to again in connexion with the sympathetic system. (2) The larger, **somatic**, or **parietal portion** becomes the main part of the anterior ramus of the nerve. It continues the original ventral course of the nerve, and, reaching the body wall, subdivides into two terminal branches—a *lateral branch*, which grows laterally and downwards and reaches the lateral aspect of the trunk, after

piercing the myotome; and a ventral or *anterior branch*, which grows onwards in the body wall to reach the ventral axis. This arrangement is met with in the trunk between the limbs and in the neck.

III. **Formation of Limb Plexuses.**—The method of growth of the spinal nerves, just described, is modified in the regions where the limbs are developed. In relation to the limbs, which exist in the form of buds of undifferentiated cellular mesoblast before the spinal nerves have any connexion with them, the development of the anterior ramus of the nerve proceeds exactly in the way described, up to the point of formation of somatic and splanchnic branches. The **somatic branches** then stream out into the limb bud, passing into it below the ends of the myotomes and spreading out into a bundle of fibres at the basal attachment of the limb. Later, the nerves separate, each into a pair of definite trunks, which are named posterior or **dorsal** and

anterior or **ventral**, and which, dividing round a central core of mesoderm, proceed to the dorsal and ventral surfaces respectively of the limb bud. While this process is going on, a *secondary union* takes place between parts of adjacent dorsal and ventral trunks. Dorsal trunks unite with dorsal trunks, ventral trunks unite with ventral trunks, to form the nerves distributed ultimately to the surfaces and periphery of the limb. These **dorsal and ventral trunks** are homologous with the **lateral** and **ventral branches** of the somatic nerves in other regions.

III. THE SYMPATHETIC NERVOUS SYSTEM.

The **Sympathetic Nervous System** is that portion of the peripheral nervous system which serves functionally to distribute efferent impulses of central origin to the involuntary musculature of the viscera, heart, blood-vessels and skin, and the glandular epithelium generally; and it further serves to collect afferent impulses from the viscera, and transmit them to the central nervous system. It consists of a

complex aggregation of ganglia, plexuses, and nerves, widely distributed throughout the whole body; but since the tissues it supplies are most abundant in the visceral or splanchnic organs, the largest and most evident part of the system is found in the body-cavities, and occasions the name "visceral" or "splanchnic" nervous system sometimes applied to it. In these regions it forms a pair of elongated gangliated trunks, lying one on each side of the vertebral column and extending throughout the length of the body from the base of the skull to the coccyx. At the cephalic end each gangliated trunk is continued into the cranial cavity in the form of plexuses round the internal carotid artery, and thereby establishes relations with some of the cerebral nerves. At their caudal ends the two gangliated trunks unite in a single median ganglion placed in front of the coccyx, the *ganglion impar*. Each gangliated trunk is connected to the peripheral spinal nerves by one series of nerves (the white and gray rami communicantes), and to the viscera by another series of nerves; in the course of the latter there occur the numerous plexuses and subsidiary ganglia of the system. These parts indicate the most obvious distribution of the sympathetic system, but since the characteristic tissues innervated by it occur also in the head region, and in the body-wall (somatic) area generally, a wider extension of the system is to be expected, and sympathetic fibres are found in connexion with tissues as far removed from the body-cavity as, for example, the eye or skin.

The sympathetic nervous system is essentially dependent on and subservient to the central nervous system, from which it can no more be separated sharply, either anatomically or developmentally, than can the rest of the peripheral nervous system. For just as the cell bodies of the motor or efferent neurones of the cerebro-spinal system lie in the gray matter of the spinal medulla, so do the efferent fibres of the sympathetic system take origin in the same part, wherein they are connected with the central regulatory mechanism of the viscera. Moreover, the two peripheral systems of fibres are closely related in the first part of their course from the central axis: in the thoracic and lumbar regions the fibres of both systems emerge together in the anterior nerve roots, and only subsequently do the sympathetic leave the spinal ones by way of the white rami communicantes to join the gangliated trunk; and in the sacral region the sympathetic fibres emerge in the second, third, and fourth sacral nerves.

There is one marked difference, however, between the efferent fibres of the two systems. Those of the cerebro-spinal nerves pass continuously from their central origins to the tissues innervated; but those of the sympathetic system always enter and terminate in a ganglion from which a new fibre passes on to the periphery. Hence in the sympathetic system there are to be distinguished two series of fibres in the efferent path: **preganglionic** (medullated) fibres running from the central nervous system to sympathetic ganglia, and **postganglionic** (nearly all non-medullated) fibres passing from the ganglia onwards to their destinations (Fig. 628, p. 776). It may be added that the interruption so formed is probably the only break in the course of the efferent path, and it may occur either in a ganglion of the trunk, or in a collateral ganglion of a plexus, or in a terminal ganglion in close relation to the nerve-ending in a viscus. The sensory or afferent visceral fibres, on the other hand, pass through the sympathetic ganglia without interruption to reach their cell stations in the posterior root ganglia of the spinal nerves.

The efferent fibres of the sympathetic system as above outlined are not the only ones of central origin which supply the involuntary musculature and glandular epithelium of the body generally. For general visceral efferent fibres are also found as components of certain cerebral nerves, namely, the oculo-motor, facial, glossopharyngeal, vagus and accessory nerves; the preganglionic fibres of this cranial outflow do not enter the ganglia of the sympathetic trunk, but end in terminal ganglia of the system. Similarly at the lower end of the central axis, there are found visceral efferent fibres in the second, third, and fourth sacral nerves, the pelvic splanchnic branches, which similarly avoid the gangliated trunk and end in the ganglia of the pelvic sympathetic plexuses. These two streams of fibres, termed cranial and sacral respectively, which emerge from the central axis and escape, as it were, above and below the gangliated trunks, have been classed together as a "**parasympathetic**" group, in contradistinction to the thoracico-lumbar efferent stream, the preganglionic fibres of which end in the ganglion of the trunk, and comprise the sympathetic system proper. A distinction between the two groups is justified not

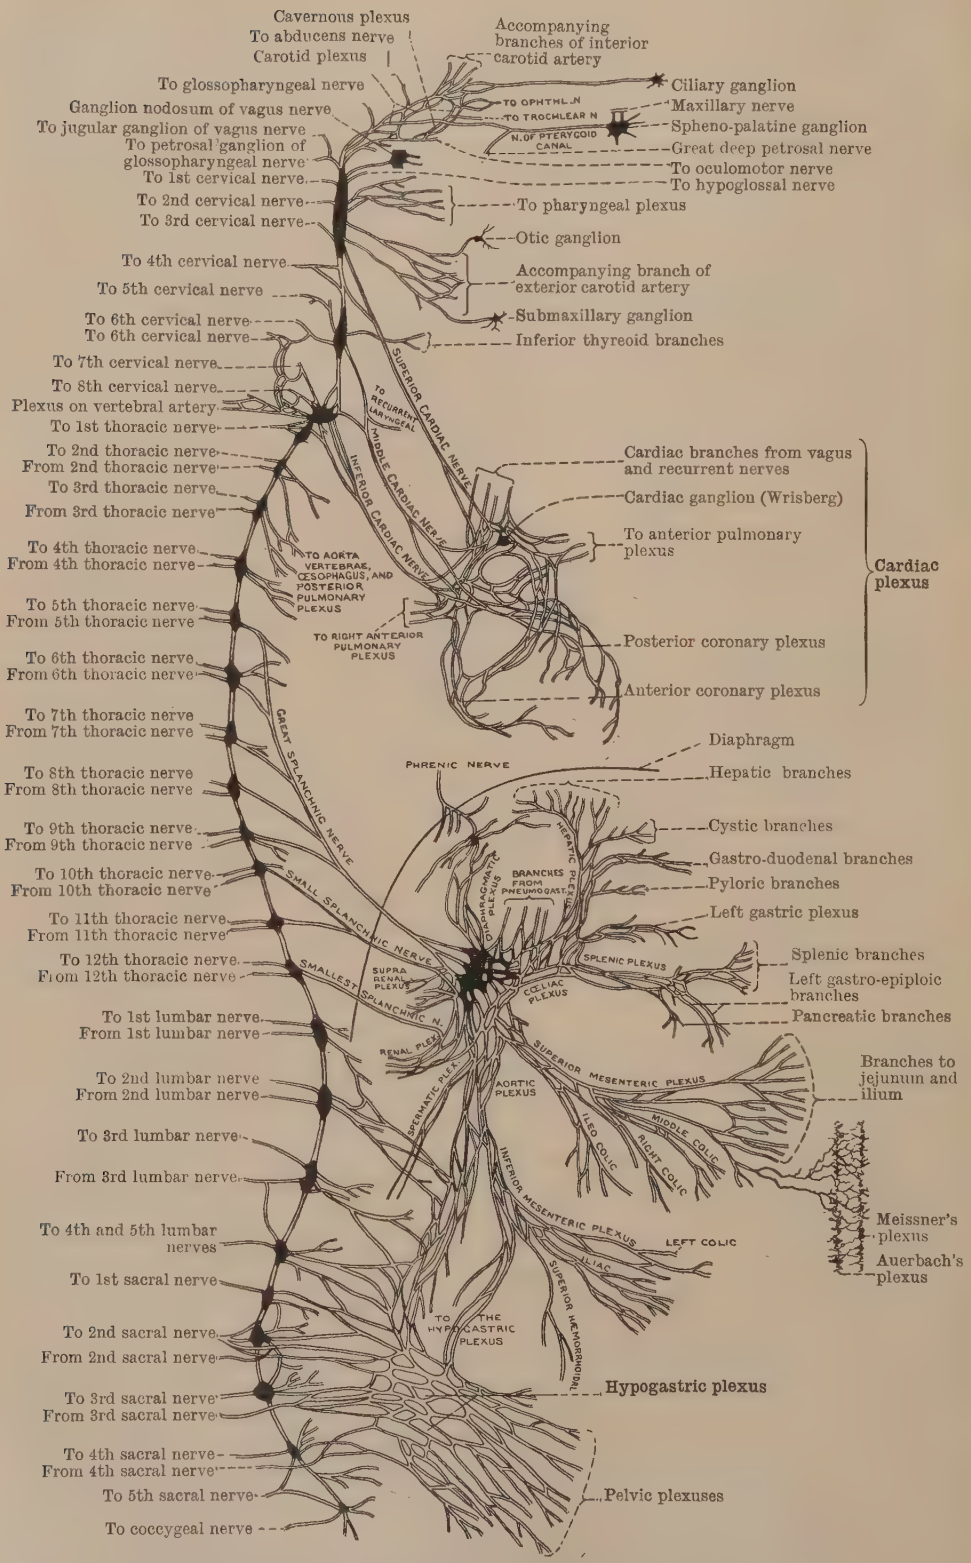

FIG. 628.—PLAN OF THE MAIN PARTS OF THE SYMPATHETIC NERVOUS SYSTEM.
(After Flower, modified, with permission of Messrs. J. and A. Churchill.)

only from their relation to the gangliated trunks, but from the fact that in response to the action of certain drugs the cranio-sacral or parasympathetic groups of neurones agree with each other and differ from the thoracico-lumbar or sympathetic ones. The chief glands and viscera receive usually a double nerve supply, one from each class, and these are held to be physiologically antagonistic.

As a designation which would include both these groups of fibres, that is, to denote the sum total of all general visceral *efferent* neurones in the body, both preganglionic and postganglionic, and whether associated with cerebral or spinal nerves, the term **Autonomic Nervous System** was introduced by Langley. The name denotes the efferent nervous system of the glands and involuntary musculature throughout the whole body. It is a *functional* and not an anatomical subdivision of the nervous system, and it includes only *efferent* neurones. Its preganglionic neurones are partly included in the cerebro-spinal system, and the terminal parts of their fibres, together with the postganglionic neurones, lie in the sympathetic system as usually denoted. The afferent visceral fibres do not form part of the autonomic system, but are considered apart from their anatomical disposition as belonging to the cerebro-spinal peripheral nervous system.

Such functional differentiation of the neurones concerned with the innervation of involuntary musculature is generally accepted, but it appears probable that a further subdivision of the system is necessary to connote the nervous mechanism responsible for those purely local reflexes which are completed in the wall of the gastro-intestinal tract, since these so-called myenteric reflexes (possibly associated with the plexuses of Auerbach and Meissner) are described as occurring after section of all the nerves leading to the gut wall. For this mechanism the term "**enteric nervous system**" is sometimes used.

General Structure of the Sympathetic System.—The sympathetic system is composed of two elements—ganglia and nerve fibres.

(A) A **ganglion** consists of a larger or smaller number of nerve cells, almost all multipolar, though a few are unipolar or bipolar. Each cell is enclosed in a nucleated capsule of connective tissue, and is provided with one axon and a number of dendrites. Some of the dendrites ramify beneath the capsule, hence being termed intracapsular; they may form a network around the cell or be localised in the form of a glomerulus. Other dendrites are extracellular; they pierce the capsule and run throughout the ganglion, taking part in the formation of an intercellular plexus, and making contact with the capsules of other cells. This plexus is joined by the ramifications of the entering preganglionic fibres, some of which also pierce the capsules of cells to meet the intracapsular dendrites. One preganglionic fibre can in this way directly influence many ganglionic neurones, which explains the difference between the comparatively small number of fibres which enter a ganglion and the large number that leave it. There appears to be no evidence of commissural neurones or sensori-motor synapses between the ganglion cells. The axon of a ganglion cell (a postganglionic fibre) is usually unmyelinated, though it may be myelinated at its origin from the parent cell. It may enter into the composition of (*a*) a gray ramus communicans; (*b*) a peripheral branch from the sympathetic trunk or from a ganglion; or (*c*) a commissural cord, and emerge from the trunk at a higher or lower level. The ganglia may be classified as follows:—

(1) Those of the sympathetic trunks or **central ganglia** (*ganglia trunci sympathici*). These are variable in form and size, but are more or less segmental in position. They are always connected together by narrow cords formed by ascending and descending fibres, and in this way the gangliated trunks are formed. There are 21 or 22 ganglia in each trunk of which 3 are associated with the cervical nerves, 10 or 11 with the thoracic, 4 with the lumbar, and 4 with the sacral spinal nerves; the ganglion impar is common to both trunks. (2) The intermediate or **collateral ganglia** (*ganglia plexuum sympathicorum*), which are found in connexion with the great prevertebral plexuses. (3) The **terminal ganglia**, which lie in close relation to the endings of the nerves in the viscera.

(B) The **nerve-fibres** in the sympathetic system are of two classes, medullated and non-medullated, though the distinction is not absolute. Those fibres which enter it from the central nervous system (**preganglionic**) are medullated, but are rather smaller than the somatic efferent fibres. The fibres which arise from cells situated in the sympathetic ganglia (**postganglionic**) are nearly all non-medullated or only partially medullated; a few possess delicate sheaths. The nerve fibres are aggregated to form the white and gray rami communicantes, the commissural cords of the gangliated trunks, and the peripheral branches of the trunk and ganglia.

(i.) The **white rami communicantes** are all medullated fibres. They take origin from the anterior rami of certain spinal nerves in two streams: **thoracico-lumbar** from the first or second thoracic to the second lumbar nerve inclusive, and **pelvic**, or **sacral**, from the second and third, or third and fourth sacral nerves. The cervical nerves do not give off white rami; those of the pelvic group do not enter the gangliated trunk, but all the rest traverse this cord to reach their destination. The roots of these white rami communicantes arise from both posterior and anterior roots of the spinal nerves, but in largest numbers from the anterior root. The *fibres from the anterior root* are of very small size. They are the axons of nerve cells within the spinal medulla, which enter the sympathetic trunk through the white ramus, and end by forming arborisations around the cells of a sympathetic ganglion; they are therefore preganglionic in position. There are three known courses for such a fibre to take in relation to the sympathetic system: (*a*) It may end in the ganglion with which the ramus is immediately related; (*b*) it may course upwards or downwards in the connecting cord to reach a neighbouring ganglion; (*c*) it may pass beyond the sympathetic trunk to end in relation to cells

FIG. 629.—NERVE CELLS FROM THE HUMAN SUPERIOR CERVICAL GANGLION. (Ranson.)
a, Unicellular dendritic glomerulus. *b*, Cell provided only with extracapsular dendrites. (Pyridine silver × 100.)

of a peripheral (collateral) ganglion along with fibres of distribution from the sympathetic ganglia. These fibres are *splanchnic efferent fibres*; they contain motor fibres for the unstriped muscular tissue of the vessels and viscera, and secretory fibres for the glands in the splanchnic area. The *fibres from the posterior root* of the spinal nerve entering into the composition of the white ramus communicans are the axons of spinal ganglion cells. They constitute the *splanchnic afferent fibres*, and traverse the sympathetic gangliated trunk, passing upwards, downwards, and peripherally, without being connected with its cells. They are the sensory fibres from the viscera, with which they are associated along with the peripheral branches arising from the sympathetic trunk itself. It is not certain that fibres from the spinal ganglia are only found in connexion with nerves provided with distinct white rami. Similar medullated fibres are found also in the gray rami communicantes.

The **gray rami communicantes** form a series of non-medullated fibres (with a small number of medullated fibres intermingled) proceeding *from the ganglia to the spinal nerves*; they are therefore postganglionic in position. These gray rami are found in connexion with each and all of the spinal nerves. Their origin from the gangliated trunk is quite irregular: they may come from the ganglia or the commissure; they may divide after their origin, so that two spinal nerves are supplied from one ganglion; or two ganglia may supply branches to a single

spinal nerve. The gray ramus is distributed along the somatic divisions of the spinal nerves, supplying branches to unstriped muscular fibres (vaso-motor, pilomotor) and glands (secretory). They also provide small recurrent branches, ending in the membranes enveloping the spinal nerve-roots. Mingled with the non-medullated fibres of the gray rami are a small number of medullated fibres, some of which may be regarded as afferent fibres—axons passing to the spinal ganglia which are incorporated with the gray rami.

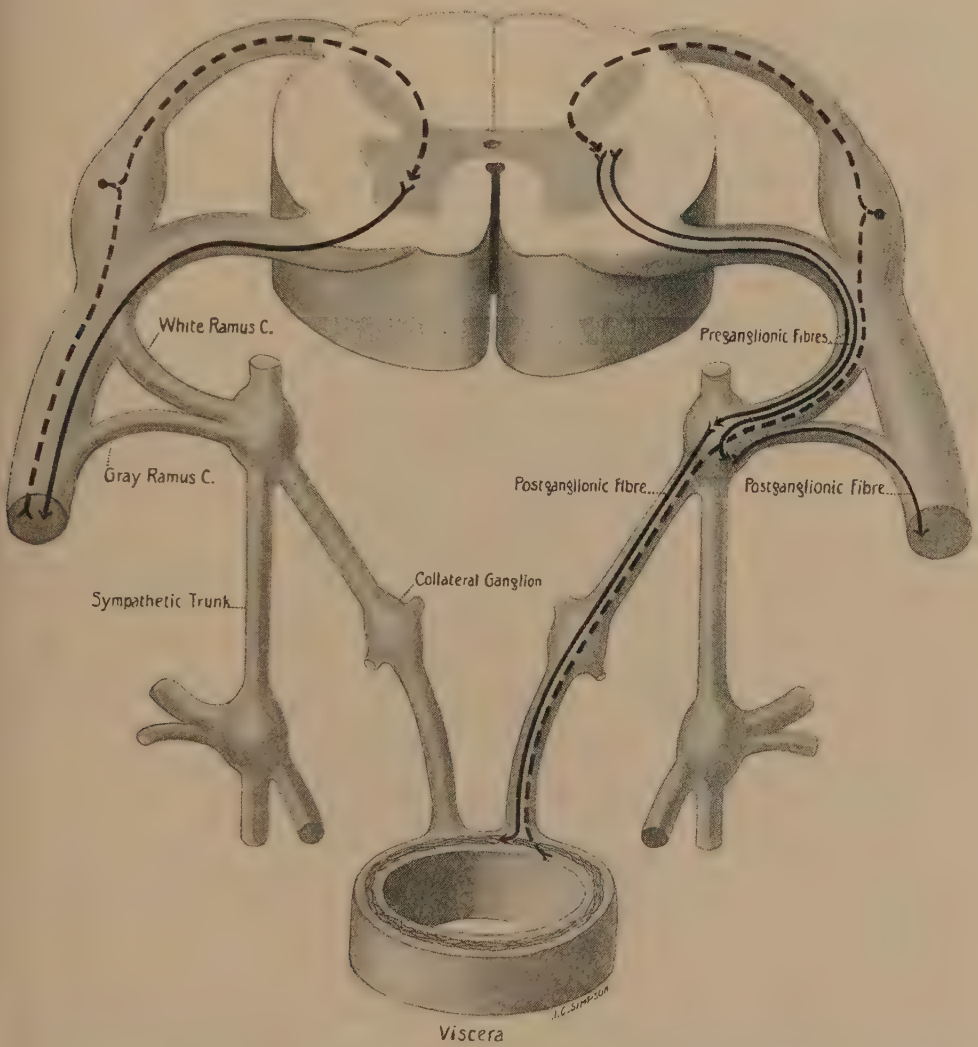

Fig. 630.—Scheme showing the Relation of the Sympathetic System to the Spinal Nerves and Medulla Spinalis.

The main splanchnic fibres are shown on the right side, and, for contrast, the somatic on the left. Afferent fibres are indicated by broken lines, efferent fibres by continuous ones.

(ii.) The **connecting cords** of the sympathetic system are composed of white and gray fibres. The *white fibres* are: (1) splanchnic efferent fibres, passing to a ganglion above or below the point of entrance into the sympathetic system; (2) splanchnic afferent fibres, guided along the connecting cord and over or through the ganglia. The *gray fibres* are the axons of sympathetic ganglion cells; like the white fibres, they may pass along the connecting cord for a certain distance upwards or downwards before entering the splanchnic area as peripheral branches. There is no evidence of a purely associative neurone uniting one ganglion of the trunk with another.

(iii.) The **peripheral branches** of the sympathetic trunk are likewise composed of white and gray fibres. (1) The *white fibres* may be either splanchnic afferent fibres on their way from the viscera through the gangliated trunk to the spinal ganglia, or splanchnic efferent fibres which, after traversing the gangliated trunk, without interruption (and being therefore still preganglionic in character) proceed to join and end in collateral or terminal ganglia in relation to viscera; (2) the *gray fibres* are postganglionic efferent branches, the axons of the ganglion cells, distributed on the one hand peripherally to the vessels and viscera of the splanchnic area, and on the other hand centrally through the gray rami communicantes and the somatic divisions of the spinal nerves, to the glands and involuntary muscles in the somatic area, as secretory, and vaso-motor and pilo-motor fibres.

Description of the Sympathetic System.—For convenience of description the gangliated trunks are dealt with first, in four regional parts, cephalic and cervical, thoracic, abdominal, and pelvic; and the great plexuses are described afterwards.

I. PARS CEPHALICA ET CERVICALIS SYSTEMATIS SYMPATHICI.

The **cephalic** and **cervical part of each sympathetic trunk** is to be regarded as an upward prolongation of the primitive sympathetic system along the great vessels of the neck into the head region. It is characterised by the absence of **segmental ganglia** and by the absence of **white rami communicantes** joining it to the spinal nerves. Its connexion with the spinal nervous system is through the white rami communicantes of the upper thoracic nerves, which join the gangliated trunk in the thorax, and stream upwards into the cervical portion of the trunk. Its branches are distributed to structures belonging to head, neck, and thorax: (1) motor fibres to involuntary muscles (*e.g.* dilator of the pupil); (2) vaso-motor fibres for arteries of the head, neck, and upper limbs; (3) pilo-motor fibres (along the cervical spinal nerves) to the skin of the head and neck; (4) cardio-motor fibres; and (5) secretory fibres (*e.g.*, submaxillary gland). No afferent fibres appear to be present in the cervical part of the trunk.

Each trunk extends from the root of the neck, where it is continuous, in front of the neck of the first rib, with the thoracic portion of the trunk, to the base of the skull, and thus constitutes the **cervical** part of the system. It is then continued upwards into the skull in the form of plexiform branches upon the internal carotid artery to join the **cephalic** part of the system (p. 782).

The **cervical part** of each sympathetic trunk is placed upon the prevertebral muscles and behind the carotid vessels. It consists of a narrow cord composed of medullated and non-medullated fibres, with two or three ganglia—a *superior* ganglion at the upper end, an *inferior* ganglion at the point of junction with the thoracic portion of the trunk, and a *middle* ganglion varying in position and often absent.

The **superior cervical ganglion** is situated at the base of the skull, and lies between the internal jugular vein and the internal carotid artery. It is the largest of the sympathetic ganglia, measuring an inch or more in length. It is thought to be formed by the coalescence of four ganglia corresponding with the upper four cervical nerves.

The **middle cervical ganglion** is of small size, is frequently absent, and may be divided into two parts, indicating ganglia corresponding to the fifth and sixth cervical nerves. It is usually placed in front of the inferior thyreoid artery as it passes behind the carotid sheath.

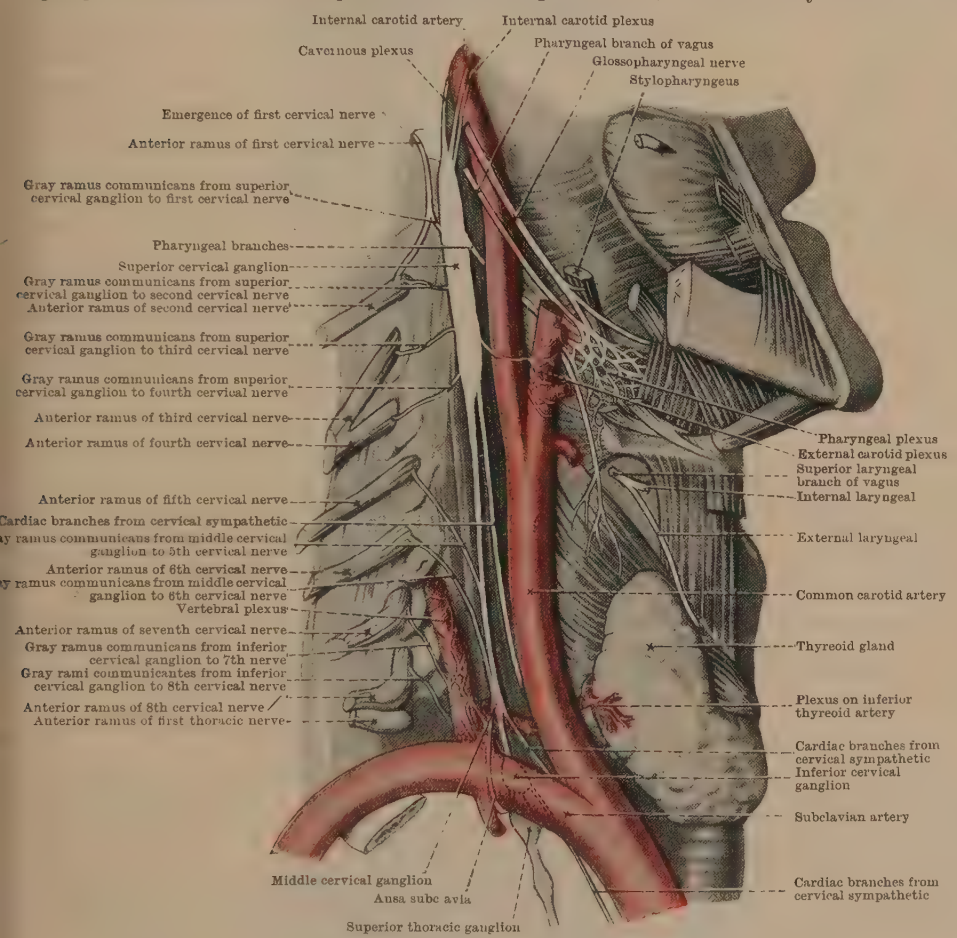
The **inferior cervical ganglion** is joined by the connecting cord to the middle (or superior) ganglion above, and is usually only imperfectly separated from the first thoracic ganglion below, the two when fused being sometimes called the *stellate ganglion*. It is of considerable size, irregular in shape, and is placed behind the first part of the vertebral artery in the interval between the last cervical transverse process and the neck of the first rib.

The **branches** from the cervical sympathetic ganglia and connecting cords are

divisible into two sets—(*A*) **Central** communicating branches for other nerves; (*B*) **Peripheral** branches of distribution, which alone, or along with other nerves, form plexuses, accompanying and supplying vessels and viscera of the head, neck, and thorax. Although this distinction is made, it is to be borne in mind that the branches of communication are as much nerves of distribution as the others.

Ganglion Cervicale Superius.

Numerous branches arise from the ganglion. They are all composed of post-ganglionic fibres, and comprise vaso-motor, pilo-motor, and secretory fibres to certain



Internal carotid artery
Internal carotid plexus
Cavernous plexus
Pharyngeal branch of vagus
Glossopharyngeal nerve
Stylopharyngeus
Emergence of first cervical nerve
Anterior ramus of first cervical nerve
Gray ramus communicans from superior cervical ganglion to first cervical nerve
Pharyngeal branches
Superior cervical ganglion
Gray ramus communicans from superior cervical ganglion to second cervical nerve
Anterior ramus of second cervical nerve
Gray ramus communicans from superior cervical ganglion to third cervical nerve
Gray ramus communicans from superior cervical ganglion to fourth cervical nerve
Anterior ramus of third cervical nerve
Anterior ramus of fourth cervical nerve
Anterior ramus of fifth cervical nerve
Cardiac branches from cervical sympathetic
y ramus communicans from middle cervical ganglion to 5th cervical nerve
Anterior ramus of 6th cervical nerve
y ramus communicans from middle cervical ganglion to 6th cervical nerve
Vertebral plexus
Anterior ramus of seventh cervical nerve
Gray ramus communicans from inferior cervical ganglion to 7th nerve
Gray rami communicantes from inferior cervical ganglion to 8th cervical nerve
Anterior ramus of 8th cervical nerve
Anterior ramus of first thoracic nerve
Pharyngeal plexus
External carotid plexus
Superior laryngeal branch of vagus
Internal laryngeal
External laryngeal
Common carotid artery
Thyreoid gland
Plexus on inferior thyreoid artery
Cardiac branches from cervical sympathetic
Inferior cervical ganglion
Subclavian artery

Superior thoracic ganglion
Cardiac branches from cervical sympathetic

Fig. 631.—Distribution of the Sympathetic in the Neck.

cerebral and spinal nerves, vaso-motor fibres to the branches of the external and internal carotid arteries, and branches to the heart (accelerator) and pharynx.

Central Communicating Branches.—1. *Gray rami communicantes* pass from the ganglion to the anterior rami of the first four cervical nerves.

2. **Communications with Cerebral Nerves.**—Just outside the skull, in the deep part of the neck, communicating branches pass to the following cerebral nerves: (*a*) to both the petrous ganglion of the glossopharyngeal and the jugular ganglion of the vagus (the *jugular nerve*); (*b*) to the ganglion nodosum of the vagus; (*c*) to the hypoglossal nerve.

Peripheral Branches of Distribution.—1. **Pharynx.**—A **pharyngeal branch** passes behind the carotid sheath to reach the wall of the pharynx, where it jo ns (along with the pharyngeal branches of the glossopharyngeal and vagus nerves) in the formation of the **ascending pharyngeal plexus**, and assists in supplying the muscles and mucous membrane of the pharynx.

2. **Heart.**—The **superior cardiac** branch is a slender nerve which, on the *right side*, descends behind the large vessels, but usually in front of the inferior thyreoid artery, and enters the thorax either in front or behind the subclavian artery to join the deep cardiac plexus at the back of the aortic arch. On the *left side* the course of the nerve is similar in the neck, but in the superior mediastinum it passes between the left common carotid and subclavian arteries, and across the aortic arch, to join with the inferior cervical cardiac branch of the vagus in the formation of the **superficial** cardiac plexus. In their course both nerves form connexions with the other cardiac nerves of the sympathetic, and with cardiac and other branches of the vagus (recurrent and external laryngeal).

3. **Vessels.**—(*a*) The **external carotid branches** pass forwards to the external carotid artery, and form the **plexus caroticus externus (external carotid plexus)**, which supplies offsets to that artery and its branches, as well as to the **glomus caroticum** (O.T. **inter-carotid body**). From the subordinate plexuses on the external maxillary and middle meningeal branches of the artery sympathetic fibres are supplied to the submaxillary ganglion and otic ganglion, respectively.

(*b*) The **internal carotid branches** form an upward prolongation of the ganglion which applies itself in the form of bundles of nerve-fibres to the internal carotid artery as it enters the carotid canal in the temporal bone. The branches separate into lateral and medial parts, which form plexuses investing the artery in the cranium. The lateral division forms the inferior or internal **carotid plexus (pl. caroticus internus)**; the medial division gives rise to the superior or **cavernous plexus (pl. cavernosus)**. Both plexuses supply offsets to the artery and its branches, and form communications with certain cerebral nerves.

The **internal carotid plexus** communicates by fine branches with (*a*) the abducent nerve, and (*b*) the semilunar ganglion, and gives off (*c*) the great deep petrosal and (*d*) the carotico-tympanic nerves. The **deep petrosal nerve** joins the greater superficial petrosal nerve from the genicular ganglion of the facial, in the foramen lacerum. By their union the **pterygoid nerve** is formed, which, after traversing the pterygoid canal, ends in the spheno-palatine ganglion. The **carotico-tympanic nerves** pass to the tympanic plexus.

The **cavernous plexus** communicates with (*a*) the oculo-motor, (*b*) the trochlear nerve, and (*c*) the ophthalmic division of the trigeminal nerve; it also (*d*) supplies twigs to the hypophysis (pituitary body), and (*e*) forms the sympathetic root of the ciliary ganglion.

Cephalic Part of the Sympathetic System.

The internal carotid nerve together with its plexuses may be considered as an upward extension of the gangliated trunk. Associated with its branches are four cephalic ganglia, the ciliary, otic, sphenopalatine, and submaxillary, comparable to the ganglia of the trunk, but more conveniently described from their closer anatomical disposition in connexion with the branches of the trigeminal nerve (see Fig. 628, p. 776 and note on p. 692). The carotid, cavernous, and tympanic plexuses, together with the above-named ganglia, and possibly with the addition of small parts of the genicular, petrosal, and jugular ganglia (since cell bodies of sympathetic neurones are found within them), form the main bulk of the cephalic part of the sympathetic system. The jugular nerve, passing from the superior cervical ganglion to the jugular ganglion of the vagus and the petrous ganglion of the glossopharyngeal, is to be considered an additional source of sympathetic fibres to this part of the system. The various branches and connexions of these ganglia and plexuses (*e.g.*, those of the otic ganglion, the tympanic plexus, and the petrosal nerves) are, again, more conveniently described in relation with the cerebral nerves.

Ganglion Cervicale Medium.

Gray Communicating Branches.—1. *Gray rami communicantes* arise from the ganglion or from the connecting cord, and join the anterior rami of the fifth and sixth cervical nerves. 2. The **ansa subclavia (Vieussenii)** is a loop of communication from this ganglion, which, after passing in front of and supplying offsets to the subclavian artery and its branches, joins the inferior cervical ganglion.

Peripheral Branches of Distribution.—1. **Heart.**—A **middle cardiac branch**, which may be the largest of the three cardiac nerves, descends, either separately or in company with other cardiac nerves, behind the large vessels into the thorax, where it ends in the deep part of the cardiac plexus on each side.

2. **Thyreoid Gland.**—Branches extend medially along the inferior thyreoid artery to supply the thyreoid gland.

When the middle ganglion is absent the branches described arise from the connecting cord.

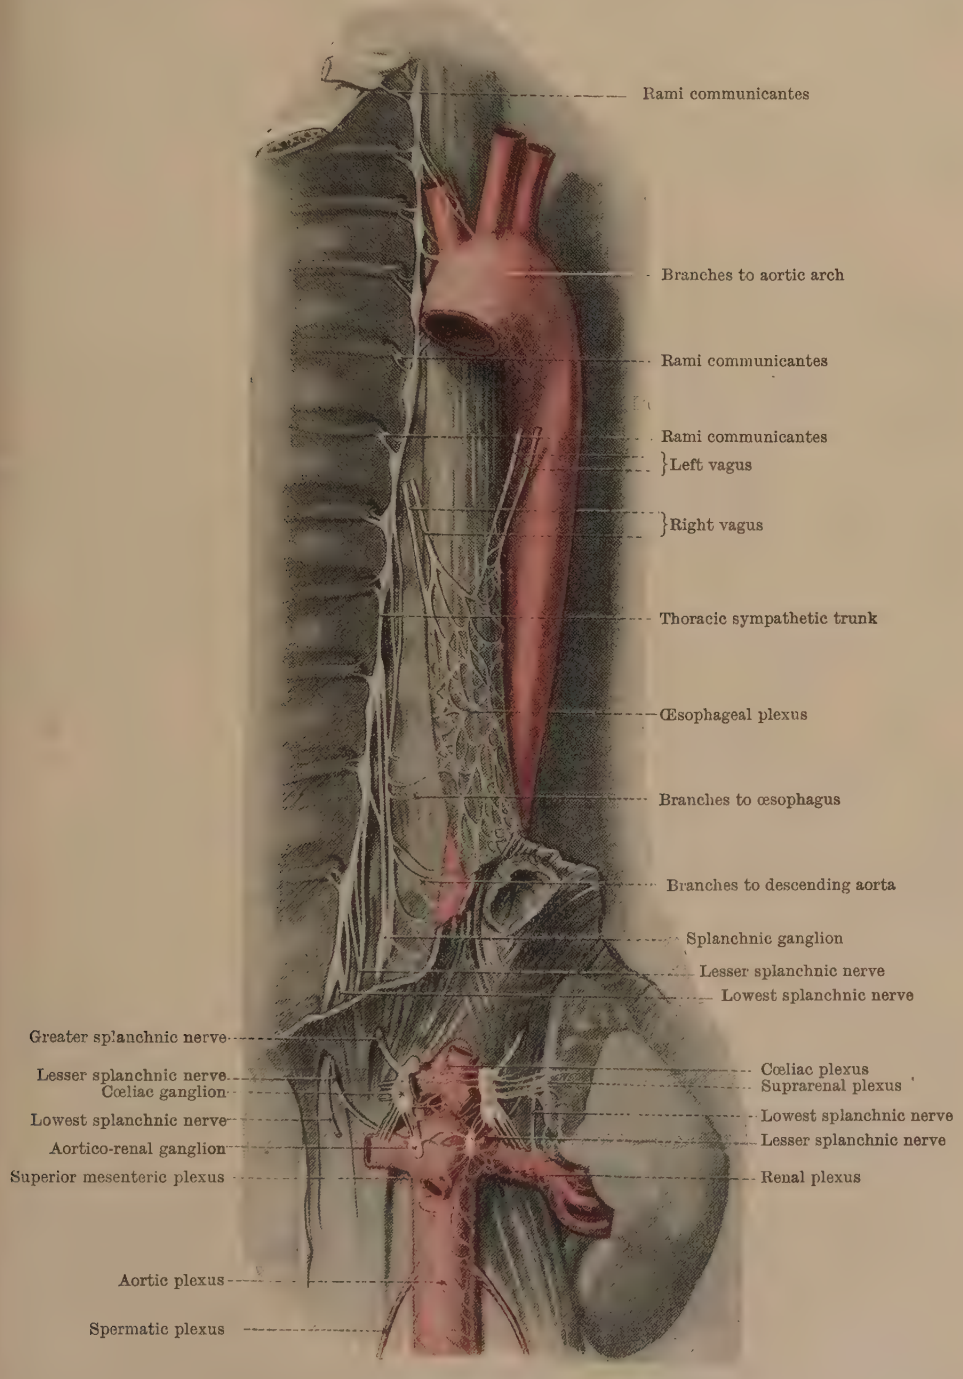

FIG. 632.—THE SYMPATHETIC TRUNK IN THE THORAX.

GANGLION CERVICALE INFERIUS.

Central Communicating Branches.—1. *Gray rami communicantes* arise from this ganglion for the anterior rami of the seventh and eighth cervical nerves.

2. The **ansa subclavia** already mentioned connects the middle and inferior ganglia over the front of the subclavian artery. 3. A communication frequently occurs with the **recurrent nerve.**

Peripheral Branches of Distribution.—1. **Heart.**—An **inferior cardiac branch** is given off on each side to enter the deep cardiac plexus. On the left side it is often blended with the middle cardiac nerve.

2. **Vessels.**—(*a*) The **vertebral plexus** is a dense plexus of fibres surrounding the vertebral artery and accompanying its branches in the neck and the cranial cavity. (*b*) The **subclavian plexus** is derived from the ansa subclavia (subclavian loop), and supplies small offsets to the subclavian artery. It gives branches to the **internal mammary artery**, and communicates with the **phrenic nerve.**

II. PARS THORACALIS SYSTEMATIS SYMPATHICI.

The **thoracic part of the sympathetic trunk** lies behind the pleura, in front of the necks of the first to the tenth ribs, and the intercostal vessels and nerves. It consists of a number of ganglia of an irregularly angular or fusiform shape, joined together by connecting bands of considerable thickness. The number of ganglia is usually ten or eleven; but the first—and sometimes others—may be so fused with the neighbouring ganglia as to reduce the number still further.

This part of the sympathetic trunk is characterised by its union with the thoracic spinal nerves. Each thoracic nerve, with the rare exception of the first, sends a **visceral branch** (white ramus communicans) to join the gangliated trunk in the thorax. These white rami separate into two main streams in relation to the sympathetic trunk. Those of the *upper five* nerves are for the most part directed upwards to be distributed through the cervical part of the sympathetic trunk in the manner already described. The white rami of the *lower thoracic* nerves are for the most part directed downwards in the inferior part of the sympathetic trunk and its branches, to be distributed in the abdomen; at the same time some of their fibres are directly supplied to certain thoracic viscera,—lungs, aorta, œsophagus.

These white rami are composed of (1) **splanchnic afferent fibres** passing from its peripheral branches through the sympathetic trunk into the ganglia of the spinal nerves—medullated nerve-fibres unconnected with sympathetic ganglion cells; and (2) **somatic** and **splanchnic efferent fibres**, small medullated nerves which, after a longer or shorter course in the gangliated trunk or its peripheral branches, become connected with the sympathetic ganglion cells, or with the cells of peripheral (collateral or terminal) ganglia, from which again (non-medullated) axons proceed to supply branches to viscera and vessels.

The peripheral branches supplying *thoracic organs* contain vaso-motor fibres for the lungs and aorta. The peripheral branches from the *lower* part of the sympathetic trunk in the thorax, receiving white rami from the lower thoracic nerves, are distributed mainly to structures below the diaphragm. They comprise (*a*) viscero-inhibitory fibres for the stomach and intestines; (*b*) motor fibres for part of the rectum; (*c*) pilo-motor fibres for the lower part of the body; (*d*) vaso-motor fibres for the abdominal aorta and its branches, and for the lower limbs; (*e*) secretory, and (*f*) sensory fibres for the abdominal viscera.

The **branches** from the gangliated trunk are, as in the neck, divisible into two sets—(*A*) Central branches, communicating with other nerves, and (*B*) peripheral branches, distributed in a plexiform manner to the thoracic and abdominal viscera.

(*A*) **Central Communicating Branches.**—The **white rami communicantes** from the thoracic nerves have already been described. Passing forwards from the anterior rami of the nerves, they become connected with the ganglia or the connecting cord of the sympathetic.

The **gray rami communicantes** are *branches* arising irregularly from each thoracic ganglion; passing backwards along with the white rami, they join the anterior rami of the thoracic nerves, and are distributed in a manner already described (p. 775).

(*B*) **Peripheral Branches of Distribution.**—These branches arise irregularly from the ganglia and the connecting cord. They are composed of non-medullated

(splanchnic efferent) fibres derived from the ganglion cells, and medullated fibres (splanchnic efferent and afferent) derived directly from the white rami, without the intervention of the cells of the ganglia.

1. **Pulmonary Branches.**—From the gangliated trunk opposite the second, third, and fourth ganglia fine filaments arise which join the posterior pulmonary plexus.

2. **Aortic Branches.**—The upper part of the thoracic aorta receives fine branches from the upper five thoracic ganglia.

3. **Splanchnic Nerves.**—Three nerves arise from the inferior part of the gangliated trunk, partly from the ganglia themselves, and partly from the connecting cord between the ganglia. Actually they consist in greater part of fibres of the white rami which merely traverse the gangliated trunks on their way to their distribution. Passing downwards over the bodies of the thoracic vertebræ they pierce the diaphragm, to end in the abdomen.

(*a*) The **greater splanchnic nerve** arises from the gangliated trunk between the fifth and ninth or tenth ganglia. By the union of several irregular strands a nerve of considerable size is formed, which descends in the posterior mediastinum, and piercing the crus of the diaphragm, joins at once the anterior end of the *cœliac ganglion*. In its course in the thorax the **splanchnic ganglion** is formed upon the nerve opposite the eleventh or twelfth thoracic vertebra; it is more prominent in the fœtus than in the adult. From both nerve and ganglion branches arise in the thorax, for the supply of the œsophagus and descending thoracic aorta (Fig. 632).

(*b*) The **lesser splanchnic nerve** arises from the gangliated trunk opposite to the ninth and tenth ganglia. It passes over the bodies of the lower thoracic vertebræ, pierces the diaphragm near or along with the greater splanchnic nerve, and ends in the **cœliac plexus** (*aortico-renal ganglion*).

(*c*) The **lowest splanchnic nerve** arises from the last thoracic ganglion of the sympathetic, or it may be a branch of the lesser splanchnic nerve. It pierces the diaphragm, and ends in the *renal plexus*. It is not always present.

III. PARS ABDOMINALIS SYSTEMATIS SYMPATHICI.

The **abdominal or lumbar part of the sympathetic trunk** is placed upon the bodies of the lumbar vertebræ, medial to the origins of the psoas major muscle, and in front of the lumbar vessels. It is connected with the thoracic portion of the trunk by an attenuated cord which either pierces or passes behind the diaphragm. It is continuous below with the pelvic portion of the trunk by means of a connecting cord, which passes behind the common iliac artery.

It is joined by medullated fibres (white rami communicantes) from the first two or three lumbar spinal nerves, and it contains, as well, medullated fibres continued down from the lower part of the thoracic sympathetic trunk, and derived from the visceral branches (white rami communicantes) of the lower thoracic nerves.

This part of the trunk is characterised by great irregularity in the number of the ganglia. They are usually four in number, but there are frequently more (up to eight); and in extreme cases fusion may occur to such an extent that the separation of individual ganglia becomes impossible.

1. **Central Communicating Branches.—White rami communicantes.**—Only the first two (or three) lumbar spinal nerves send visceral branches (white rami communicantes) to the upper lumbar ganglia or to the sympathetic trunk. These nerves form the lower limit of the thoracic-lumbar visceral branches of the spinal nerves. They comprise vaso-motor fibres (for the genital organs), and motor fibres for the bladder and uterus.

Gray rami communicantes pass from the gangliated trunk to the anterior rami of the lumbar nerves in an irregular manner. One ramus may divide so as to supply branches to two adjacent spinal nerves; or one spinal nerve may be joined by several (two to five) gray rami from the sympathetic trunk.

The rami course deep to the origin of the psoas major muscle and over the bodies of the vertebræ. Gray rami sometimes pierce the fibres of the psoas muscle.

2. **Peripheral Branches of Distribution.**—From the lumbar sympathetic trunk numbers of small branches arise irregularly, and supply the abdominal aorta, reinforcing the **aortic plexus** (derived from the cœliac plexus).

IV. PARS PELVINA SYSTEMATIS SYMPATHICI.

The **pelvic** or **sacral part of the sympathetic trunk,** like the cervical and lower abdominal portions of this system, receives no *white rami communicantes* from the spinal nerves. The **visceral branches** (*pelvic splanchnic*) of the third sacral nerve, and usually, also, the second or fourth sacral nerve, enter the **pelvic plexus** without being directly connected with the sympathetic trunk. These nerves, however, are to be regarded as homologous with the white rami communicantes of the thoracico-lumbar nerves (*abdominal splanchnic*).[1] They convey to the pelvic viscera—(1) motor and inhibitory fibres for rectum, uterus, and bladder, (2) vaso-dilator fibres for the genital organs, and (3) secretory fibres for the prostate gland.

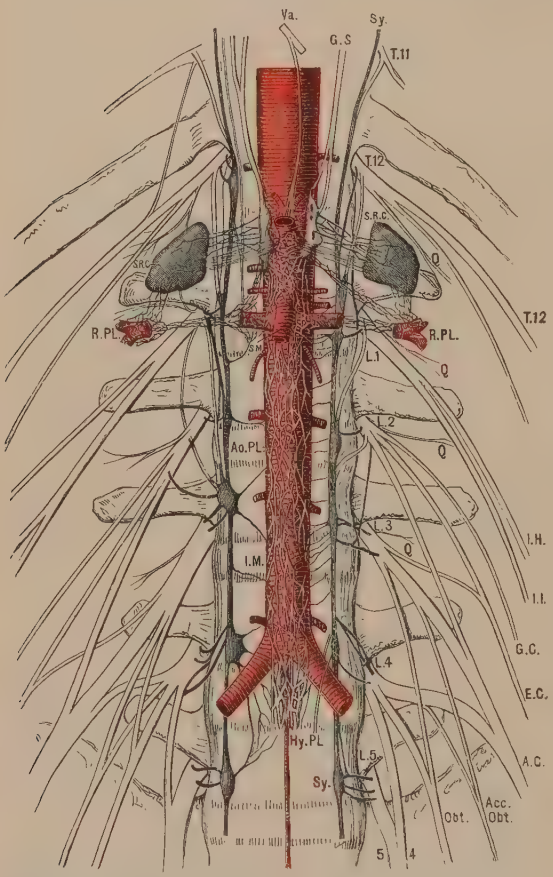

FIG. 633.—THE LUMBAR PORTION OF THE SYMPATHETIC GANGLIATED TRUNK AND LUMBAR PLEXUS. (From a dissection.)

T.11, T.12, L.1, L.2, L.3, L.4, L.5, Anterior rami of spinal nerves, with white and gray rami communicantes.

Sy., Sympathetic trunk.; Va., Vagus nerve; G.S., Greater splanchnic nerve, joining cœliac ganglion; S.R.C., Suprarenal gland and plexus; R.Pl., Renal plexus; Ao.Pl., Aortic plexus; S.M., Superior mesenteric plexus; I.M., Inferior mesenteric plexus; Hy.Pl., Hypogastric plexus; Q., Nerves to quadratus lumborum; I.H., Ilio-hypogastric nerve; I.I., Ilio-inguinal nerve; G.C., Genito-femoral nerve; E.C., Lateral cutaneous nerve; A.C., Femoral nerve; Acc. Obt., Accessory obturator nerve; Obt., Obturator nerve; 4, 5, Lumbo-sacral trunk.

This portion of the sympathetic trunk is placed on the pelvic surface of the sacrum, medial to the anterior sacral foramina. It is connected above by a cord with the abdominal portion of the sympathetic, and below it ends in a plexiform union over the coccyx with the trunk of the other side, the two being frequently connected by the **ganglion impar** or **coccygeal ganglion.** The number of ganglia is variable; there are commonly four. They are of small size, gradually diminishing from above downwards.

Gray communicating branches arise irregularly in the form of **gray rami communicantes** from the sacral ganglia, which join the anterior rami of the sacral and coccygeal nerves.

Peripheral Branches of Distribution.—(1) **Visceral branches** of small size arise from the upper part of the pelvic sympathetic trunk, and join the **pelvic plexus** (see below).

(2) **Parietal branches**, also of small size, ramify over the front of the sacrum, and form, in relation to the middle sacral artery, a plexiform union with branches from the sympathetic trunk of the other side.

[1] These pelvic splanchnic nerves form the sacral part of the cranio-sacral or **parasympathetic** system referred to in the note on p. 775.

PLEXUS SYMPATHICI.

The **smaller plexuses** associated with the branches of the cervical sympathetic ganglia, namely, the carotid and cavernous, the external carotid, pharyngeal, thyreoid, vertebral and subclavian plexuses, have been described above.

The **pulmonary** and **œsophageal** plexuses, though receiving branches from the thoracic ganglia, are described with the vagus nerve, since it contributes much more to their formation.

There remain the great **prevertebral plexuses** situated in the thorax, abdomen, and pelvis, and named the **cardiac, cœliac, hypogastric,** and **pelvic** plexuses; each of these main networks is continued on into a large number of subsidiary smaller plexuses.

Plexus Cardiacus.

The cardiac branches of both sympathetic trunks combine with the cervical and thoracic cardiac branches of both vagus nerves to form the **cardiac plexus.** This is situated at the base of the heart, and is divided into a superficial and a deep part.

The **superficial cardiac plexus** is placed in the hollow of the aortic arch, superficial to the pericardium. It usually contains a small ganglion (**cardiac ganglion of Wrisberg**), situated on the right side of the ligamentum arteriosum, and is joined by two small nerves—(1) the cardiac branch from the superior cervical ganglion of the sympathetic, and (2) the inferior cervical cardiac branch of the vagus—both of the left side—which reach it after passing over the arch of the aorta.

Branches and **Communications.**—From the plexus branches of communication pass (1) to the left half of the **deep cardiac plexus,** between the aortic arch and the bifurcation of the pulmonary artery; (2) to the left **anterior pulmonary plexus** along the left branch of the pulmonary artery; (3) the branches of distribution to the heart extend along the pulmonary artery to join the **anterior (right) coronary plexus,** which supplies the substance of the heart in the course of the right coronary artery.

The **deep cardiac plexus** is much larger. It is placed behind the arch of the aorta, on the sides of the trachea, just above its bifurcation. It consists of two lateral parts, joined together by numerous communications around the termination of the trachea. The two portions of the plexus are different in their constitution and distribution. The *right half* of the plexus is joined by both the cervical and thoracic branches of the right vagus and by the branches of the right recurrent nerve, as well as by branches from the superior, middle, and inferior cervical ganglia of the sympathetic. The *left half* of the plexus is joined by the upper cervical cardiac branch of the left vagus, by branches from the left recurrent nerve, and by branches from the middle and inferior cervical ganglia of the left sympathetic; it also receives a contribution from the superficial cardiac plexus. In other words, all the cardiac branches both from the vagi and cervical sympathetic ganglia of the two sides combine to form the deep cardiac plexus, save only the cardiac branch of the left superior sympathetic ganglion and the lower cervical cardiac branch of the left vagus, which form the superficial plexus (see Fig. 634).

The deep cardiac plexus is distributed to the heart and lungs. The *right half* of the plexus for the most part constitutes the **right** or **anterior coronary plexus,** reaching the heart alongside the ascending aorta, and is distributed to the heart substance in the course of the right coronary artery. It is reinforced by fibres from the superficial cardiac plexus, which reach the heart along the pulmonary artery. Fibres from the right half of the deep cardiac plexus pass also to join the **posterior coronary plexus,** and others extend laterally to join the **anterior pulmonary plexus** of the right side.

The *left half* of the deep cardiac plexus, reinforced by fibres from the superficial cardiac plexus, is distributed to the heart in the form of the **left** or **posterior coronary plexus**, which is joined by a few fibres behind the pulmonary artery from the right half of the plexus, and supplies the heart substance in the course of the

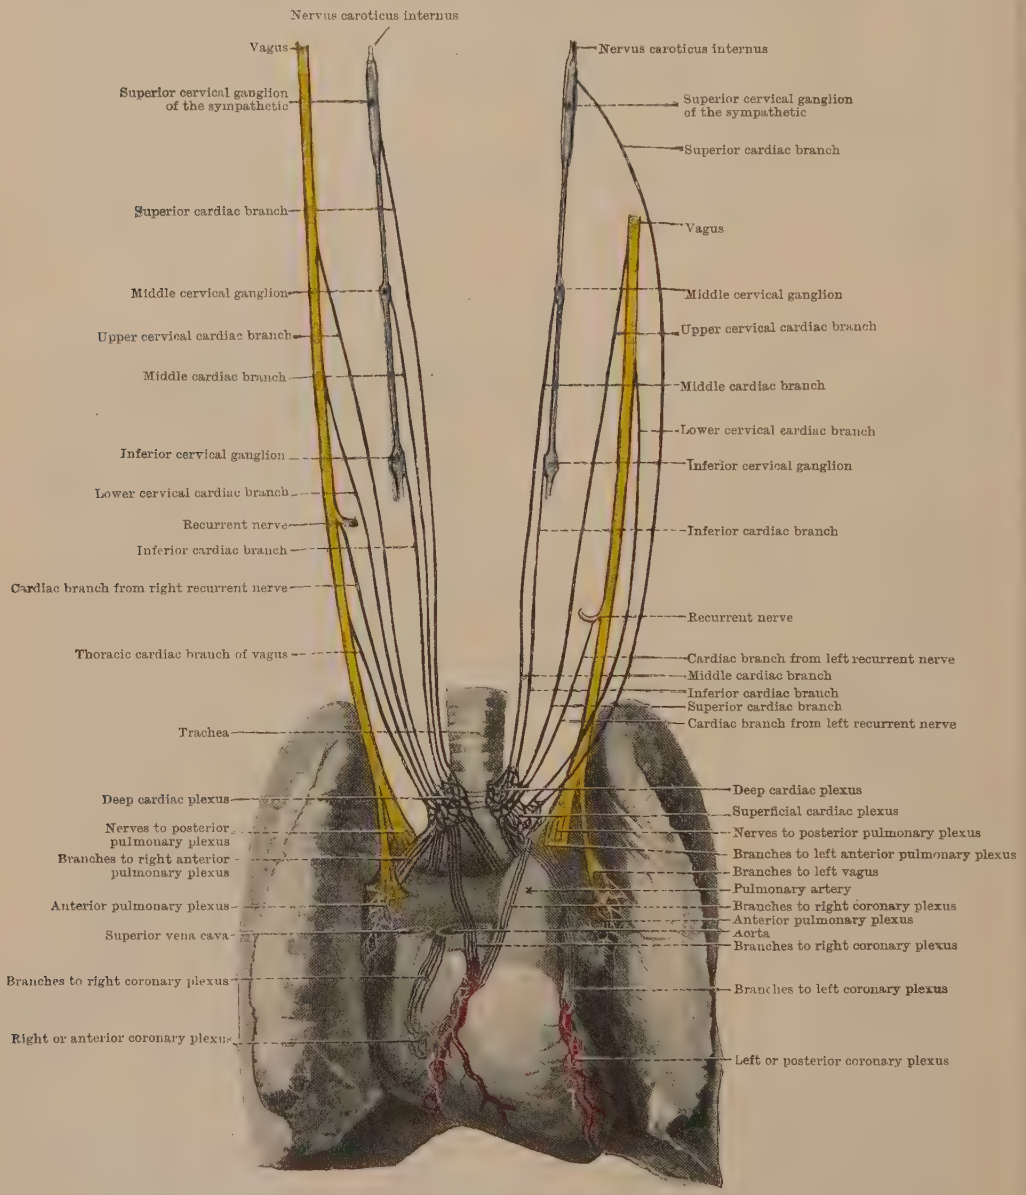

FIG. 634.—THE CARDIAC BRANCHES OF THE VAGUS AND THE PULMONARY PLEXUSES.

left coronary artery. The left half of the plexus contributes also to the **left anterior pulmonary plexus** by fibres which extend laterally to the root of the lung along the left branch of the pulmonary artery.

The pulmonary plexuses are described on p. 703 in connexion with the vagus nerve.

THE CŒLIAC AND PELVIC PLEXUSES.

These great plexuses serve to distribute nerves to the viscera and vessels of the abdominal and pelvic cavities. Taken together they include three plexuses—the

cœliac plexus, the hypogastric plexus, and the pelvic plexus, which are associated in the main with the aorta and the hypogastric arteries, whilst their numerous extensions form subsidiary plexuses which invest and are generally named after the branches of these vessels. They are constituted by peripheral branches of the lower thoracic, abdominal, and upper pelvic parts of the sympathetic trunk; and they are related to the central nervous system by means of the visceral branches (white rami communicantes) of the lower thoracic and upper lumbar nerves on the one hand, and by the visceral branches of the second and third, or third and fourth sacral nerves, on the other hand. The thoracico-lumbar series join the sympathetic trunk, and reach the cœliac plexus mainly through the splanchnic nerves, and to a lesser extent through the abdominal part of the sympathetic trunk The sacral series enter the pelvic plexus without connexion with the sympathetic trunk. The hypogastric plexus serves as a connecting link between the cœliac and pelvic plexuses.

Plexus Cœliacus.

The **cœliac** or **solar plexus**, the largest of the prevertebral plexuses, lies on the posterior abdominal wall in relation to the abdominal aorta and behind the stomach. It is composed of three elements: the **cœliac plexus** surrounding the origin of the cœliac artery, between the crura of the diaphragm; and two **cœliac ganglia**, each lying on the corresponding crus of the diaphragm, and overlapped by the suprarenal gland, and on the right side by the inferior vena cava. The plexus is continuous with subordinate plexuses, diaphragmatic, suprarenal, renal, and superior mesenteric. It is continued downwards into the aortic plexus, which, by means of the **hypogastric nerves**, is connected with the **hypogastric plexus**, which again forms the chief origin of the **pelvic plexuses.**

The **cœliac ganglia** constitute the chief ganglionic centres in the cœliac plexus. They are irregular in form. They are often partially subdivided, and one detached portion at the lower end is named the **aortico-renal ganglion.** Other small scattered masses of cells are present in the cœliac plexus. At the upper end the cœliac ganglion receives the *greater splanchnic nerve.* The aortico-renal ganglion at its lower end receives the *lesser splanchnic nerve.* Branches from the ganglion radiate in all directions—medially to join the cœliac plexus, upwards to form the diaphragmatic plexus, laterally to the suprarenal plexus, downward to the renal, superior mesenteric, and aortic plexuses.

The **cœliac plexus** forms a considerable plexiform mass surrounding the cœliac artery. It consists of a dense meshwork of fibres with ganglia intermingled, joined by numerous branches from the cœliac ganglion on each side, and by branches from the right vagus nerve. It is continuous below with the superior mesenteric and aortic plexuses. Investing the cœliac artery, it forms subsidiary plexuses which are distributed along the branches of the artery. The **left gastric plexus** supplies branches to the œsophagus and stomach; the **hepatic plexus** supplies branches to the liver and gall-bladder, stomach, duodenum, and pancreas; and the **splenic plexus** sends offsets to the spleen, pancreas, and stomach.

Subordinate plexuses are formed on the aorta and its branches by nerves derived from the cœliac ganglia and cœliac plexus.

(*a*) The **phrenic plexus** consists of fibres arising from the cœliac ganglion, and it accompanies the inferior phrenic artery. Besides supplying the diaphragm, it gives branches to the suprarenal plexus, and—on the right side to the inferior vena cava—on the left side to the œsophagus. It communicates on each side with the phrenic nerve. At the junction of the plexus and the phrenic nerve of the right side a ganglion is formed **(phrenic ganglion).**

(*b*) The **suprarenal plexus** is of considerable size. It is mainly derived from branches of the cœliac ganglion, reinforced by nerves from the inferior part of the cœliac plexus which stream laterally on the suprarenal arteries. It is joined by branches from the phrenic plexus above and from the renal plexus below. The nerves enter the substance of the suprarenal gland.

(*c*) The **renal plexus** is derived from (1) branches of the cœliac ganglion, and

(2) fibres from the aortic plexus, extending laterally along the renal artery to the hilum of the kidney. It receives also the lowest splanchnic nerve, and is connected by numerous branches to the suprarenal plexus.

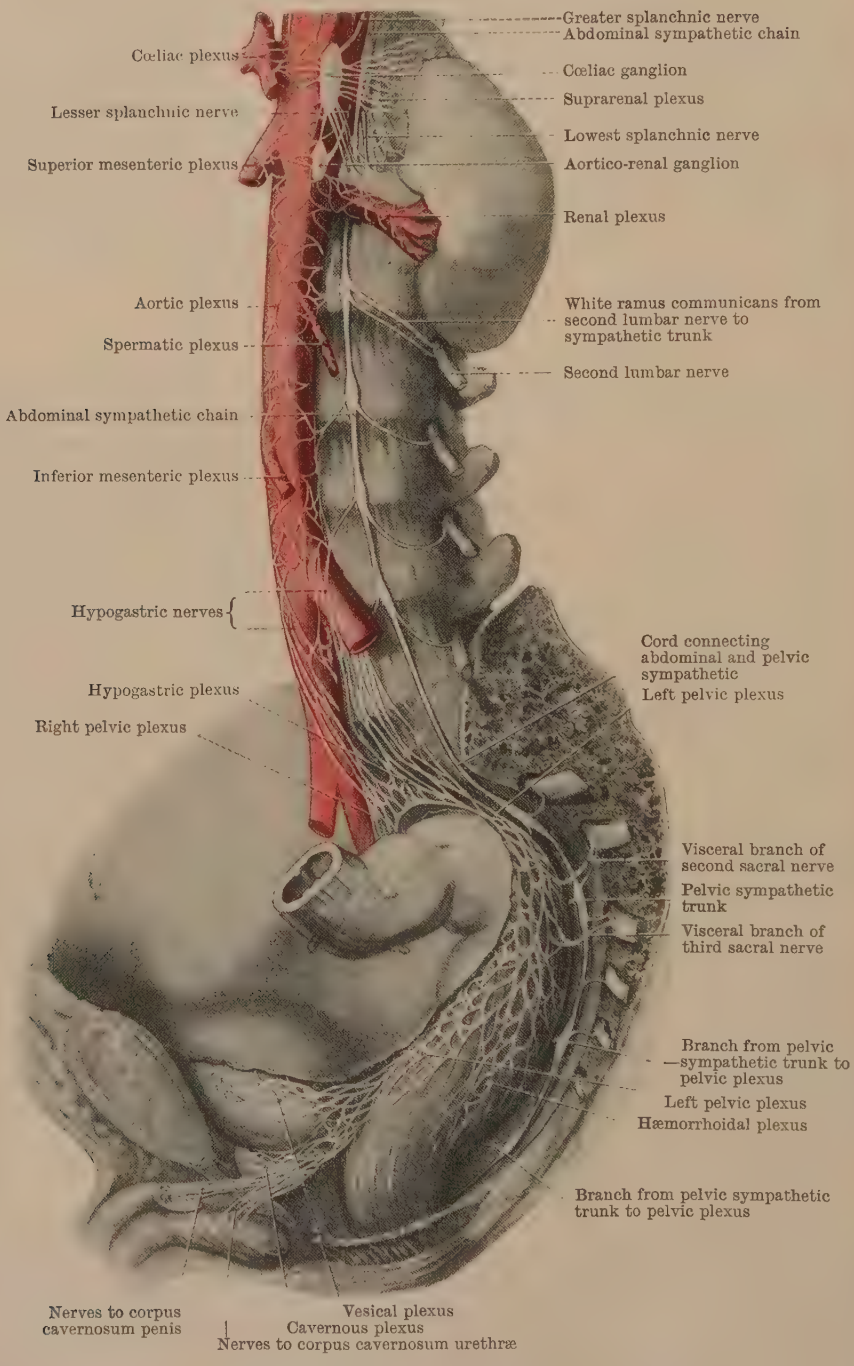

Fig. 635.—The Sympathetic in the Abdomen and Pelvis.

(*d*) The **superior mesenteric plexus** is inseparable above from the cœliac plexus, and is joined on each side by fibres from the cœliac and aortico-renal ganglia. It is continuous below with the aortic plexus. A separate detached ganglionic mass (**superior mesenteric ganglion**) is present in the plexus. Accompanying the superior

mesenteric artery it forms subordinate plexuses around the branches of the vessel. The plexuses at first surround the intestinal arteries, but near the intestine they form fine plexuses between the layers of the mesentery, from which branches pass to the wall of the gut. This plexus supplies the small intestine, cæcum, vermiform process, ascending and transverse portions of the colon.

(*e*) The **aortic plexus** is the continuation of the cœliac plexus downwards around the abdominal aorta. It is continuous above with the cœliac and superior mesenteric plexuses; it is reinforced by the peripheral branches of the lumbar sympathetic trunk; and it is connected with the hypogastric plexus below by the **hypogastric nerves**. Besides investing and supplying the aorta, the plexus is connected with various subordinate plexuses on the branches of the artery. It contributes to the suprarenal and renal plexuses, and it gives rise to the spermatic or ovarian, and the inferior mesenteric plexuses.

The **spermatic plexus** invests and accompanies the spermatic artery. It is derived from the aortic plexus, and receives a contribution from the renal plexus. It supplies the spermatic cord and testis.

The **plexus of the ovarian artery** in the female arises like the spermatic plexus. It accompanies the ovarian artery to the pelvis, and supplies the ovary, broad ligament, and uterine tube. It forms communications in the broad ligament with the **uterine plexus** (from the pelvic plexus), and sends fibres to the uterus.

The **inferior mesenteric plexus** is a derivative from the aortic plexus, prolonged along the inferior mesenteric artery. It forms subordinate plexuses on the branches of the artery (colic, sigmoid, and superior hæmorrhoidal), and is distributed to the descending colon, iliac colon, pelvic colon, and upper part of the rectum.

Plexus Pelvini.

The **hypogastric nerves** form the continuation of the aortic plexus into the pelvic cavity. They consist of numerous plexiform bundles of nerve-fibres which descend along the front and back of the bifurcation of the aorta and the origin of the common iliac arteries, and over the sacral promontory, where, becoming inextricably mingled, they constitute the hypogastric plexus.

The **hypogastric plexus** is continued downwards in front of the sacrum on each side of the rectum, and ends in the pelvic plexuses.

The **pelvic plexuses** are formed by the separation of the hypogastric plexus into two halves at the sides of the rectum. Each is joined by fibres from the upper portion of the pelvic part of the sympathetic trunk, and by the **visceral** or **pelvic splanchnic branches** (white rami communicantes) from the second and third or third and fourth sacral nerves. Accompanying the hypogastric artery and its branches, each pelvic plexus gives off subordinate plexuses for the pelvic viscera.

(*a*) The **hæmorrhoidal plexus** supplies the rectum, and joins the superior hæmorrhoidal plexus from the inferior mesenteric plexus.

(*b*) The **vesical plexus** accompanies the vesical arteries to the bladder-wall. Besides supplying the muscular wall and mucous membrane of the bladder, it forms subordinate plexuses for the lower part of the ureter, the vesicula seminalis, and the ductus deferens.

(*c*) The **prostatic plexus** is of considerable size. It is placed on both sides of the gland, and, in addition to supplying its substance and the prostatic urethra, it sends offsets to the neck of the bladder and the vesicula seminalis. It is continued forwards on each side to form the **plexus cavernosus penis (cavernous plexus of the penis)**. Bundles of nerves pierce the layers of the fascia of the urogenital diaphragm, and, after supplying the membranous urethra, give off branches which enter and supply the corpus cavernosum penis. The cavernous nerves communicate with branches of the pudendal nerve and give offsets to the corpus cavernosum urethræ and the penile portion of the urethra.

(*d*) The **uterine plexus** passes upwards with the uterine artery between the layers of the broad ligament, and is distributed to the surfaces and substance of

the organ. It communicates between the layers of the broad ligament with the plexus of the ovarian artery.

The **vaginal plexus** is formed mainly by the visceral branches of the sacral nerves entering the pelvic plexus. It supplies the wall and mucous membrane of the vagina and urethra, and provides a **cavernous plexus** for the clitoris. The uterine and vaginal plexuses of the female correspond to the prostatic plexus of the male.

DEVELOPMENT OF THE SYMPATHETIC NERVOUS SYSTEM.

Though primarily developed from cells which arise in the neural crest, the ganglia of the sympathetic system also contain cells which, in the trunk region at least, are derived from the neural tube. Embryologically, then, the sympathetic ganglia, plexuses, and nerves have a common origin with the remainder of the peripheral nervous system, and differ from it only in that the sympathetic cells have wandered farther from their place of origin than have those of the cerebro-spinal nerves.

When the neural tube detaches itself from the general ectodermal covering of the embryonic body, the neural crest becomes divided into right and left crests, each of which migrates ventro-laterally into the space between the neural tube and the myotomes. These crests extend continuously on each side from the caudal end of the neural tube forwards to the auditory vesicle.

In the **spinal region** each crest becomes segmented into primitive ganglia, which contain not only the primordia of the spinal ganglia but also cells destined for the sympathetic and chromaffin systems. From the ventral border of these primitive spinal ganglia the sympathetic neuroblasts detach themselves and individually migrate outwards along the paths of the developing dorsal roots of the spinal nerves. Meanwhile other cells have wandered out along the ventral roots from the neural tube to join the cells of neural-crest origin. Once the cells from each of these sources have mingled it is impossible to distinguish between them, nor is it possible to state precisely what part each plays in the subsequent development of the sympathetic system. Leaving the spinal nerves, these errant cells migrate into the neighbourhood of the aorta, where by rapid proliferation they form compact masses which fuse from segment to segment and produce a continuous longitudinal cord, the **gangliated trunk.**

In the meantime, from the dorsal and ventral roots of the spinal nerves, centrifugal fibres grow out along the path previously followed by the cells. Somewhat later centripetal fibres are pushed out from the sympathetic trunk to join the spinal nerve trunk. The centrifugal fibres become myelinated and form the **white rami communicantes,** whilst the centripetal ones remain unmyelinated and form the **gray rami.** With the development of commissural fibres, the segmental character of the sympathetic trunks becomes evident throughout the thoracic and abdominal regions; the condensations which result in the three cervical ganglionic masses are also apparent.

The cells which form the ganglia of the **prevertebral plexuses** have the same origin as have those of the gangliated trunks, differing only in that, instead of stopping in the neighbourhood of the aorta, they have migrated onwards in the loose mesoderm to come into closer relationship with the structures they supply. The cells of terminal plexuses, on the contrary, though arising from the neural crest, do not make any connexion with the gangliated trunk; those of the cardiac, pulmonary, and greater part of the enteric plexuses migrate along the vagus nerve, whilst those of the enteric plexus in the terminal part of the digestive tube travel along the lumbar and sacral nerves.

In the **head region** the sympathetic ganglia are not segmentally arranged, though, just as in the spinal region, they are developed primarily from cells which arise in the neural crest and migrate outwards through the cerebro-spinal ganglia on their way to the periphery. Moreover, just as the ganglia of the sympathetic trunk are connected with one another by commissural fibres, so are the cranial ganglia connected with one another and with the gangliated trunk by means of the plexuses along the internal carotid artery. The four small **cephalic sympathetic ganglia** arise from cells the majority of which are developed in connexion with the semilunar ganglion, though there are probably added to these ganglia some few cells of either oculo-motor, facial, or glossopharyngeal origin.

The **ciliary ganglion** receives the majority of its cells from the semilunar ganglion by way of the ophthalmic nerve, but a few are contributed *via* the oculo-motor nerve.

The **sphenopalatine ganglion** is also derived mainly from the semilunar, its cells migrating along the maxillary nerve. The earliest cells, however, advance peripherally along the greater superficial petrosal branch of the facial nerve.

The **otic ganglion** arises from cells which migrate along the lesser superficial petrosal nerve from the petrosal ganglion, but it also receives some from the semilunar ganglion through the mandibular nerve.

The **submaxillary ganglion** arises from cells which have migrated along the mandibular and lingual nerves, but probably also derives some cells from the facial by way of the chorda tympani nerve.

ORGANA SENSUUM ET INTEGUMENTUM COMMUNE.

By Robert Howden, M.B., C.M., D.Sc.
Professor of Anatomy in the University of Durham.

ORGANA SENSUUM.

The **organs of the senses** constitute the apparatus by which man is made acquainted with his surroundings.

Every sense-organ consists of (*a*) a peripheral or receptive portion, where impulses are generated in response to external stimuli, (*b*) an intermediate or conductive part, along which the impulses are conveyed, and (*c*) a central or perceptive portion, where they are collected and transformed into sensations. The intermediate and central parts have been described in the section on the Nervous System; the peripheral parts form the subject matter of this chapter, and may be grouped under two headings:—(1) those connected with the *special senses* of smell, sight, hearing, and taste, and located in the nose, eye, ear, and mouth, respectively; and (2) those of *general sensations* (the muscular sense, and the senses of pressure, heat, cold, and pain), which are widely distributed throughout the body.

ORGANON OLFACTUS.

The nose is the peripheral **olfactory organ** and consists of the nasus externus, which projects from the face, and the cavum nasi, which is divided by a vertical septum into right and left chambers.

Nasus Externus.—The **external nose** is a more or less triangular pyramid, of which the upper angle or **root** is usually separated from the forehead by a depression, while the **base**, directed downwards, is perforated by two elliptical orifices, the **nares** or **nostrils**, which are separated from one another by a median septum. The free angle is named the **apex**; and the anterior border, joining root and apex, the **dorsum**; the upper part of the dorsum is supported by the nasal bones, and is termed the **bridge**. Each side of the nose forms an open angle (*naso-facial angle*) with the cheek, and ends below in a rounded eminence, the **ala nasi**, the free edge of which forms the lateral boundary of the corresponding naris; the ala nasi is limited above by a furrow, the **alar sulcus**. Over the root of the nose the skin is thin and movable, but over the apex and alæ it is thick and adherent, and contains numerous large sebaceous glands.

The external nose receives its blood-supply from the external maxillary and ophthalmic arteries; its veins open into the anterior facial vein and also communicate with the ophthalmic vein. Its principal lymph-vessels follow the course of the anterior facial vein and open into the submaxillary lymph-glands,—but from the root of the nose one or two lymph-vessels run lateralwards in the upper eyelid and end in the upper anterior auricular lymph-glands, and a third group runs below the orbit to the lower anterior auricular lymph-glands. The muscles of the external nose are supplied by the facial nerve, and the skin covering it is supplied by the

infra-trochlear and naso-ciliary branches of the ophthalmic nerve and the infra-orbital branch of the maxillary nerve.

CARTILAGINES NASI.

Five chief cartilages are concerned in the formation of the nose; they are the lateral and greater alar cartilages on either side, and the cartilage of the septum.

Cartilago Nasi Lateralis.—The **lateral cartilage** (Figs. 637, 638) is triangular in shape and is situated immediately below the nasal bone. Its posterior edge is thin and is attached to the maxilla and to the nasal bone by fibrous tissue. Its anterior edge is thick; its upper part is directly continuous with the cartilage of the septum, but its lower part is separated from this cartilage by a narrow fissure. Its lower edge is joined, by fibrous tissue, to the upper margin of the greater alar cartilage.

Cartilago Alaris Major.—The **greater alar cartilage** (Figs. 636, 637, 638) encircles the anterior part of the nostril and assists in keeping it open. It consists

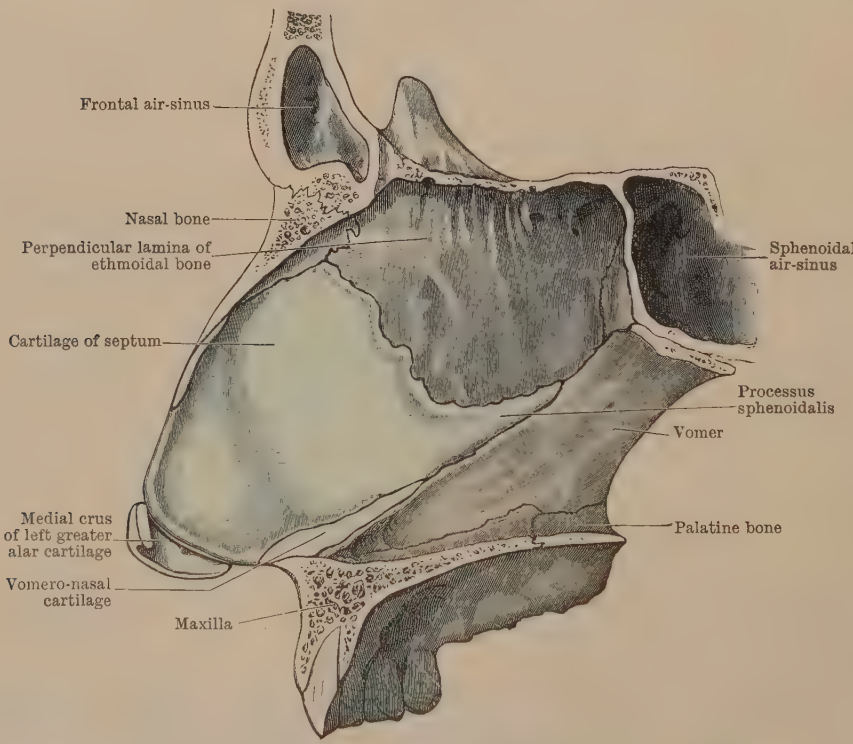

FIG. 636.—VIEW OF THE NASAL SEPTUM FROM THE LEFT SIDE.

of a lateral and a medial crus, which unite in a rounded angle at the apex of the nose. The **lateral crus** is oval in outline and is attached to the lateral cartilage and to the maxilla by fibrous tissue. Above and behind it two or three *lesser alar cartilages* are embedded in the fibrous tissue. The inferior edge of the lateral crus does not descend as far as the opening of the nostril, the lower part of the ala nasi being devoid of cartilage, and composed of fatty and connective tissue covered with skin. The **medial crus** (Fig. 639) bounds the medial wall of the nostril and lies in the septum mobile nasi below the cartilage of the septum, and in contact with the medial crus of the opposite greater alar cartilage. The medial crura of the greater alar cartilages are separated, in front, by a notch which corresponds with the apex of the nose.

Cartilago Septi Nasi.—The **cartilage of the septum** (Fig. 636) is of an irregularly quadrilateral form. Its postero-superior edge is attached to the perpendicular lamina of the ethmoidal bone; its postero-inferior margin to the vomer and to

the nasal crests of the maxillæ. Its antero-superior border is thick, and is fixed above to the back of the internasal suture; immediately below this suture it is directly continuous with the upper parts of the lateral cartilages, which may be looked upon as its wing-like expansions. The lower part of each lateral cartilage is separated from the cartilage of the septum by a fissure which is filled by fibrous tissue; in this fibrous tissue a small accessory cartilage is usually seen. The antero-inferior border of the cartilage of the septum is short, and is attached by fibrous tissue to the medial crura of the greater alar cartilages; its anterior angle is rounded and does not reach as far as the apex of the nose. The cartilage of the septum may be prolonged backwards (especially in children) as a narrow process, the **processus sphenoidalis**, into the angle between the vomer and the ethmoidal bone.

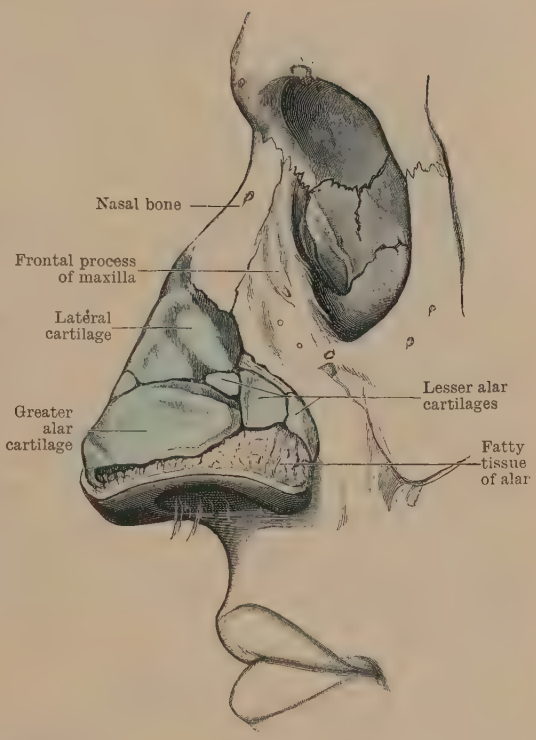

FIG. 637.—PROFILE VIEW OF THE BONY AND CARTILAGINOUS SKELETON OF THE EXTERNAL NOSE.

On either side of the postero-inferior edge of the cartilage of the septum, there is a narrow band of cartilage, the **vomero-nasal cartilage** (Fig. 636); it is attached to the vomer, and is best seen in a frontal section of the nose.

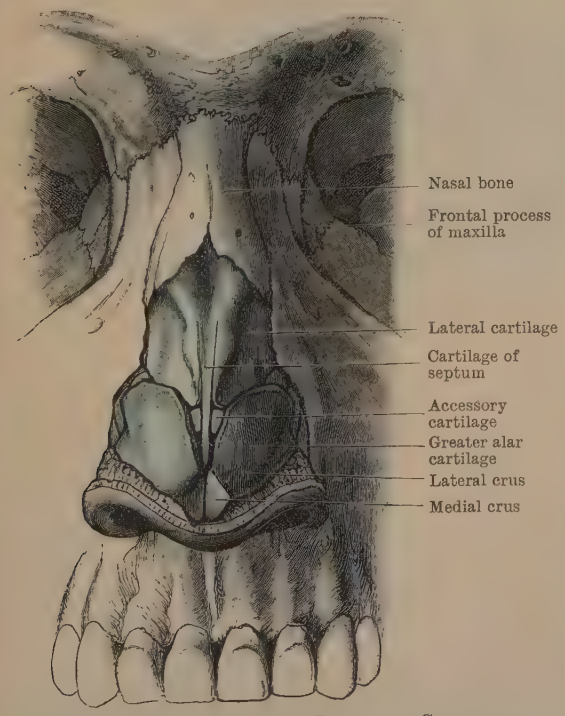

FIG. 638.—FRONT VIEW OF THE BONY AND CARTILAGINOUS SKELETON OF THE EXTERNAL NOSE.

The lowest part of the nasal septum is not formed by the septal cartilage, but by the medial crura of the greater alar cartilages and by the skin, and, being freely movable, is termed the **septum mobile nasi**.

CAVUM NASI.

The **nasal cavity** (Fig. 640) is divided by the nasal septum into a right and a left cavity; these extend from the nares or nostrils in front to the choanæ behind, and open, through the latter, into the nasal part of the pharnyx. On the lateral wall of each cavity are the orifices of the frontal, ethmoidal, sphenoidal, and maxillary air-sinuses, and the orifice of the naso-lacrimal duct.

Immediately above the naris there is a slightly expanded area, the **vestibule**, which is bounded laterally by the lateral crus of the

greater alar cartilage, and medially by the lower part of the septum. It is lined with skin, and is prolonged as a small recess towards the apex of the nose. The vestibule is partly subdivided by a curved ridge; and, in its lower part, there are hairs and sebaceous glands, the hairs being curved downwards to guard the entrance to the nostril; the upper part is smooth, and is limited superiorly by a slightly marked arched prominence, the **limen nasi**, which is caused by the lower edge of the lateral cartilage.

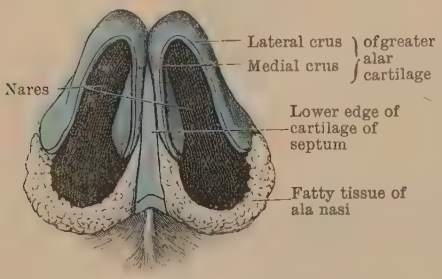

FIG. 639.—CARTILAGES OF NOSE FROM BELOW.

Each nasal cavity is divided into a superior or olfactory, and an inferior or respiratory region. The **olfactory region**, to which alone the olfactory nerves are distributed, is a narrow slit-like space, and comprises the anterior part of the superior nasal concha and the corresponding portion of the septum nasi. The **respiratory region** includes the rest of the cavity.

Septum Nasi (Fig. 636).—The septum nasi consists of a bony and a cartilaginous part. The bony part is formed, in front, by the frontal spine, and the crest of the nasal bones; in the middle, by the lamina perpendicularis of the ethmoidal bone; behind, by the vomer and by the rostrum of the sphenoidal bone; below, by the nasal crests of the maxillæ and palatine bones. The bony part is deficient below and in front, and the gap is filled by the septal cartilage (p. 794). In the septum nasi, a little above and in front of the naso-palatine recess, is a minute orifice, not always recognisable, from which a blind pouch, the **vomero-nasal organ of Jacobson**, extends upwards and backwards for a distance of from 2 to 9 mm., and is supported by the vomero-nasal cartilage. In man the vomero-nasal organ is rudimentary, but in many of the lower animals it is well developed (Fig. 641), and is lined with epithelium similar to that covering the olfactory region, and supplied by branches of the olfactory nerve.

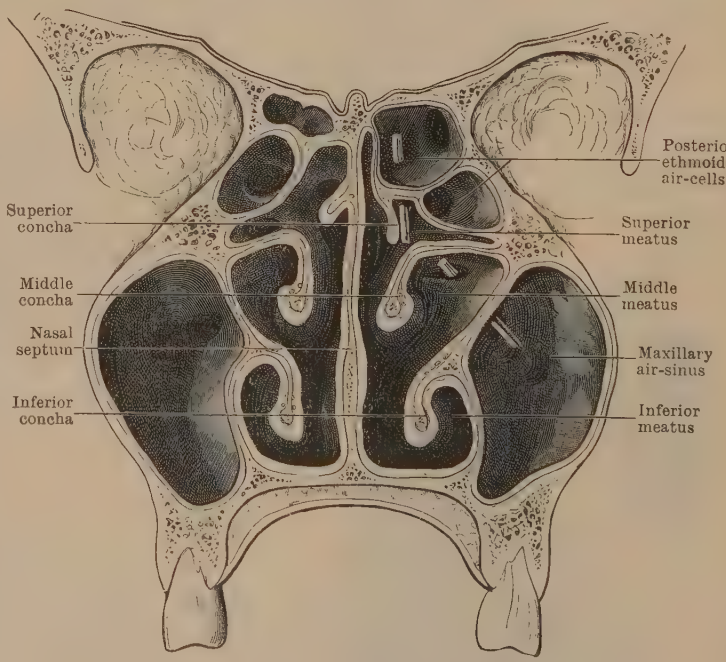

FIG. 640.—FRONTAL SECTION THROUGH THE NASAL CAVITIES; ANTERIOR HALF OF SECTION VIEWED FROM BEHIND.

Until the seventh year of life the nasal septum lies, as a rule, in the median plane, but after this age it is very often bent to one or other side—more frequently to the right—the deflection being greatest usually along the line of junction of the vomer with the perpendicular lamina of the ethmoidal bone. Deflection of the septum is more common in European than in non-European skulls—occurring in about 53 per cent. of the former and in about 28 per cent. of the latter (Zuckerkandl). Associated with, or apart from, this deviation, crests or spurs of bone are found, projecting from the septum into one or other nasal cavity, in about 20 per cent. of skulls.

Lateral Wall (Fig. 642).—In the lateral wall of the nasal cavity, above the superior nasal concha, there is a narrow recess, the **recessus sphenoethmoidalis**, into the posterior part of which the sphenoidal air-sinus opens. The **superior meatus** of the nose is a short oblique fissure, below and lateral to the superior nasal concha; the posterior ethmoidal air-cells open into this meatus by one or more orifices. A small meatus, bounded superiorly by a concha suprema, frequently exists above the superior meatus.

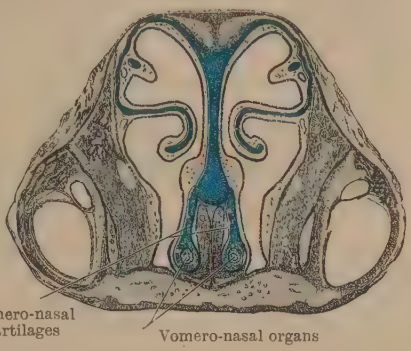

FIG. 641.—SECTION THROUGH NOSE OF A KITTEN, showing position of the vomero-nasal organs.

The **middle meatus**, situated below and lateral to the middle nasal concha, is a roomy passage, and is continued forwards into a slightly depressed area, termed the **atrium meatus nasi**, which lies immediately above the vestibule. The atrium is limited superiorly and anteriorly by a low ridge, the **agger nasi**, the representative of the *naso-turbinal* found in many mammals. If the middle nasal concha be removed the lateral wall of the meatus is exposed. On it there is a narrow semilunar cleft, the **hiatus semilunaris**, which is bounded above by a rounded elevation, the **bulla ethmoidalis**, and below by the sharp edge of the pro-

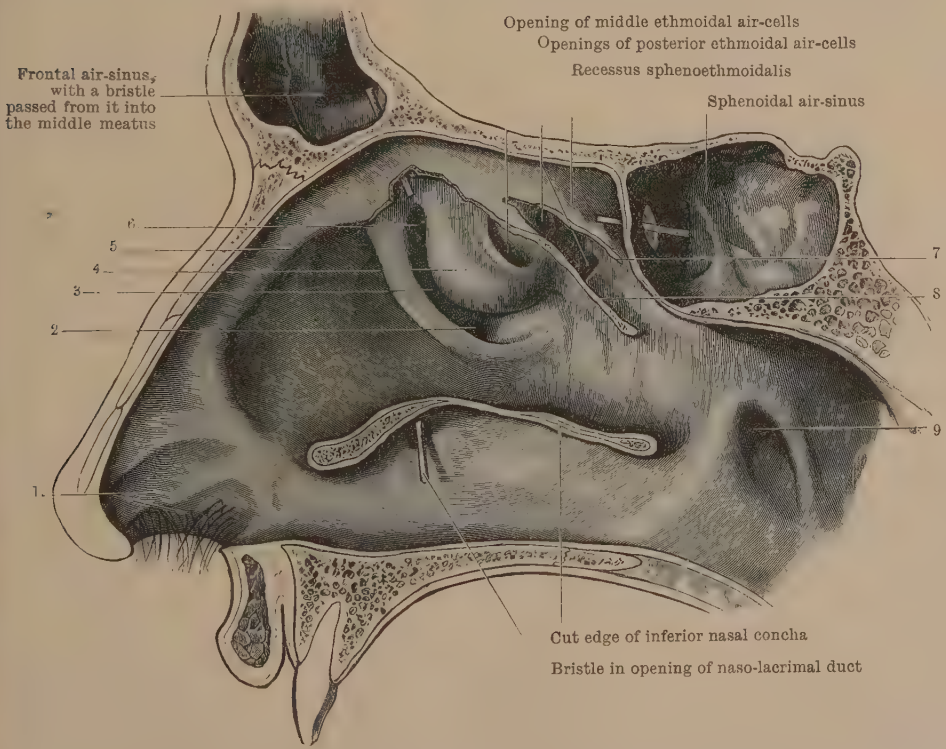

FIG. 642.—VIEW OF THE LATERAL WALL OF THE NOSE—THE NASAL CONCHÆ HAVING BEEN REMOVED.

1. Vestibule.
2. Opening of maxillary air-sinus.
3. Hiatus semilunaris.
4. Bulla ethmoidalis.

6. Opening of anterior ethmoidal air-cells.
7. Cut edge of superior nasal concha.
8. Cut edge of middle nasal concha.
9. Pharyngeal orifice of auditory tube.

cessus uncinatus of the ethmoidal bone. The size of the bulla varies with that of the middle ethmoidal air-cells, which are contained within it and open on or near its upper surface. Through the hiatus semilunaris the middle meatus opens into the **infundibulum** or **frontal recess**, a curved channel, limited above by the bulla ethmoidalis, and below by the lateral surface of the processus uncinatus. The

anterior end of the infundibulum receives the openings of the anterior ethmoidal air-cells, and, in rather more than fifty per cent. of skulls, is continued upwards as the **fronto-nasal duct** into the frontal air-sinus; in the remainder it is shut off from the lower end of the fronto-nasal duct by the union of the bulla ethmoidalis with the upper part of the processus uncinatus, and the fronto-nasal duct then opens into the anterior part of the middle meatus. The **ostium maxillare** or opening of the maxillary air-sinus is placed below the bulla ethmoidalis, and is hidden by the lower end of the processus uncinatus; an accessory ostium is frequently seen in the middle meatus, above the posterior part of the inferior nasal concha. The narrow slit-like interval between the nasal septum and the medial surface of the middle nasal concha is named the **olfactory cleft** or **sulcus.**

The **inferior meatus** lies below and lateral to the inferior nasal concha; the slit-like orifice of the naso-lacrimal duct opens into the anterior part of this meatus (p. 820).

Roof.—The roof of the nasal cavity is very narrow, except at its posterior part, and is divisible into three portions, fronto-nasal, ethmoidal, and sphenoidal, in accordance with the bones which enter into its formation.

Floor.—The floor of the nasal cavity is formed by the palatine process of the maxilla and the horizontal part of the palatine bone. In it, close to the inferior margin of the septum and immediately over the incisive foramen, a funnel-shaped depression, the *naso-palatine recess*, is sometimes seen; it is directed downwards and forwards, and indicates the position of a communication which existed between the nasal and buccal cavities in early fœtal life.

Membrana Mucosa Nasi.—The **nasal mucous membrane** lines the entire nasal cavity except the vestibule; it is firmly bound to the subjacent periosteum and perichondrium. It is continuous, through the choanæ, with the mucous lining of the nasal part of the pharynx; through the naso-lacrimal and lacrimal ducts, with the conjunctiva; and, through the apertures leading into the accessory air-sinuses of the nose, with the delicate lining of these cavities.

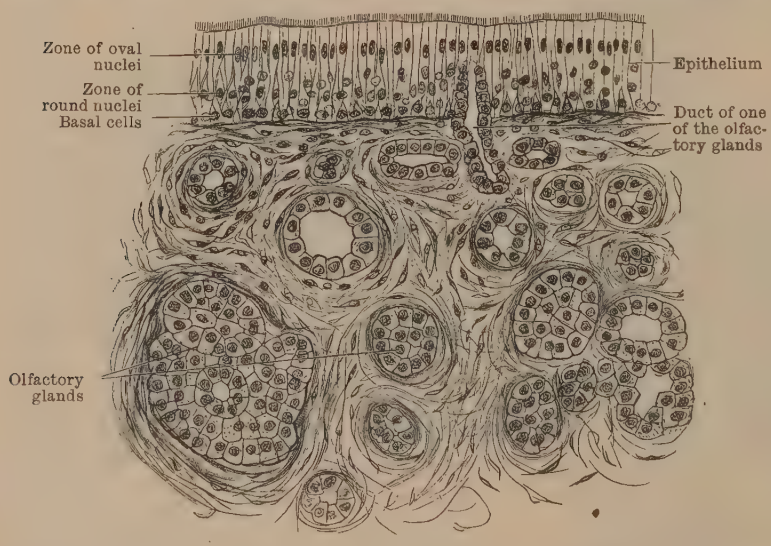

Fig. 643.—Section through the Olfactory Mucous Membrane.

Throughout the respiratory region the mucous membrane is covered with columnar, ciliated epithelium, interspersed amongst which are goblet or mucous cells; between the bases of the columnar cells smaller pyramidal cells are interpolated. It is highly vascular, and contains a freely anastomosing venous plexus. Many acinous glands are embedded in it, and are especially large and numerous in the posterior halves of the nasal cavities. In children a considerable amount of adenoid tissue is present.

In the olfactory region the mucous membrane is thin, yellowish in colour, and covered with non-ciliated columnar epithelium (Figs. 643, 644). Embedded in it are numerous tubular and branched **olfactory glands (glands of Bowman)**, which are lined with polygonal cells, and open by fine ducts. The epithelium of the olfactory region consists of—supporting, olfactory, and basal cells (Fig. 644).

Supporting Cells.—The superficial parts of these cells are columnar in

shape and contain fine granules of yellow pigment, whilst the deep portions are continued for some distance as attenuated or branched processes. These cells contain elliptical or oval nuclei, which are situated at the deep ends of the columnar parts of the cells, and form the *zone of oval nuclei*. In many animals the free surface of this columnar epithelium is covered by a thin limiting membrane.

Olfactory Cells.—These are bipolar nerve-cells, the central processes of which are continued as the axons of the olfactory nerve-fibres. They are homologous with the nerve-cells of the spinal ganglia, but differ from them in that they retain their primitive position in the surface epithelium. The cell-bodies are spindle-shaped and are arranged in several rows between the deeper, attenuated parts of the supporting cells. Each cell-body consists of a large, spherical nucleus enveloped by a small amount of protoplasm; the nuclei form a layer of some thickness, termed the *zone of round nuclei*. The peripheral process of each olfactory cell is rod-like, and extends between the columnar portions of the supporting cells as far as their free surfaces, where it pierces the external limiting membrane and divides into a number of fine hair-like processes, named **olfactory hairs**; the central process, a delicate, beaded filament, is continued upwards as the axon of an olfactory nerve-fibre.

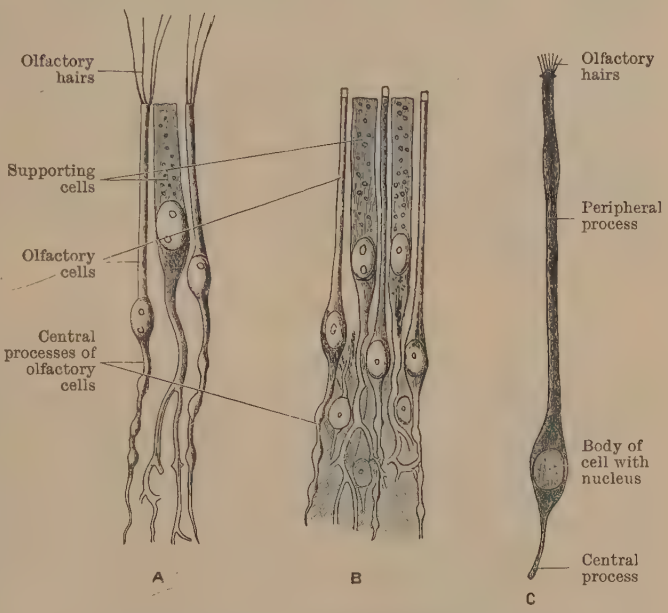

FIG. 644.—OLFACTORY AND SUPPORTING CELLS.

A. Frog } M. Schultze. C. Human (v. Brunn).
B. Human }

Basal Cells.—These cells are branched, and lie between the deep ends of the supporting and olfactory cells.

Olfactory Nerves.—The fibres of the olfactory nerves are devoid of medullary sheaths, but are provided with primitive sheaths; they arise, as stated, from the olfactory cells. They are collected into fasciculi which form a plexiform network under the mucous membrane and ascend on the medial and lateral walls of the olfactory region of the nasal cavity. They are lodged, near the base of the skull, in grooves or canals in the ethmoidal bone, and pass into the cranial cavity through the foramina in the lamina cribrosa of that bone. They enter the olfactory bulb, in the glomeruli of which they subdivide and form synapses with the dendrites of the mitral cells of the bulb.

The trigeminal nerve supplies branches of ordinary sensation to the nasal mucous membrane as follows:—The septum is chiefly supplied by the naso-palatine nerve, but its posterior part receives some filaments from the spheno-palatine ganglion and from the nerve of the pterygoid canal, and its anterior portion from the naso-ciliary branch of the ophthalmic nerve. The lateral wall is supplied—(1) by the upper nasal branches of the spheno-palatine ganglion; (2) by the lower nasal branches of the anterior palatine nerve; and in front by (3) the naso-ciliary branch of the ophthalmic nerve. The floor and the anterior part of the inferior meatus are supplied by a nasal branch of the anterior superior alveolar nerve.

Blood-vessels.—The chief artery of the nose is the spheno-palatine branch of the internal maxillary artery. This reaches the nasal cavity through the spheno-palatine foramen, and divides into—(*a*) posterior lateral nasal branches, which ramify over the meatuses and conchæ, and also send branches to the maxillary and frontal air-sinuses and the ethmoidal air-cells; and (*b*) naso-palatine, the artery of the septum. The upper portion of the cavity receives twigs from the anterior and posterior ethmoidal arteries, and the posterior part some small branches

from the descending palatine artery. The nostrils are supplied by the lateral nasal branch of the external maxillary artery, and by the septal branch of the superior labial artery. The maxillary air-sinus is supplied by the infra-orbital and posterior superior alveolar arteries, whilst the sphenoidal air-sinus gets its chief supply from the spheno-palatine artery. The **veins** form a dense cavernous plexus which is well seen in the respiratory region, and especially so over the inferior nasal concha and the lower and posterior parts of the septum. The venous blood is carried in three chief directions, viz., *anteriorly* into the anterior facial vein, *posteriorly* into the pterygoid plexus through the spheno-palatine vein, and *superiorly* into the ethmoidal veins. The ethmoidal veins communicate with the ophthalmic veins and the veins of the dura mater; one ethmoidal vein passes up through the lamina cribrosa of the ethmoidal bone, and opens either into the venous plexus of the olfactory bulb or directly into one of the veins on the orbital surface of the frontal lobe of the brain. The **lymph-vessels** form an irregular network in the superficial part of the mucous membrane and communicate with the lymph-spaces which surround the branches of the olfactory nerve; they can be injected from the subdural and subarachnoid cavities. The chief lymph-vessels are directed posteriorly towards the choanæ, and are collected into two trunks, one passing to a lymph-gland in front of the epistropheus, the other to one or two lymph-glands near the greater cornu of the hyoid bone.

The Accessory Air-sinuses of the Nose.

The **accessory air-sinuses of the nose** are the frontal, ethmoidal, sphenoidal, and maxillary; they open into the nasal cavities, and are lined by mucous membrane, continuous with that of the nasal cavities.

The **frontal air-sinuses** are two in number, and are placed behind the superciliary arches; they are rarely symmetrical because the septum which separates them frequently deviates from the median plane. Their average measurements are:—height, 3·16 cm.; breadth, 2·58 cm.; depth from before backwards, 1·8 cm. Each opens, through the fronto-nasal duct, into the anterior part of the middle meatus of the nose.

The **ethmoidal air-sinuses** consist of numerous air-cavities in the labyrinths of the ethmoidal bone, and completed by the frontal, maxillary, lacrimal, sphenoidal, and palatine bones. They are separated from the orbital cavities by thin bony laminæ, and are arranged in three groups, anterior, middle, and posterior. The anterior and middle groups open into the middle meatus, and the posterior group into the superior meatus, of the nose.

The **sphenoidal air-sinuses** are two cavities in the body of the sphenoidal bone; they are rarely symmetrical, since the septum between them is often bent to one or other side of the median plane. Their average measurements are:—height, 2 cm.; width, 1·8 cm.; antero-posterior depth, 2·1 cm. Each opens into the spheno-ethmoidal recess, above the superior nasal concha.

The **maxillary air-sinuses** are pyramidal cavities in the bodies of the maxillæ. Their average measurements are:—height, opposite the first molar tooth, 3·5 cm.; width, 2·5 cm.; antero-posterior depth, 3·2 cm. In the upper part of the base of each air-sinus is an opening (*ostium maxillare*) through which it communicates with the lower part of the hiatus semilunaris in the middle meatus of the nose. An accessory ostium is frequently seen above the posterior part of the inferior nasal concha.[1]

The development of the nose is described in the section on "General Embryology."

ORGANON VISUS.

BULBUS OCULI.

The bulb of the eye (O.T. eyeball) constitutes the peripheral part of the **organ of sight**; associated with it are certain accessory structures, such as the eyelids, lacrimal apparatus, etc.

Bulbus Oculi.—The bulb of the eye is situated in the anterior part of the

[1] The measurements of the accessory sinuses are those given by A. Logan Turner, *Accessory Sinuses of the Nose*, 1901.

orbital cavity; it is protected in front by the eyelids, and is pierced behind by the optic nerve. The tendons of the ocular muscles are attached to its outer surface, and the posterior part of the bulb is enveloped by a loose membrane termed the fascia bulbi (O.T. capsule of Tenon).

The bulb of the eye is not quite spherical, being composed of the segments of two spheres, viz., an anterior, corneal segment, with a radius of about 8 mm., and a posterior, scleral segment, with a radius of about 12 mm. (Fig. 645). The anterior or corneal segment, in consequence of its shorter radius, projects in front of the scleral portion, the union of the two parts being indicated, externally, by a slight groove, the **sulcus scleræ**. The central points of the anterior and posterior curved surfaces of the bulb constitute, respectively, its **anterior** and **posterior poles**, and a straight line joining the two poles is termed the **axis oculi**; an imaginary line encircling the bulb, midway between the poles, is named the **equator**. The axes

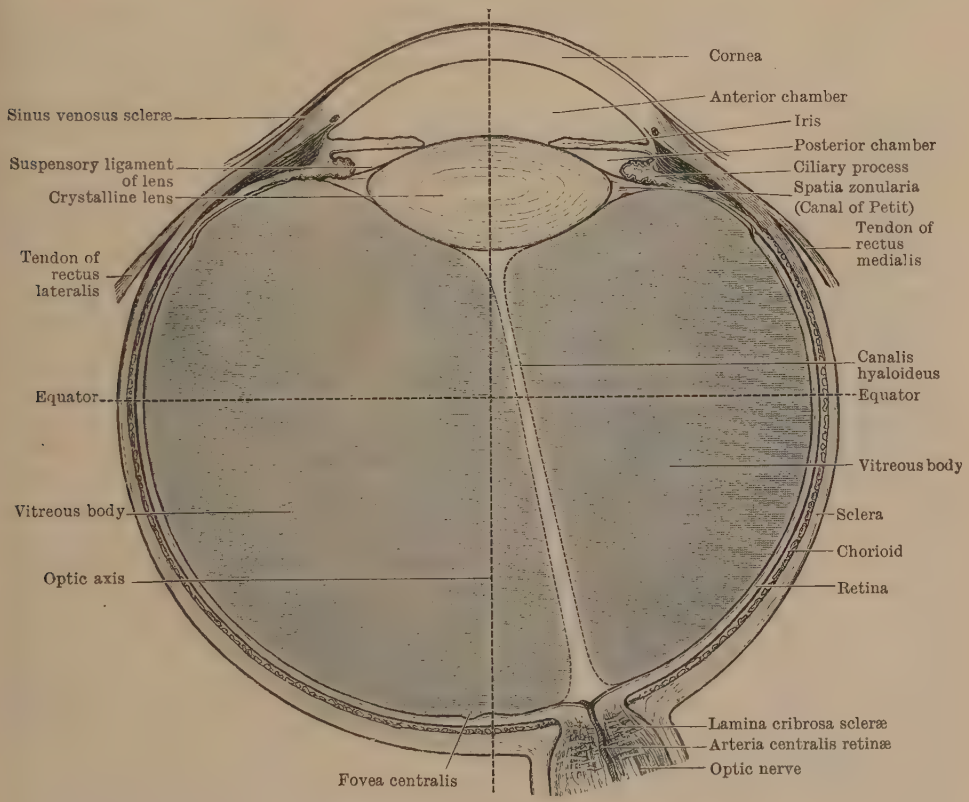

FIG. 645.—DIAGRAM OF A HORIZONTAL SECTION THROUGH THE LEFT BULBUS OCULI AND THE OPTIC NERVE (×4).

of the two bulbs are almost parallel, converging only slightly behind; but the axes of the optic nerves converge markedly behind, and, if prolonged backwards, would meet in the region of the dorsum sellæ of the sphenoidal bone. The sagittal and transverse diameters of the bulb are nearly equal—about 24 mm.; the vertical diameter is about 23·5 mm. All three diameters are rather less in the female than in the male, but the size of the bulb is fairly constant in the same sex. What are popularly described as large eyes owe their apparent size to a greater prominence of the bulb and to a wider palpebral fissure.

At birth the bulb of the eye is nearly spherical and has a diameter of about 17·5 mm. By the age of puberty this has increased to 20 or 21 mm., after which it rapidly reaches its adult size. In the myopic the sagittal diameter is greater, and in the hypermetropic it is less than normal.

Fascia Bulbi.—The **fascia bulbi** is a thin fibrous tunic which envelops the bulb of the eye from the entrance of the optic nerve to the sclero-corneal junction; it forms a socket for the bulb, and separates it from the other contents of the orbital cavity. Between the fascia and the sclera is a potential **episcleral space**; this, although often described as a lymph-space, is not lined by endothelium, but is traversed by a meshwork of fine connective tissue. Around the entrance of the optic nerve the fascia bulbi is pierced by the ciliary nerves and the posterior ciliary vessels which render this part of the fascia somewhat difficult to define. The fascia is not continued backwards to form a sheath for the optic nerve. Near the equator of the bulb the fascia is perforated by the venæ vorticosæ, and the more anteriorly by the ocular muscles. The part of the fascia in front of the insertions of the recti muscles is thin; it lies between the bulbar part of the conjunctiva and the sclera, and fuses with the latter immediately behind the sclero-corneal junction.

The sheaths of the ocular muscles are thin and almost invisible posteriorly, but they become thick and opaque anteriorly, and blend with the fascia bulbi at the points where the latter is pierced by the muscles. Immediately behind these points the muscle-sheaths are united by their edges to form an **intermuscular membrane**; this membrane is best developed between the superior and lateral recti, and there passes beneath the lacrimal gland.

Offsets pass from the outer surfaces of the muscle-sheaths to the walls of the orbital cavity, and as these offsets probably check the actions of the corresponding muscles, they are named **check ligaments**; they are best developed in association with the lateral and medial recti. The outer part of the sheath of the rectus lateralis is greatly thickened anteriorly, and forms a triangular mass of tissue which constitutes the check ligament of this muscle; it is chiefly attached to the tubercle on the orbital surface of the zygomatic bone, but is also fixed to the lateral palpebral ligament and the lateral conjunctival fornix. The check ligament of the rectus medialis is of a similar shape; it is fixed to the lacrimal bone behind the posterior lacrimal crest, and to the caruncula lacrimalis and the medial conjunctival fornix. The sheath of the rectus superior blends with that of the levator palpebræ superioris, and the stratum so formed is attached to the superior conjunctival fornix; the sheath of the tendon of the obliquus superior extends as far as, and is fixed to, the fibrous pulley through which the tendon passes. A band is sometimes continued backwards and lateralwards to the floor of the orbital cavity from the sheath of the obliquus inferior; this sheath also blends with that of the rectus inferior, and the blended sheaths send forwards one thin lamella into the lower eyelid, and another to unite with the fascia bulbi. The margins of the sheath of the rectus inferior join the margins of the sheaths of the lateral and medial recti, and as the latter sheaths are fixed to the medial and lateral walls of the orbital cavity by the check ligaments, already described, a continuous band, named the **suspensory ligament** (Lockwood), is slung from side to side like a hammock beneath the bulb of the eye. The ends of this suspensory ligament blend not only with the check ligaments, but with the lateral and medial horns of the aponeurosis of the levator palpebræ superioris, and the masses of tissue thus formed are often named the **lateral** and **medial ocular retinacula.**

The wall of the bulb of the eye (Fig. 645) consists of three concentric tunics or coats; enclosed within it are three transparent refracting media. The three tunics are: (1) an outer, fibrous tunic, the **tunica fibrosa oculi**; (2) an intermediate, vascular, pigmented, and partly muscular tunic, the **tunica vasculosa oculi**; (3) an internal, nervous tunic, the **retina.** The three refracting media are named, from behind forwards, the **vitreous body**, the **crystalline lens,** and the **aqueous humour.**

TUNICA FIBROSA OCULI

The fibrous tunic of the bulb of the eye consists of an opaque, posterior part, the **sclera,** and a transparent, anterior part, the **cornea.**

Sclera.—The **sclera** is firm and opaque, and forms the greater part of the outer tunic. Thickest posteriorly (about 1 mm.), it thins at the equator of the bulb to

0·4 or 0·5 mm., and again increases to 0·6 mm. near the sulcus scleræ. In the child it is thinner than in the adult, and presents a bluish appearance caused by the pigment of the chorioid shining through it; in old age it assumes a yellowish tinge. The tendons of the ocular muscles are attached to it, and the fascia bulbi closely envelops it. The sclera is pierced posteriorly, by the optic nerve, the entrance for which is funnel-shaped, wide behind and narrow in front, and is situated 3 mm. to the nasal side of the posterior pole. The fibrous sheath of the nerve blends with the outer part of the sclera, while the nerve-bundles pass through a series of orifices; this perforated portion is named the **lamina cribrosa scleræ.** Around the entrance of the optic nerve are fifteen or twenty small apertures for the passage of the ciliary nerves and short ciliary arteries. The two long posterior ciliary arteries pierce the sclera, one on either side, at a little distance from the entrance of the optic nerve; near the equator are four openings, two above and two below, for the exit of veins (**venæ vorticosæ**) from the chorioid; near the sulcus scleræ it is perforated by the anterior ciliary arteries. The deep surface of the sclera is of a brownish colour, and is lined with flattened endothelial cells; between it and the chorioid is an extensive space, the **spatium perichorioideale,** traversed by the ciliary nerves and arteries just mentioned, and by a delicate meshwork of fine, pigmented, connective tissue, the **lamina fusca,** which loosely attaches the sclera to the chorioid. At the sclero-corneal junction the fibrous tissue of the sclera passes continuously into that of the cornea, and in the deeper part of this junction there is a circular canal, the **sinus venosus scleræ** (O.T. **canal of Schlemm**) (Fig. 646). When seen in a meridional section of the sclero-corneal junction, the sinus venosus scleræ appears as a narrow cleft; its outer wall is formed by the compact tissue of the sclera; its inner wall consists of a triangular mass of trabecular tissue; the apex of this triangular mass is directed forwards and is continuous with the posterior elastic lamina of the cornea. The sinus is lined with endothelium, and occasionally contains a few red blood-corpuscles. It communicates with the anterior ciliary veins, and, through the spatia anguli iridis in the trabecular tissue, with the anterior chamber of the eye.

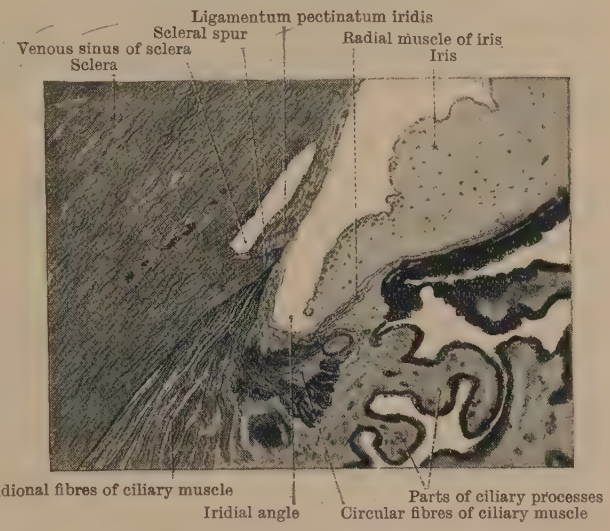

FIG. 646.—SECTION OF IRIDIAL ANGLE. (Arthur Thomson.)

Structure.—The sclera consists of bundles of white fibrous tissue, together with some fine elastic fibres, the bundles forming equatorial and meridional layers, which interlace with one another. Numerous spaces containing connective tissue cells and migratory cells exist between the fibres. Pigmented cells are plentiful in the lamina fusca, and a few are found in the tissue of the sclera near the entrance of the optic nerve and in the region of the sclero-corneal junction.

Vascular and Nervous Supply.—The sclera receives its blood-supply from the short posterior ciliary and the anterior ciliary arteries; its veins open into the venæ vorticosæ and anterior ciliary veins. The cell-spaces probably play the part of lymph-vessels; they communicate with the perichorioidal and episcleral spaces. The nerves of the sclera are derived from the ciliary nerves, which, after losing their medullary sheaths, pass between the fibrous bundles; their exact mode of ending is not known.

Cornea.—The **cornea** is transparent and forms the anterior part of the outer tunic; its index of refraction is from 1·33 to 1·35; the thickness of its central part is about ·95 mm., that of its peripheral part, about 1·19 mm. Its anterior surface

is covered with a stratified epithelium, continuous with that of the conjunctiva; its posterior surface is directed towards the anterior chamber of the eye and is in contact with the aqueous humour. The degree of curvature of the cornea varies in different individuals; it is greater in youth than in old age, and is, as a rule, slightly greater in the vertical than in the horizontal plane; it diminishes from the centre to the circumference of the cornea, and is less on the nasal than on the temporal side of the anterior pole. The outline of the anterior surface of the cornea is almost circular, measuring 11 mm. vertically and 11·9 mm. transversely; that of the posterior surface is circular and has a diameter of 13 mm. The arc of the cornea is equal to about one-sixth of the total circumference of the bulb of the eye.

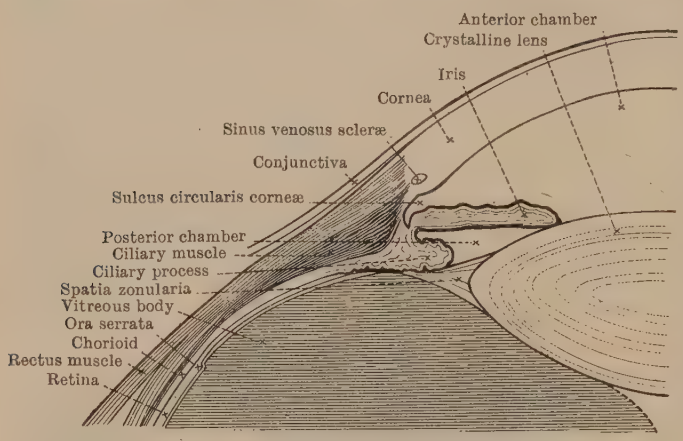

Fig. 647.—Section of a Portion of the Bulb of the Eye, showing the Sulcus Circularis Corneæ.

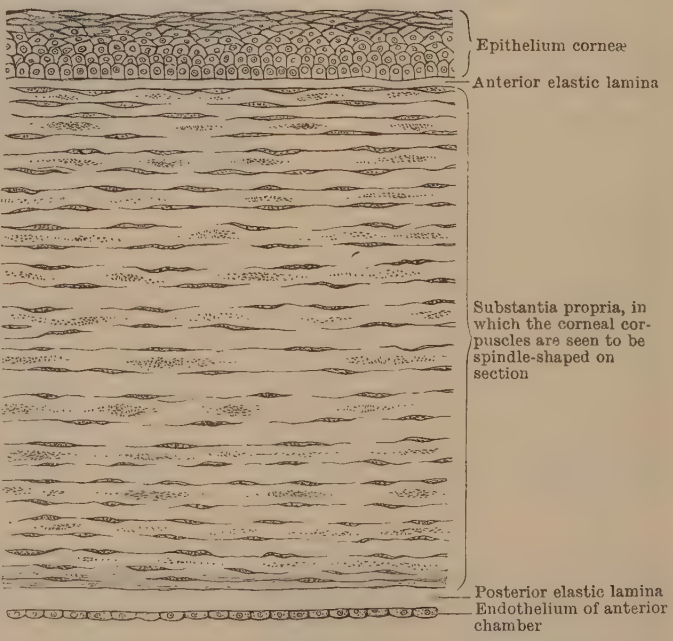
The tissue of the cornea is continuous posteriorly with that of the sclera, the line of union being known as the **sclero-corneal junction**. Directly in front of this junction the inner surface of the cornea projects in the form of a rounded rim; behind this rim, in the interval between the sclero-corneal junction and the attachment of the iris, is a groove, the **sulcus circularis corneæ** (Arthur Thomson)[1] (Fig. 647). The outer wall of this sulcus is composed of a stratum of trabecular tissue placed on the inner side of the sinus venosus scleræ (Fig. 647). Between this trabecular tissue and the front of the circumference of the iris is a narrow recess which on section appears as an acute angle; it is named the **filtration angle** or **angle of the iris**.



Epithelium corneæ
Anterior elastic lamina
Substantia propria, in which the corneal corpuscles are seen to be spindle-shaped on section
Posterior elastic lamina
Endothelium of anterior chamber

Fig. 648.—Vertical Section of Cornea (magnified).

Structure.—The cornea consists, from before backwards, of the following strata, (Fig. 648):—

1. Epithelium corneæ.
2. Anterior elastic lamina.
3. Substantia propria.
4. Posterior elastic lamina.
5. Endothelium of anterior chamber.

[1] *Atlas of the Eye*, Clarendon Press, Oxford, 1912.

1. The **epithelium corneæ** is continuous with the epithelium covering the free surface of the conjunctiva, and consists of six or eight strata of nucleated cells. Deepest of all is a single layer of perpendicularly arranged columnar cells, the flattened bases of which rest on the anterior elastic lamina, while their opposite ends are round and contain the nuclei. Superficial to this layer are three or four strata of polygonal cells, most of which exhibit finger-like processes joining with the corresponding processes of neighbouring cells; the more superficial layers consist of squamous cells. The thickness of this stratified epithelium is about 45 μ at the centre, and about 80 μ at the periphery, of the cornea.

2. The **anterior elastic lamina**, from 19-20 μ thick, is merely a differentiation of the anterior part of the substantia propria, from which it is difficult to separate; it is not stained yellow by picrocarmine, thus differing from true elastic tissue. Its degree of development varies in different animals.

3. The **substantia propria** presents, in a fresh condition, a homogeneous appearance; but, with the assistance of reagents, it is seen to consist of modified connective tissue, with a few elastic fibres. An amorphous interstitial substance binds the fibres into bundles, and, in turn, cements the bundles into lamellæ which are flattened from before backwards. The fibres of any one lamella cross those of adjacent lamellæ almost at right angles, while the superimposed lamellæ are joined by sutural fibres and by amorphous substance. Between the lamellæ are the **cell-spaces** or **lacunæ** of the cornea—irregularly stellate in shape, and communicating freely with each other by means of fine canaliculi. The corneal cells are contained in these lacunæ, without, however, completely filling them, the remainder of the lacunæ being occupied by lymph. The cells are nucleated, flattened, and star-like, and their branched processes join those of neighbouring cells in the canaliculi. Lymph-cells are also found in the cell-spaces.

After middle age a grayish opaque ring, 1·5 to 2 mm. in breadth, is frequently seen near the periphery of the cornea; it is termed the **arcus senilis**, and results from a deposit of fat granules in the lamellæ and corneal cells.

4. The **posterior elastic lamina** is a clear homogeneous membrane, covering the posterior surface of the substantia propria and having a thickness of 6-8 μ at the centre and 10-12 μ at the periphery of the cornea. Less firmly attached to the substantia propria than the anterior elastic lamina, it may be stripped off, when it will be found to roll up with its attached surface inwards. Between the ages of twenty and thirty years small wart-like projections appear on its deep surface, near its periphery, and these increase in size and number as age increases, so that in old people the membrane may attain a thickness of 20 μ. At the sclero-corneal junction the posterior elastic lamina splits into bundles of fine fibres which interlace and form the triangular area of trabecular tissue already referred to (p. 804), and which is usually spoken of under the name of the **ligamentum pectinatum iridis**. The spaces between the trabeculæ are termed the **spatia anguli iridis** (**O.T. spaces of Fontana**), and are lined with endothelium prolonged from the endothelium of the anterior chamber. They communicate internally with the filtration angle and externally with the sinus venosus scleræ, and form important channels through which fluid may filter from the anterior chamber into the sinus and thence into the anterior ciliary veins. When the trabecular tissue of the ligamentum pectinatum iridis is followed backwards most of its fibres are seen to be attached to the anterior surface of an inwardly directed rim of scleral tissue; in a meridional section this rim appears as a triangular projection, and is named the **scleral spur**. A few fibres of the trabecular tissue are carried past the apex of the scleral spur on to the inner surface of the origin of the meridional fibres of the ciliary muscle, and, running behind the filtration angle, are prolonged into the iris (Fig. 646), where they are directly continuous with the fibres of the dilatator pupillæ muscle (Arthur Thomson).[1]

5. The **endothelium of the anterior chamber** consists of a single stratum of nucleated, flattened, polygonal cells, which present a fibrillar structure and are continued as a lining to the spatia anguli iridis; this layer of endothelium is also reflected on to the anterior surface of the iris.

Vascular and Nervous Supply of the Cornea.—In the fœtus the cornea is traversed, almost as far as its centre, by capillaries; but in the adult it is devoid of blood-vessels, except at its margin. The capillaries of the conjunctiva and sclera pass into this marginal area for a distance of about 1 mm., where they end in loops. The rest of the cornea is nourished by the lymph which percolates into its cell-spaces and canaliculi.

The nerves of the cornea are derived from the ciliary nerves. Around its periphery they form an annular plexus, from which nerve-fibres pass into the cornea, where, after a distance of 1 or 2 mm., they lose their medullary sheaths and ramify in the substantia propria, forming the fundamental or stroma plexus. Fibres extend from this plexus through the anterior elastic lamina and form a subepithelial plexus, from which fine filaments ramify between the epithelial cells as far as the superficial layers. From the annular and stroma plexuses fibrils pass to the substantia propria and come into close relation with the corneal cells.

TUNICA VASCULOSA OCULI.

The vascular and pigmented tunic of the bulb of the eye comprises, from behind forwards, the chorioid, the ciliary body, and the iris (Fig. 645).

Chorioidea.—The **chorioid** intervenes between the sclera and the retina, reaching

[1] *Op. cit.*

as far forwards as the ora serrata of the latter (p. 809). It is dark brown or black in colour, and is thicker behind than in front; posteriorly it is pierced by

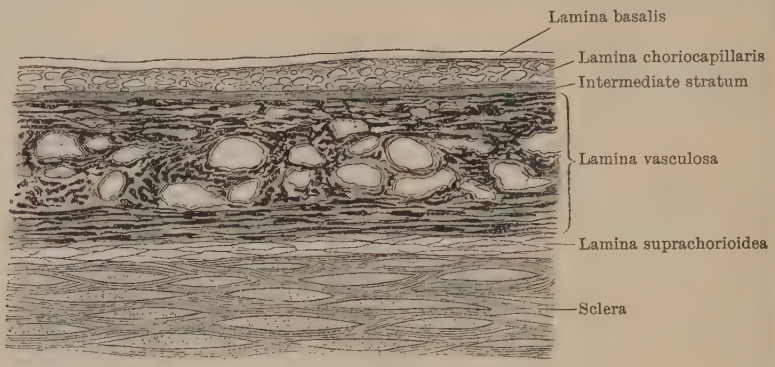


Fig. 649.—Vertical Section of Chorioid and Inner Part of Sclera.

the optic nerve, and is there firmly attached to the sclera. Its outer surface is flocculent and is loosely connected to the sclera by the lamina fusca; its inner surface is smooth and is adherent to the pigmented layer of the retina.

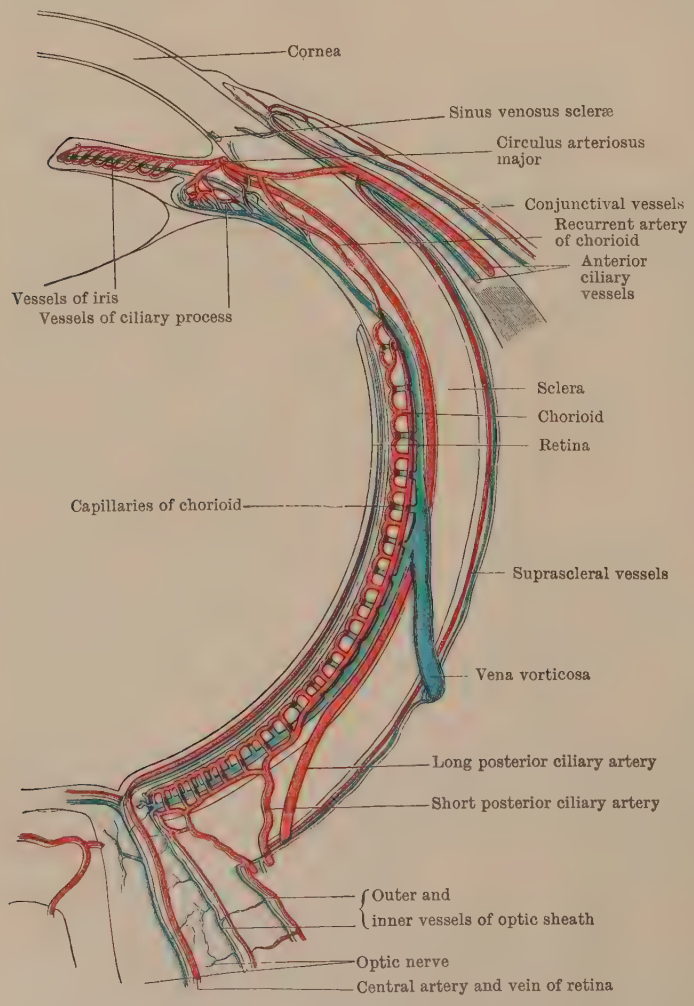

Fig. 650.—Diagram of the Circulation in the Eye. (Leber.)

Structure.—The chorioid consists of a loose connective tissue, embedded in which are blood-vessels and branched, pigmented cells; from without inwards it consists of three layers, (*a*) the lamina suprachorioidea; (*b*) the proper tissue of the chorioid; and (*c*) the lamina basalis (Fig. 649).

The **lamina suprachorioidea** resembles the lamina fusca of the sclera, and consists of a series of fine non-vascular lamellæ, each containing a delicate network of elastic fibres, amongst which are stellate, pigmented cells, and amœboid cells. The spaces between the laminæ are lined with endothelium, and together form the spatium perichorioideale, already referred to (p. 803).

The **proper tissue of the chorioid** consists of blood-vessels and numerous pigmented cells, supported by connective tissue, elastic fibres, and some non-striped muscular fibres. Its outer part contains the larger blood-vessels, and is named the **lamina vasculosa**. Its inner portion is composed of a close network of capillaries embedded in a finely granular or almost homogeneous tissue, and is termed the **lamina choriocapillaris**. These

two laminæ are joined by a thin **intermediate stratum** consisting of a network of delicate elastic fibres.

Vascular and Nervous Supply of the Chorioid.—The arteries of the chorioid are derived from the short posterior ciliary vessels which pierce the sclera around the entrance of the optic nerve, and form a wide-meshed plexus in the lamina vasculosa. The circular muscular coats of the arteries are well developed, and longitudinal muscular fibres also are present in the larger branches. The veins, destitute of muscular tissue, are superficial to the arteries; they are surrounded by perivascular lymph-sheaths and converge to form whorls, which open into the venæ vorticosæ (p. 803). In the tissue between the blood-vessels are numerous stellate, flattened, and pigmented cells.

Tapetum.—In many animals a brilliant iridescence is seen on the postero-lateral part of the chorioid; to this the name **tapetum** is applied. Absent in man, it may be due, as in the horse, to a markedly fibrous condition of the stratum intermedium (tapetum fibrosum), or as in the seal, to the presence of five or six layers of flattened iridescent cells (tapetum cellulosum), lying immediately outside the lamina choriocapillaris.

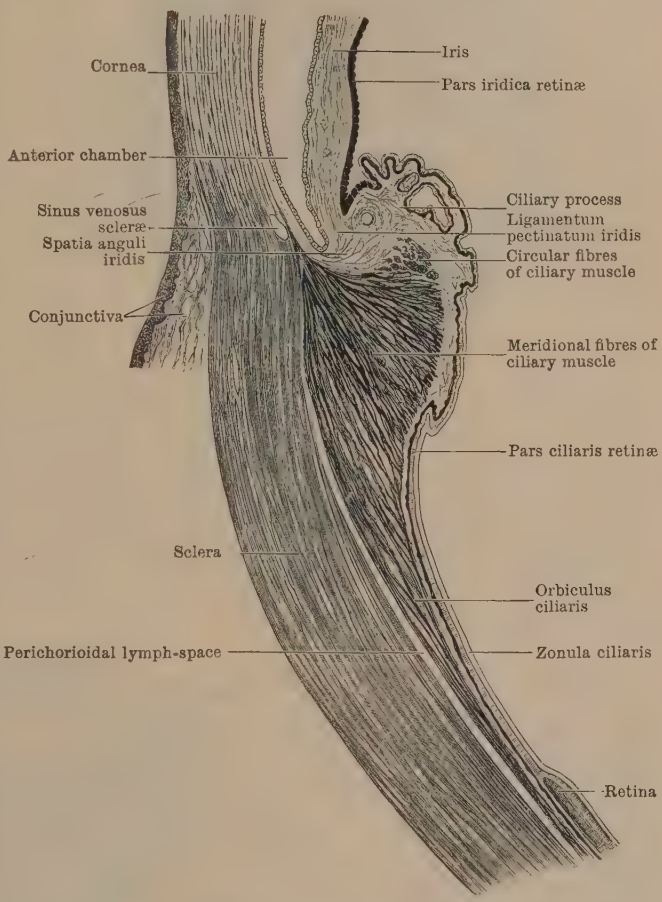

Fig. 651.—Section through Ciliary Region of the Bulb of the Eye.

Corpus Ciliare.—The **ciliary body** connects the chorioid to the circumference of the iris (Fig. 651), and comprises three zones, (*a*) the orbiculus ciliaris, (*b*) the ciliary processes, and (*c*) the ciliary muscle.

The **orbiculus ciliaris** is a zone, about 4 mm. wide, immediately adjoining the chorioid; it exhibits numerous radially arranged ridges.

Processus Ciliares.—The **ciliary processes**, about seventy in number, form a circle of radial thickenings, each of a somewhat triangular shape; the base of the triangle is directed forwards, towards the equator of the lens, while the apex is continuous behind with three or four of the ridges of the orbiculus ciliaris. They vary in size, the largest having a length of 2-5 mm.

Structure.—The structure of the orbiculus ciliaris and ciliary processes is similar to that of the chorioid, but the capillaries are larger and more tortuous, and there is no lamina choriocapillaris. The deep surface of the ciliary processes is covered by two strata of columnar epithelium, the anterior layer of which is pigmented; these two strata are continued forwards from the retina and constitute the **pars ciliaris retinæ**; this epithelium is invaginated to form more or less tubular glands.

M. Ciliaris.—The **ciliary muscle** is triangular on horizontal or vertical section, and consists of two sets of fibres—meridional and circular (Fig. 651). The **meridional fibres** arise from the scleral spur, and radiate backwards, to be attached to the ciliary processes and orbiculus ciliaris; the **circular fibres** form a triangular zone behind the filtration angle, close to the periphery of the iris. When the ciliary muscle contracts the chorioid is drawn forwards and the lens becomes more

convex, owing to the relaxation of its suspensory ligament (p. 813). Considerable individual differences exist as to the degree of development of the two portions of the ciliary muscle; the meridional fibres are always more numerous than the circular fibres, the latter being absent or rudimentary in myopic eyes, but well developed, as a rule, in hypermetropic eyes.

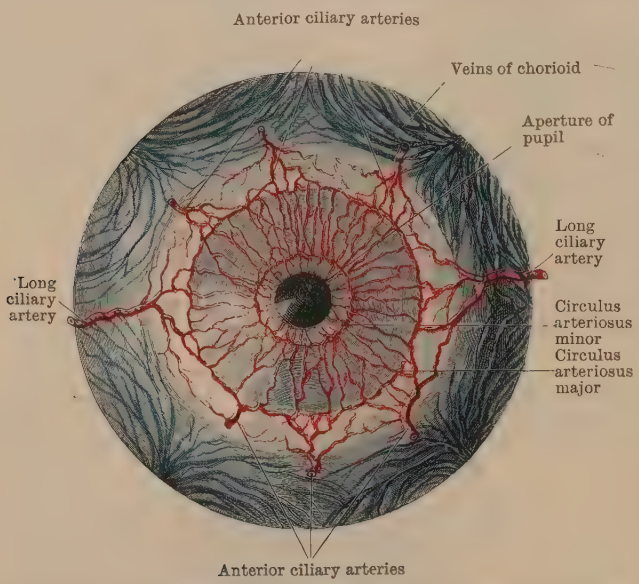

FIG. 652.—BLOOD-VESSELS OF IRIS AND ANTERIOR PART OF CHORIOID, viewed from the front (Arnold).

Iris.—The **iris** forms a contractile diaphragm in front of the lens, and is pierced, a little to the nasal side of its centre, by an almost circular aperture, the **pupil**, which, during life, is continually varying in size in order to regulate the amount of light admitted into the interior of the bulb. It partially divides the space between the cornea and lens into two portions, which are filled by the aqueous humour, and are named, respectively, the **anterior and posterior chambers** of the eye. The iris is thinnest at its peripheral or ciliary margin which is directly continuous with the ciliary body, and, through the medium of the ligamentum pectinatum iridis, with the posterior elastic lamina of the cornea. Its pupillary or free margin forms the circumference of the pupil, and rests upon the anterior surface of the capsule of the lens.

The colour of the eye depends on the arrangement of the pigment in the iris; in the blue eye the pigment is limited to the posterior surface of the iris, but in the brown or black eye it is also scattered throughout its stroma; in the albino the pigment is absent.

The pupil is closed, during the greater part of fœtal life, by a thin, vascular membrane, the **membrana pupillaris**, continuous with the pupillary margin of the iris. Its vessels are derived from the vessels of the iris and the vessels of the capsule of the lens; they converge towards the middle of the membrane, near which they form loops so as to leave the central part non-vascular. About the seventh month the vessels begin to be obliterated, from the centre towards the circumference; and this is followed by a thinning and absorption of the membrane, which becomes perforated by the aperture of the pupil. This perforation gradually en-

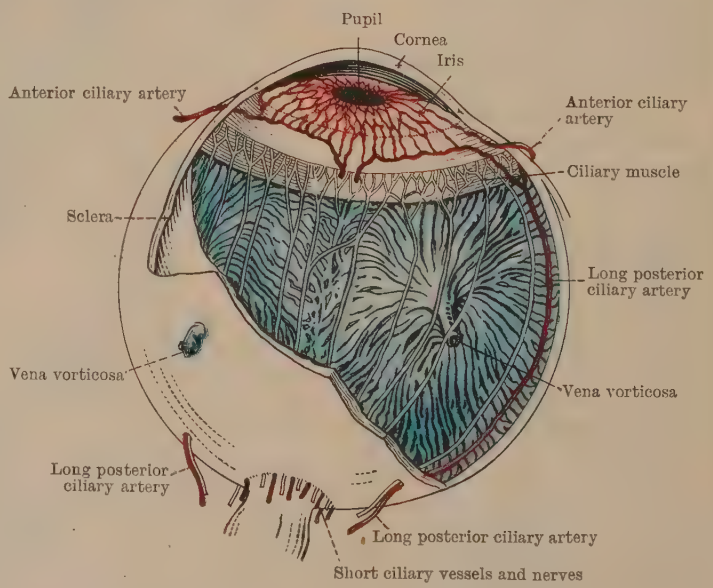

FIG. 653.—DISSECTION OF THE EYEBALL SHOWING THE VASCULAR TUNIC AND THE ARRANGEMENT OF THE CILIARY NERVES AND VESSELS.

larges, and at birth the membrane has entirely disappeared; in exceptional cases it persists.

Structure.—On the anterior surface of the iris is a layer of flattened endothelium, placed on a basement-membrane, and continuous with the endothelium of the anterior chamber. Depressions or crypts are seen here and there in which the endothelium and basement-membrane are absent, and are, by some, regarded as stomata, through which the lymph-vessels of the iris communicate with the cavity of the anterior chamber. The posterior surface of the iris is covered with a basement-membrane, on which are placed two layers of columnar, pigmented epithelium, continuous with the pars ciliaris retinæ, and termed the **pars iridica retinæ**. The **stroma iridis**, or proper tissue of the iris, consists of delicate connective tissue and elastic fibres, with pigmented cells, blood-vessels, nerves and non-striped muscular fibres.

The **non-striped muscular fibres** of the iris are arranged in two sets: (*a*) circular, (*b*) radial. The **circular fibres** form a band, the **m. sphincter pupillæ**, around the pupillary aperture; by the contraction of these fibres the size of the pupil is lessened. The **radial fibres** constitute the **m. dilatator pupillæ** and radiate from the sphincter to the ciliary margin of the pupil. Many anatomists maintain that the radial fibres, in man and most mammals, are elastic, not muscular.

Vascular Supply.—The **arteries of the iris** (Fig. 652) are derived from the long ciliary and the anterior ciliary arteries. The long ciliary arteries, two in number, pierce the sclera on the medial and lateral sides of the optic nerve respectively, and extend forwards, between the sclera and chorioid, towards the ciliary margin of the iris. There each artery divides into a superior and an inferior branch, and the resulting four branches anastomose in the form of a circle, termed the **circulus arteriosus major**. This circle is joined by a varying number of anterior ciliary arteries, derived from the lacrimal and muscular branches of the ophthalmic artery, and, after supplying the ciliary muscle, sends converging branches towards the aperture of the pupil, where a second circle, the **circulus arteriosus minor**, is formed. The **veins** proceed towards the ciliary margin of the iris, and communicate with the veins of the ciliary processes and with the sinus venosus scleræ. The convergence of the blood-vessels towards the aperture of the pupil gives a striated appearance to the anterior surface of the iris.

The **nerves of the chorioid and iris** (Fig. 653) are derived from the long and short ciliary nerves. The former, two or three in number, are branches of the naso-ciliary nerve; the latter, from eight to fourteen in number, are derived from the ciliary ganglion. Piercing the sclera around the entrance of the optic nerve, the ciliary nerves traverse the perichorioidal lymph-space, where they form a plexus, rich in nerve-cells, from which filaments are supplied to the blood-vessels of the chorioid. In front of the ciliary muscle a second plexus, also rich in nerve-cells, is formed; this supplies the ciliary muscle and sends filaments into the iris, as far as its pupillary margin, for the supply of its muscular fibres and blood-vessels. The sphincter pupillæ and the ciliary muscle are supplied by the oculo-motor nerve, the dilatator pupillæ by the sympathetic.

RETINA.

The **retina**, or nervous tunic of the eyeball, is a soft, delicate membrane, in which the fibres of the optic nerve are spread out. It consists of two strata, (*a*) an outer, pigmented layer, attached to the chorioid; and (*b*) an inner nervous lamina, the retina proper, in contact with the hyaloid membrane of the vitreous body, but attached to it only around the entrance of the optic nerve and in the region of the ciliary processes. Expanding from the entrance of the optic nerve, the retina appears to end, a short distance behind the ciliary body, in a wavy border, the **ora serrata** (Fig. 654). There its nervous elements cease and the membrane becomes suddenly thinned, but a delicate continuation of it is prolonged over the posterior surfaces of the ciliary body and iris. This continuation consists of the pigmented layer, together with a layer of columnar epithelium, and constitutes the **pars ciliaris retinæ** and **pars iridica retinæ**, already referred to (p. 809). The portion behind the ora serrata is termed the **pars optica retinæ**, and its thickness gradually diminishes from 0·4 mm. near the entrance of the optic nerve, to 0·1 mm. at the ora serrata. It presents, near the posterior pole of the eye, a small, oval yellowish spot, the **macula lutea**, the greatest diameter of which is transverse. The central part of the macula is depressed and is named the **fovea centralis**. About 3 mm. to the nasal side and slightly below the level of the posterior pole is a whitish, circular disc, the **optic disc**, which corresponds with the entrance of the optic nerve, and has a diameter of about 1·5 mm. The circumference of the optic disc is slightly raised and is named the **papilla nervi optici**, while its depressed central portion is termed the **excavatio papillæ nervi optici** (O.T. **optic cup**). The optic disc consists merely of nerve-fibres; it is insensitive to light, and is named the "blind spot."

The nervous layer of the retina is transparent during life, but becomes opaque

and of a grayish colour soon after death. If an animal be kept in the dark before the removal of its eyeball, the retina presents a purple tinge, due to the presence of a colouring matter named **rhodopsin** or **visual purple**, which is rapidly bleached on exposure to sunlight. This colouring matter is absent from the macula lutea, and absent also over a narrow zone, 3-4 mm. in width, near the ora serrata.

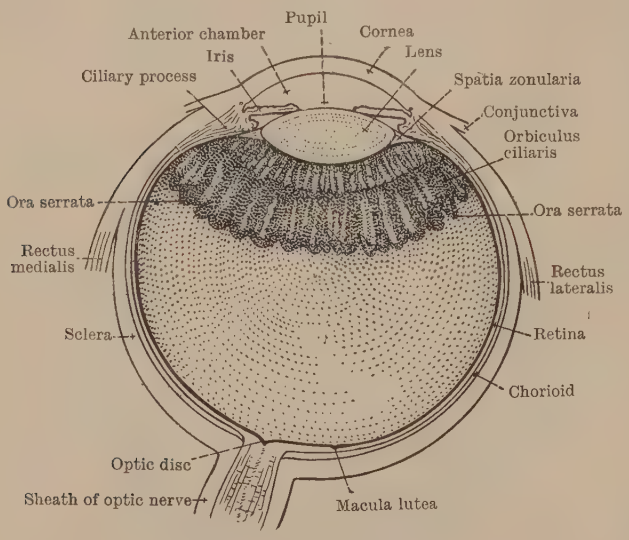

FIG. 654.—A SECTION OF THE BULBUS OCULI SHOWING THE ORA SERRATA (semidiagrammatic).

Structure of the Retina (Figs. 655, 656, 657). —The nervous elements of the retina are supported by non-nervous or **sustentacular fibres**, and are arranged in seven layers; the pigmented layer consists of a single stratum.

The layers from within outwards, *i.e.* from vitreous body to chorioid, are:

1. Stratum opticum or layer of nerve-fibres.
2. Ganglionic or nerve-cell layer.
3. Inner molecular or inner plexiform layer.
4. Inner nuclear layer or layer of inner granules.
5. Outer molecular or outer plexiform layer.
6. Outer nuclear layer or layer of outer granules.
7. Layer of rods and cones.
8. Stratum pigmenti.

1. **Stratum Opticum or Layer of Nerve-fibres.**—Most of the fibres of this stratum are centripetal, and are direct continuations of the axons of the cells in the ganglionic layer; a few are centrifugal and ramify in the inner molecular or inner nuclear layers of the retina.

2. **Ganglionic or Nerve-cell Layer.**—The cells of this stratum vary in size; they are oval or piriform in shape, and form a single layer, except at the macula lutea, where several strata are present. Each cell contains a large nucleus, and gives off, from its inner surface, an axon which is continued as a fibre of the stratum opticum. From the outer surface of each cell numerous dendrites arise, and form arborisations in the inner molecular layer. The cells may be divided into uni-stratified, multi-stratified, and diffuse, according as their dendrites ramify in one or in several strata of the inner molecular layer, or extend throughout nearly its whole thickness.

3. **Inner Molecular or inner Plexiform Layer.**—This is constituted chiefly by the interlacement of the dendrites of the cells of the ganglionic

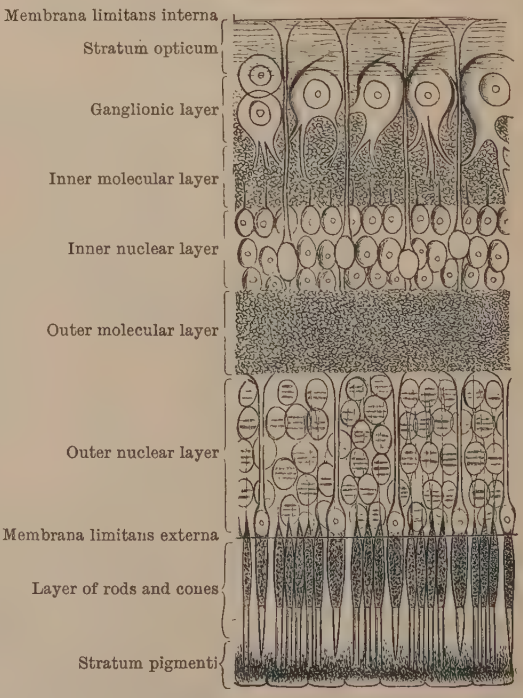

FIG. 655.—DIAGRAMMATIC SECTION OF THE HUMAN RETINA (modified from Schultze).

layer with those of the inner nuclear layer. It sometimes contains horizontal cells, the branched processes of which ramify in it.

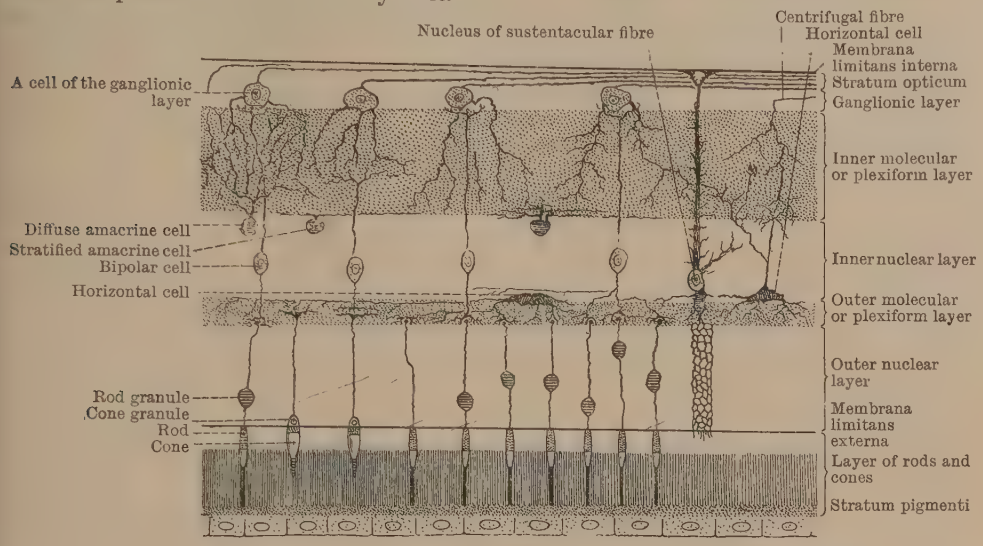

FIG. 656.—A PLAN OF THE RETINAL NEURONS. (After Cajal.)

4. **Inner nuclear Layer or Layer of inner Granules.**—This consists of numerous cells which may be divided into, (*a*) bipolar cells, (*b*) horizontal cells, and (*c*) amacrine cells.

(*a*) The **bipolar cells**, by far the most numerous, are fusiform and nucleated. They are divided into rod bipolars and cone bipolars, and each gives off an external and internal process. The external processes of the **rod bipolars** end in arborisations around the button-like ends or spherules of the rod fibres; their internal processes end in branches which mostly become applied to the cells of the ganglionic layer. The external processes of the **cone bipolars** end in flattened arborisations in the outer molecular layer, in contact with the ramifications of the foot-plates of the cone fibres; their internal processes ramify in one or other of the five strata of the inner molecular layer.

(*b*) The **horizontal cells** are of two varieties: (1) small, flattened, star-like cells, lying immediately internal to the outer molecular layer, and sending a tuft of dendrites outwards, towards the bases of the cone fibres, while their axons are directed horizontally, for a variable distance; (2) large, irregular cells, lying internal to the above and ending in finger-like ramifications in the outer molecular layer. Their axons run horizontally for some distance, and end, in extensive arborisations, under the spherules of the rod fibres.

(*c*) The **amacrine cells** are situated in the innermost part of the inner nuclear layer; their processes ramify in the inner molecular layer, it may be in one stratum (stratified cells) or in several strata (diffuse cells).

5. **Outer Molecular or outer Plexiform Layer.**—This is constituted by the interlacement of the dendrites of the bipolar and horizontal cells, just described, with the spherules of the rod fibres and the ramifications of the foot-plates of the cone fibres. It is divisible into two strata: (*a*) *external*, indicating the contact of the rod bipolars with the spherules of the rod fibres; (*b*) *internal*, the line of contact between the cone bipolars and the branches of the cone fibres.

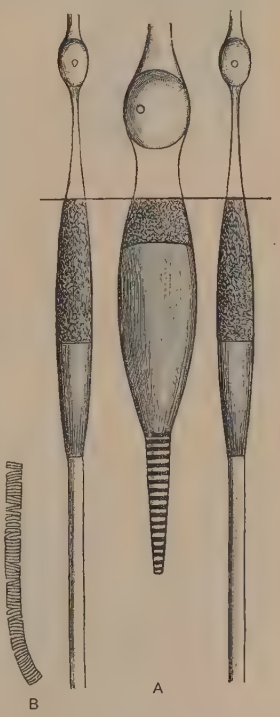

FIG. 657.

A, A cone and two rods from the human retina (modified from Max Schultze); B, Outer part of rod separated into discs.

6. **Outer Nuclear Layer or Layer of outer Granules.**—This is made up of clear granules which somewhat resemble those of the inner nuclear layer, and are divisible into two kinds: (*a*) cone granules, (*b*) rod granules. The **cone granules** are the larger, and each contains an oval nucleus; they lie immediately inside the

outer limiting membrane, through which they are continuous with the cones of the next layer. Each is prolonged internally as a straight fibre; in the outer molecular layer this fibre expands to form a foot-plate, from which several horizontal fibrils are given off. The **rod granules** are far more numerous than the cone granules, and each contains a small oval nucleus, which, in some animals, is transversely striated. Their external processes are continuous, through the outer limiting membrane, with the rods of the next layer, while their internal processes end in the outer molecular layer as free, unbranched spherules amongst the arborisations of the rod bipolars.

7. **Layer of Rods and Cones.**—This consists of two sets of structures, viz., **rods** and **cones**. Except at the macula lutea the rods are far more numerous than the cones, and assume the form of elongated cylinders, while the cones are shorter than the rods, and taper externally to fine points. Each rod and cone consists of two segments—inner and outer. The inner segment of the rod only slightly exceeds the outer in diameter, whereas the inner segment of the cone greatly exceeds the outer in diameter. The inner segments of both rods and cones have an affinity for staining reagents, and each consists of a basal homogeneous portion and an outer longitudinally striated part, the proportion of the latter to the former being greater in the cones than in the rods. The outer segments have not the same affinity for reagents, but tend to break transversely into numerous discs (Fig. 657, B). The colouring matter, *rhodopsin*, already referred to, is found only in the outer segments of the rods, the terminal parts of which extend into the layer of pigmented epithelium.

8. **Stratum Pigmenti.**—This consists of a single stratum of cells which, on surface view, are hexagonal (Fig. 658), their outer flattened surfaces being firmly attached to the chorioid. When seen in profile the outer part of each cell contains a large oval nucleus and is devoid of pigment, while the inner portion is filled with pigment and extends as a series of thread-like processes amongst the outer segments of the rods and cones. When the eye is in the dark the pigment accumulates near the outer part of the cell, but when the eye is exposed to light the pigment streams in between the rods and cones.

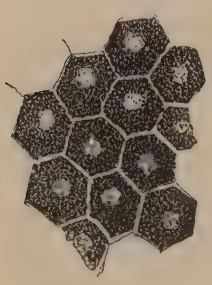

FIG. 658. — STRATUM PIGMENTI OF HUMAN RETINA (viewed from the surface).

Sustentacular Fibres of the Retina.—These form a framework for the support of the nervous structures (Fig. 656). They begin at the inner surface of the nerve-fibre layer in single or forked expanded bases, by the apposition of which a delicate membrane, the **membrana limitans interna**, is formed. In the ganglionic layer they give off a few side branches, and in the inner nuclear layer supply ramifications amongst the inner granules for their support; in this part of each fibre there is an oval nucleus. In the outer nuclear layer they break up into a network of fibrils which surround the rod and cone granules and fibres, and end at the bases of the rods and cones in a delicate membrane, the **membrana limitans externa**.

Structure of the Macula Lutea and Fovea Centralis.—The yellow colour of the macula is due to the presence of pigment in the inner layers of the retina. At the circumference of the macula the nerve-fibre layer is greatly thinned and the rods are few in number; the ganglionic layer, on the other hand, is thickened and may contain from seven to nine strata of cells, while the outer granular layer also is thicker and its granules have an oblique direction. At the fovea centralis the retina is much thinned, since here its nerve-fibre and ganglionic layers are absent and its other strata greatly attenuated. The stratum pigmenti, on the other hand, is thicker and its pigmentation more pronounced. The cone nuclei are situated some distance internal to the outer limiting membrane. There are no rods, and the cones, closely crowded together, are narrower and their outer segments more elongated than elsewhere. The fovea centralis and macula lutea are spoken of by physiologists as the "region of distinct vision."

At the ora serrata the nervous layers of the retina suddenly cease; the layer of rods and cones ends a little behind the margin of the ora serrata; the other nervous strata persist as far as its margin. In front of the ora serrata the retina is prolonged over the ciliary processes in the form of two layers of cells: (*a*) an inner layer of columnar epithelium, and (*b*) an outer, consisting of the stratum pigmenti, the two forming the pars ciliaris retinæ. The same layers are prolonged over the back of the iris, where both are pigmented and form the pars iridica retinæ.

Vessels of the Retina (Fig. 659).—The retina is supplied by the **arteria centralis retinæ**, a branch of the ophthalmic artery; it pierces the sheath of the optic nerve about 2 cm. behind the bulb of the eye, and makes its appearance in the centre of the optic papilla.

There it divides into an upper and a lower branch, and each of these again bifurcates into a medial or nasal, and a lateral or temporal, branch. The resulting four branches ramify towards the periphery of the retina, and are named the superior and inferior temporal and the superior and inferior nasal arteries. The temporal arteries pass laterally above and below the macula lutea, to which they give small branches; these do not, however, extend as far as the fovea centralis, which is devoid of blood-vessels. The macula also receives two small

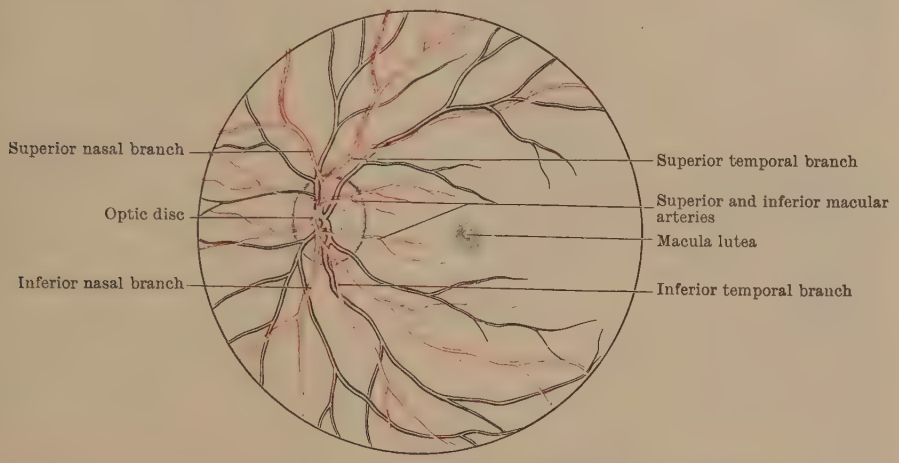

Fig. 659.—Blood-vessels of the Retina.

arteries (superior and inferior macular) directly from the stem of the arteria centralis. The larger vessels run in the nerve-fibre layer near the membrana limitans interna and form two capillary networks, one in the nerve-fibre layer, and another in the inner nuclear layer. The inner network arises directly from the arteries, and sends numerous small branches to form the outer network, from which the veins take origin. The vessels do not penetrate deeper than the inner nuclear layer, nor do the arteries anastomose, except through the capillary plexuses. The **veins** follow the course of the arteries; they have no muscular coats, but consist merely of a layer of endothelial cells, outside which is a perivascular lymph-sheath, surrounded by delicate retiform tissue.

REFRACTING MEDIA.

Corpus Vitreum.—The **vitreous body** is a transparent, jelly-like substance situated between the crystalline lens and the retina, and occupying the posterior four-fifths of the bulb of the eye (Fig. 645). In front it presents a deep concavity, the **hyaloid fossa** (O.T. **fossa patellaris**), for the reception of the posterior convexity of the lens. It is enclosed within a thin transparent membrane, the **membrana hyaloidea**, which is in contact with the membrana limitans interna of the retina, and is adherent to it at the entrance of the optic nerve. The portion of the membrana hyaloidea in front of the ora serrata is thickened and strengthened by radial fibres, and is termed the **zonula ciliaris.** Situated behind the ciliary body, the zonula is radially folded and presents a series of alternating furrows and elevations. The ciliary processes are received into, and are firmly adherent to, the furrows, with the result that, if removed, some of their pigment remains attached to the zonula. The elevations of the zonula are not attached to the interciliary depressions, but are separated by a series of lymph-spaces named the **recessus cameræ posteriores**; these may be regarded as diverticula of the posterior chamber with which they communicate. Near the equator of the lens the zonula ciliaris splits into two chief layers: (*a*) a thin posterior lamina, which lines the hyaloid fossa, and (*b*) a thicker anterior layer, the **suspensory ligament** of the lens

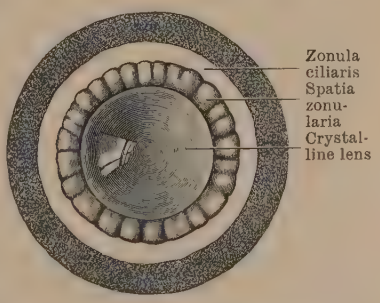

Fig. 660.—The Spatia Zonularia distended and viewed from the Front (enlarged).

(Fig. 654), which blends with the front of the lens capsule a short distance from the equator of the lens. Scattered fibres of this ligament are also attached to the lens capsule at the equator and to the regions immediately anterior and posterior to it. By this suspensory ligament the lens is retained in position, and its convexity varies inversely with the degree of tension of the ligament. The ciliary muscle, by pulling forward the ciliary processes and the attached zonula ciliaris, relaxes the ligament, and thus allows the lens to become more convex. Behind the suspensory ligament, a sacculated lymph-space surrounds the equator of the lens; it is named the **spatia zonularia** (O.T. **canal of Petit**), and may be easily inflated on introducing a fine blow-pipe through the suspensory ligament (Fig. 660). In the fœtus an artery, the **arteria hyaloidea**, runs forwards from the arteria centralis retinæ through the vitreous body, for the supply of the capsule of the lens. Its position, in the adult, is represented by a lymph-channel, termed the **canalis hyaloideus** of Stilling (Fig. 645); the presence of this canal can be demonstrated by shaking up the vitreous body in a solution of picrocarmine, when some of the pigment may be seen to enter the canal (Anderson Stuart [1]).

When the vitreous body is treated by a weak solution of chromic acid it presents a series of concentric, peripherally arranged striæ, together with numerous radial striæ. Between these the more fluid part lies, and it frequently contains vacuolated amœboid cells scattered through it. The vitreous body consists of 98·4 per cent of water, having in solution about 1·4 per cent of sodium chloride and traces of extractives and albumen.

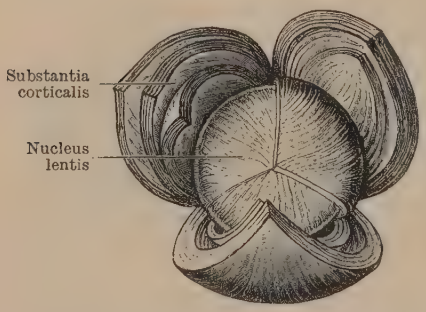

Fig. 661.—Lens hardened in Formalin and dissected to show its Concentric Laminæ (enlarged).

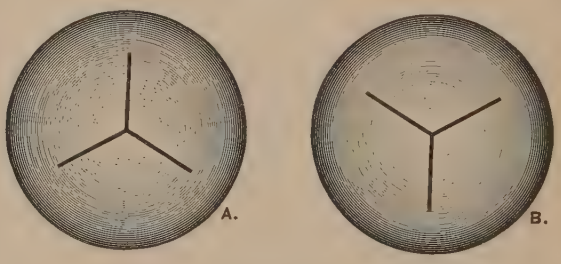

Fig. 662.—Diagrammatic Representation of the Radial Lines of the Fœtal Lens.

A, Seen from the front; B, From behind.

Lens Crystallina.—The **crystalline lens** lies in front of the vitreous body and behind the iris. It is a biconvex, transparent body (Fig. 662), enclosed in a thin, transparent, homogeneous capsule, the *capsule of the lens*. The central points of its anterior and posterior surfaces are termed respectively its **anterior** and **posterior poles**; a line joining the poles is known as its **axis**; its peripheral circumference is named the **equator**. Its axial measurement is 4 mm., and its transverse diameter from 9 to 10 mm. Its anterior surface is less convex than the posterior and is in contact with the pupillary margin of the iris; the central part of this surface corresponds with the aperture of the pupil and is directed towards the anterior chamber; the peripheral part is separated from the iris by the aqueous humour of the posterior chamber. The posterior surface of the lens is more convex than the anterior, and occupies the hyaloid fossa of the vitreous body. The curvatures of the surfaces of the lens, especially that of the anterior surface, are constantly varying, during life, for the purpose of focussing on the retina near or distant objects.

Structure.—The **substantia lentis** consists of a soft outer part, the **substantia corticalis**, easily crushed between the finger and thumb, and of a dense central part, the **nucleus lentis**. The refractive index of the substantia corticalis is about 1·4; that of the nucleus lentis about 1·45. Faint radial lines run from the anterior and posterior poles of the lens towards its equator. In the fœtus they are three in number, and form angles of 120° with each other (Fig. 662). From the anterior pole one ray ascends vertically and the other two diverge downwards, whilst from the posterior pole one ray descends vertically and the other two diverge

[1] T. P. Anderson Stuart, *Journal of Anatomy and Physiology*, vol. xxv.

upwards. In the adult the rays may be increased to six or more. They represent the free edges of a corresponding number of septa which dip into the substance of the lens, and along which the extremities of the different groups of lens fibres come into contact, and are attached by a clear, amorphous substance. The lens, when hardened, exhibits a series of concentrically arranged laminæ (Fig. 661), superimposed like the scales of an onion and attached to each other by a clear, amorphous substance. Each lamina is split along the radiating lines, and consists of a series of hexagonal, riband-like fibres, the **fibræ lentis**, which are adherent to each other by their margins; the fibres of the deeper laminæ are small and serrated, but non-nucleated; while those of the superficial coats are large and nucleated, but non-serrated. The fibres extend in a curved manner from the rays on the anterior surface to the rays on the posterior surface, but no fibre extends from pole to pole. Fibres which start at or near one pole end at or near the equator on the opposite surface, and *vice versa*, while the intervening fibres take up intermediate positions. Between the substantia lentis and the anterior part of the capsule there is a layer of nucleated columnar cells, the **epithelium lentis**. Towards the equator the cells of this epithelium become gradually elongated and transformed into lens fibres, which, when fully formed, lose all trace of their nuclei, except in the more superficial laminæ. Each lens fibre represents, therefore, a greatly elongated columnar cell (Fig. 663).

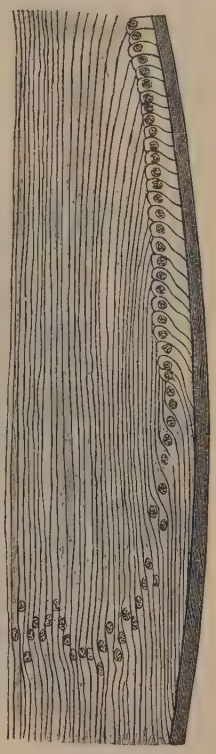

Fig. 663.

Section through the Equator of the Lens.

Showing the gradual transition of the epithelium into lens fibres. (After Babuchin.)

In the fœtus the lens is soft, of a pinkish colour, and nearly spherical; in old age it becomes somewhat flattened, and assumes a yellowish tint.

Cameræ Oculi (Fig. 645).—As already stated (p. 808), the space between the cornea and the lens is divided by the iris into two unequal parts, viz., the camera oculi anterior, and the camera oculi posterior. These are filled with the **aqueous humour**, and, in the adult, communicate freely through the aperture of the pupil; in the fœtus they are separated by the membrana pupillaris. The **camera oculi anterior** or **anterior chamber** is bounded in front by the cornea, behind by the iris and lens, whilst peripherally it communicates with the spatia anguli iridis. The **camera oculi posterior** or **posterior chamber** is triangular on section, and is bounded in front by the iris, behind by the circumferential part of the lens and its suspensory ligament; the base of the triangle corresponds with the broad, anterior extremities of the ciliary processes. It communicates with the recessus cameræ posteriores and spatia zonularia.

The aqueous humour has a refractive index of about 1·336, and consists of about 98 per cent of water, with 1·4 per cent of sodium chloride, and traces of albumen.

SUPERCILIA.

The **supercilia** or **eyebrows** are two arched eminences of thickened skin which surmount the orbits, and are covered by short stout hairs. Deep to the skin are the interlacing fibres of the frontalis, corrugator, and orbicularis oculi muscles, whilst between these and the galea aponeurotica is a layer of fatty and areolar tissue, which is thickest in the lower part of the eyebrow.

PALPEBRÆ.[1]

The **palpebræ** or **eyelids** are two movable curtains situated in front of the bulb of the eye, and named, from their positions, **superior** and **inferior**. The superior is the larger, and the more movable, being provided with an elevator muscle, the *m. levator palpebræ superioris*. The interval between the eyelids is termed the **palpebral fissure** (rima palpebrarum), and measures transversely about 30 mm., but varies considerably in different individuals and in different races. When the eye is open the fissure is elliptical in shape, but when closed it assumes the form of a transverse slit, which lies on a level with the lower margin of the cornea. The two eyelids meet at the extremities of the fissure, and form the **lateral** and

[1] For further details of the structure of the eyelids, lacrimal apparatus, etc., the reader is referred to *The anatomy of the human orbit and accessory organs of vision*, by S. Ernest Whitnall, 1921.

medial commissures. Their free margins are flattened, and their points of meeting are named the medial and lateral *angles* or *canthi*. The free margins are surmounted by eyelashes, from the lateral angle to a point about 6 mm. from the medial angle —a point indicated by a small papilla, the **papilla lacrimalis**. Medial to this papilla the margins are rounded and destitute of eyelashes, and form the upper and lower boundaries of a triangular space, termed the **lacus lacrimalis**, which is occupied by a small pink body, the **caruncula lacrimalis**. The caruncula consists of a small island of modified skin, and contains sebaceous glands, fine hairs and one or more acinotubular glands. Posteriorly the lids are lined with mucous membrane, the conjunctiva, and are in contact with the bulb of the eye, except near the medial commissure, where there intervenes a vertical fold of conjunctiva, the **plica semilunaris conjunctivæ**, which in many animals contains a plate of cartilage.

Structure.—In each eyelid there is a plate of condensed fibrous tissue, which gives consistence and shape to the lid, and is termed the **tarsus**. In front of the tarsus are the fibres of the orbicularis oculi muscle and the skin, while embedded in the posterior surfaces of the tarsi, and covered by the conjunctiva, are numerous modified sebaceous glands, named the **tarsal glands**. The superior tarsus is larger than the inferior, and of a half oval shape, its greatest vertical diameter measuring about 10 or 11 mm. Its upper margin is thin and convex, and is continuous with the deep lamella (the non-striped muscle of Müller) of the aponeurosis of the levator palpebræ superioris muscle, while its lower edge is thick and straight. The inferior tarsus is a narrow plate, with a nearly uniform vertical diameter of about 5 mm.; its lower edge is united to the orbital septum.

FIG. 664.—EYELIDS SLIGHTLY EVERTED TO SHOW THE CONJUNCTIVA (enlarged).

In the commissures of the eyelids the ends of the tarsi unite to form the lateral and medial palpebral ligaments which fix the tarsi to the wall of the orbital cavity. The **lateral tarsal ligament** is thin; it connects the lateral ends of the tarsi to a small tubercle on the orbital surface of the zygomatic bone, and is separated from the lateral palpebral raphe by a narrow cleft which may contain a few lobules of the lacrimal gland. The *lateral palpebral raphe* is formed by the interlacing ends of the palpebral fibres of the orbicularis oculi, strengthened by the underlying orbital septum; "it does not represent the lateral termination of the tarsal plates as is erroneously described" (Whitnall). The **medial palpebral ligament** (O.T. tendo oculi) is a strong fibrous band, continuous with the medial ends of the tarsi. It is fixed to the anterior one-half of the anterior lacrimal crest, and to the adjacent part of the frontal process of the maxilla; it is also adherent to the lacrimal fascia (p. 820) which roofs over the lacrimal fossa. The upper part of the medial palpebral ligament is thin, and blends with the periosteum; the lower part is thick, and ends inferiorly in a free edge. The orbicularis oculi arises from the greater part of the anterior surface of the ligament. Superficial to the ligament are the angular artery and vein: deep to it is the upper one-half of the lacrimal sac. Close to its origin from the tarsal plates, the medial palpebral ligament gives off a posterior thin lamella, which passes behind the lacrimal fossa, clothes the anterior surface of the pars lacrimalis muscle, and is fixed to the posterior lacrimal crest.

The eyelids are further strengthened by a membranous sheet, named the **orbital septum**, which extends into them from the margin of the base of the orbit where it is continuous with the periosteum. In the upper eyelid this septum fuses with the superficial lamella of the aponeurosis of the levator palpebræ superioris; in the lower eyelid it is thin, and blends with the anterior surface of the inferior tarsus. It is perforated by the vessels and nerves which pass from the orbital cavity to the face or scalp.

The skin covering the eyelids is thin, and is continuous, at their free margins, with their conjunctival lining. It contains numerous small sudoriferous glands and fine hairs, the latter being provided with sebaceous follicles. Branched pigment-cells are present in the cutis, and pigment exists also in the deep layers of the epidermis. The subcutaneous tissue is loose and devoid of fat, and in it are found the fibres of the orbicularis oculi muscle—a small separate slip of which, termed the **ciliary bundle** or **muscle of Riolan**, occupies the margin of the lids behind the eyelashes.

The **glandulæ tarsales** (O.T. **Meibomian glands**) are elongated sebaceous glands with numerous lateral offshoots (acini); they are embedded in the tarsi, and are filled with cubical epithelium. There are from twenty-five to thirty in the upper eyelid, and from twenty to twenty-five in the lower; they open by small ducts, about 1 mm. in length, along the lid margins, behind the eyelashes. The ducts are lined with cubical epithelium, placed on a basement-membrane; in

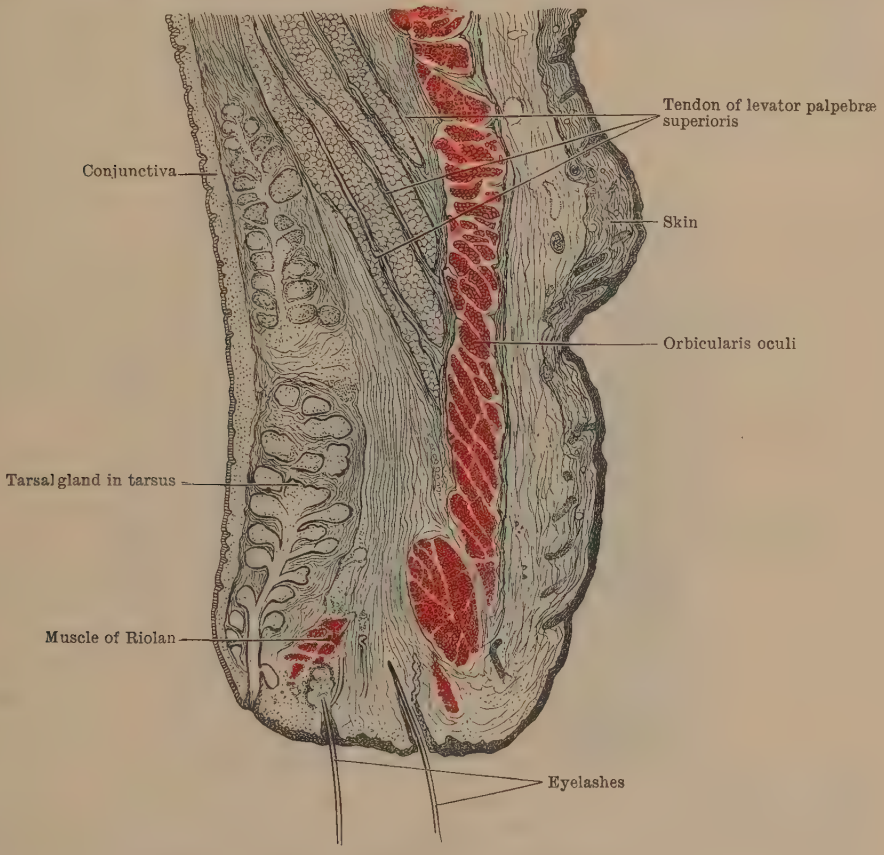

FIG. 665.—SAGITTAL SECTION THROUGH SUPERIOR EYELID.

the mouths of the ducts the epithelium is stratified. Between the eyelashes and the muscle of Riolan are two or three rows of modified sudoriferous glands, termed the **glands of Moll**.

H. Müller described a layer of non-striped muscle in each eyelid: in the superior eyelid it extends from the aponeurosis of the levator palpebræ superioris to the upper tarsus (p. 816); in the inferior eyelid it arises from the sheath of the obliquus inferior and divides into two lamella, one ending in the bulbar conjunctiva, the other in the lower eyelid.

The eyelashes are curved, short hairs which project from the free margins of the eyelids; in the upper eyelid they are curved upwards, and are longer and more numerous than those in the lower eyelid, which are bent downwards.

Conjunctiva.—The **conjunctiva** is the mucous membrane which clothes the deep surfaces of the eyelids, and is reflected, from them, on to the front of the bulb of the eye; the line of reflection is known as the **conjunctival fornix**, which in different regions is referred to as the superior, inferior, lateral or medial fornix. The part on the eyelids is termed the **tunica conjunctiva palpebrarum**, that on the bulb of the eye the **tunica conjunctiva bulbi**. The tunica conjunctiva palpebrarum is highly vascular, and intimately adherent to the tarsi. It is covered with a

layer of columnar epithelial cells, beneath the bases of which are small flattened cells; near the upper and lower fornices a number of acino-tubular glands, much more plentiful in the upper than in the lower eyelid, open on its free surface; these glands are structurally identical with the lacrimal gland. The tunica conjunctiva bulbi is thinner than the tunica conjunctiva palpebrarum. A short distance behind the sclero-corneal junction it blends with the fascia bulbi, which separates it from the sclera. On the cornea the conjunctiva is represented merely by the epithelium corneæ (p. 805). The plica semilunaris conjunctivæ has already been referred to (p. 816).

Vessels and Nerves.—The chief **arteries** of the eyelids are the superior and inferior palpebral branches of the ophthalmic artery; these pierce the orbital septum above and below the medial palpebral ligament, and run lateralwards in the corresponding lid near its free margin; the lower eyelid also receives twigs from the external maxillary artery. At the lateral palpebral commissure they anastomose with each other and with twigs from the lacrimal, superficial temporal, and transverse facial arteries, and in this way a primary arch is formed in either lid. Secondary smaller arches are found, one above the primary arch in the upper lid, and another below that of the lower lid, while the upper lid receives branches also from the supra-orbital and frontal arteries. The **veins** are arranged in two sets: (*a*) subconjunctival or retrotarsal, opening into the muscular tributaries of the ophthalmic veins, and (*b*) pretarsal, opening into the angular and superficial temporal veins. The **lymph-vessels**, like the veins, form pre- and retrotarsal networks, which communicate with each other through the tarsal plates. The lymph is drained chiefly into the anterior auricular and parotid lymph-glands, but partly, by vessels which accompany the anterior facial vein, into the submaxillary lymph-glands. The **sensory nerves** of the eyelids are supplied by the trigeminal nerve—the upper lid chiefly by the supra-orbital and supra-trochlear branches of the ophthalmic nerve; the lower, by the infra-orbital branch of the maxillary nerve. The region of the lateral commissure receives some filaments from the lacrimal nerve, that of the medial from the infra-trochlear nerve. These sensory nerves form a marginal plexus behind the orbicularis oculi muscle. The levator palpebræ superioris muscle is supplied by the oculo-motor nerve and the non-striped fibres of the eyelids by the sympathetic.

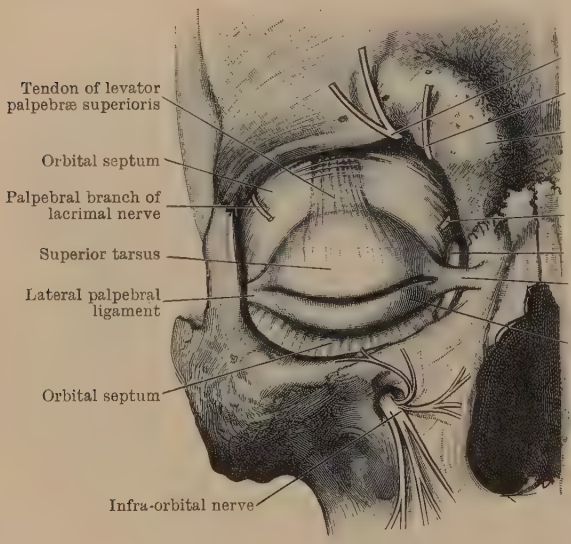

FIG. 666.—DISSECTION OF THE RIGHT EYELID. The orbicularis oculi has been removed.

APPARATUS LACRIMALIS.

The **lacrimal apparatus** consists of: (1) the lacrimal gland, which secretes the tears; and (2) the lacrimal ducts, lacrimal sac and naso-lacrimal duct, through which they are conveyed into the nasal cavity.

Glandula Lacrimalis.—The **lacrimal gland** (Fig. 667) is of about the size and form of an almond; it is situated in the upper and lateral part of the orbital cavity, and consists of two portions—superior and inferior—imperfectly separated from each other by the aponeurosis of the levator palpebræ superioris muscle. The **glandula lacrimalis superior** is firm, and much larger than the inferior; it measures transversely about 20 mm., and sagittally from 12 to 14 mm. It occupies the fossa on the medial surface of the zygomatic process of the frontal bone. The anterior part of its ocular surface lies on the aponeurosis of the levator palpebræ superioris,

but the posterior part, which is continuous with the glandula lacrimalis inferior, lies on the fascial expansion which passes from the sheath of the rectus superior to that of the rectus lateralis, whereby it is separated from the fascia bulbi. The **glandula lacrimalis inferior**, from one-half to one-third the size of the glandula lacrimalis superior, consists of small, loosely aggregated lobules; it lies below and in front of the orbital portion, and projects into the posterior part of the upper eyelid, where its deep surface is in contact with the palpebral conjunctiva. The ducts draining the glandula superior are from three to five in number; they pass between the lobules of the glandula inferior, and open at the upper and lateral part of the fornix conjunctivæ superior. The ducts of the glandula inferior number from three to nine; some of them join those from the glandula superior, while others open separately at the fornix conjunctivæ superior. In close relation with the conjunctival fornices (especially the superior fornix) are numerous small *accessory lacrimal glands*, the secretion from which may serve to moisten the conjunctiva after the extirpation of the two main parts of the gland.

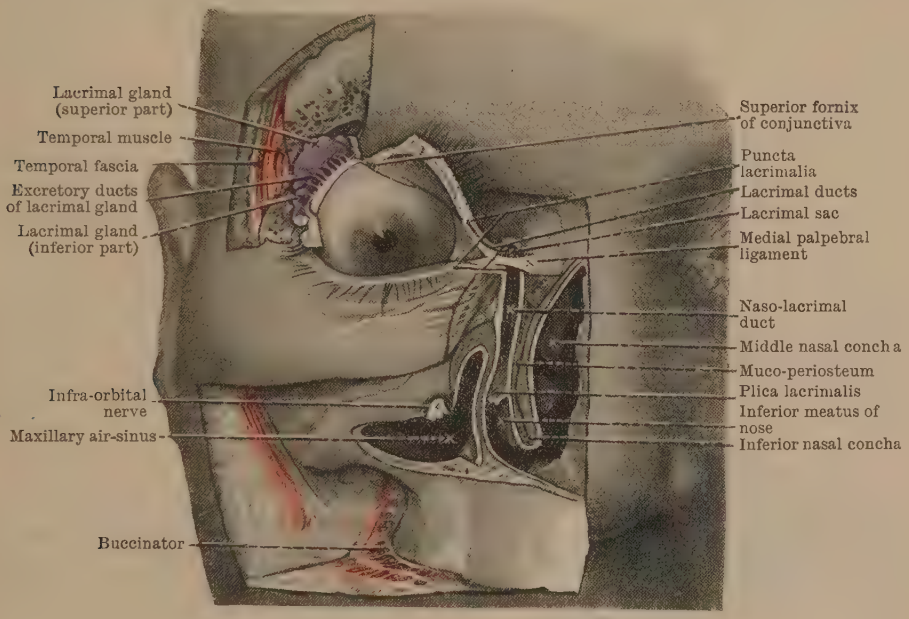

FIG. 667.—DISSECTION TO SHOW THE LACRIMAL APPARATUS.

Structure.—The structure of the lacrimal gland resembles that of the parotid gland; it is supplied by the sympathetic, lacrimal, and facial nerves, and by the lacrimal artery; its veins open into the ophthalmic vein.

Ductus Lacrimales.—The **lacrimal ducts** (Fig. 667), one in either eyelid commence in minute orifices, termed *puncta lacrimalia*, situated at the apices of the papillæ lacrimales (p. 816), and are directed along the medial parts of the margins of the eyelids, above and below the lacus lacrimalis; each duct is about 10 mm. long. The superior duct at first ascends for a short distance and then inclines downwards; the inferior duct descends for a short distance and then runs horizontally; at the angles they are dilated into ampullæ. The two ducts open close together into the lateral and front part of the lacrimal sac, a little above its middle; sometimes they open into a pouch-like dilatation of the sac, termed the *sinus of Maier*. The ducts are lined with stratified epithelium placed on a basement-membrane, outside which is a layer of striped muscular fibres continuous with the lacrimal part of the orbicularis oculi. These muscular fibres are arranged somewhat spirally around the ducts, but at the base of each papilla lacrimalis they are circular in direction and form a species of sphincter. On contraction they probably serve to empty the contents of the lacrimal ducts into the lacrimal sac.

The **saccus lacrimalis** and **ductus nasolacrimalis** together form the passage by which the tears are conveyed from the lacrimal ducts to the nasal cavity.

The **lacrimal sac** (Figs. 666, 667) is the upper part of the passage, and measures about 12 mm. in length; its upper part is flattened from side to side, and may be likened to the end of a quill pen seen sideways. It lies in the lacrimal fossa or groove formed by the lacrimal bone and the frontal process of the maxilla; its upper end is closed; its lower end is continued into the naso-lacrimal duct. At the junction of the sac and duct a fold of mucous membrane, named the *valve of Beraud*, together with a laterally directed pouch, the *sinus of Arlt*, are sometimes present. A fascia, continuous with the orbital periosteum, and named by Whitnall the **lacrimal fascia**, stretches from the anterior to the posterior lacrimal crest, and roofs over the lacrimal fossa; there is usually a minute plexus of veins between this fascia and the lacrimal sac. The medial palpebral ligament lies in front of the upper one-half of the lacrimal sac, and the pars lacrimalis muscle behind it; the lower one-half of the sac is below these two structures. The anterior ethmoidal air-cells lie on the medial or nasal side of the upper part of the lacrimal fossa.

The **naso-lacrimal duct** (Fig. 667) is about 18 mm. long, and has a diameter of from 3 to 4 mm. Rather narrower in the middle than at its extremities, it is directed downwards and slightly backwards, and opens into the inferior meatus of the nose at the junction of its anterior one-fourth with its posterior three-fourths, *i.e.* a distance of about 30 mm. from the posterior boundary of the nostril. Its lower orifice is very variable in form and position; it is frequently guarded by a fold of mucous membrane, termed the **plica lacrimalis (Hasneri)**. The mucous membrane of the duct is thrown into inconstant folds, several of which have been described as valves. Its epithelium is columnar and in part ciliated.

The nerves of the lacrimal ducts and sac are derived from the infra-trochlear branch of the naso-ciliary nerve; the lower part of the naso-lacrimal duct receives a branch from the anterior superior alveolar nerve. The arteries of the lacrimal sac and naso-lacrimal duct are derived from the palpebral branches of the ophthalmic artery, the angular branch of the external maxillary artery, and the infra-orbital branch of the internal maxillary artery. The veins of the naso-lacrimal duct are large, and form a well-marked venous plexus.

Development of the Eye.

The retina and optic nerve are developed from a hollow outgrowth of the fore-brain, termed the **optic vesicle** (pp. 38 and 54). This extends towards the side of the head, and its connexion with the brain is gradually elongated to form the **optic stalk**. The ectoderm overlying the optic vesicle becomes thickened, invaginated, and finally cut off as a hollow island of cells, which is named the **lens vesicle**. This vesicle indents the outer and lower part of the optic vesicle, converting it into a cup (**optic cup**), which is lined by two layers of cells continuous with each other at the margin of the cup. The inner of these layers, thicker than the outer, is named the **retinal layer**, and becomes differentiated into the nervous and supporting elements of the retina; while the outer, named the **pigmentary layer**, forms the stratum pigmenti. The edge of the optic cup extends in front of the equator of the lens, and bounds the future aperture of the pupil. In front of the lens, and also opposite its equator, the retinal layer is thin, and is represented only by a stratum of columnar cells which becomes closely applied to the pigmentary layer, the two forming the pars ciliaris and pars iridica retinæ. The indentation of the optic cup extends as a groove for some distance along the postero-inferior aspect of the optic stalk, forming what is termed the **chorioidal fissure** (Fig. 669). Through this fissure mesoderm passes inwards between the lens and the retina to form a part of the vitreous body, while the arteria centralis retinæ also becomes enclosed in it and so gains its future position in the centre of the optic nerve. The arteria centralis is prolonged forwards from the porus opticus through the vitreous body, as a cone of branches, as far as the back of the lens. By the fifth or sixth month all these branches have disappeared except one, the **arteria hyaloidea**, which persists until the last month of fœtal life, when it also atrophies, leaving only the **canalis hyaloideus** to indicate its position.

The vitreous body is developed between the optic cup and the lens, and is derived partly from ectoderm and partly from mesoderm. It consists primarily of a series of fine protoplasmic fibres which project from the cells of the retinal layer of the cup and form a delicate reticular tissue. At first these fibres are seen in relation to the whole of the optic cup, but later they are limited to the ciliary region, where by a process of condensation they appear to form the zonula ciliaris of the hyaloid membrane. When the mesoderm enters the cup through the chorioidal fissure it unites with this reticular tissue to form the vitreous body.

The lens, at first in contact with the ectoderm from which it is derived, is soon separated from it by mesoderm, and then consists of a rounded vesicle with epithelial walls. The anterior

wall remains as a single layer of cells—the anterior lens epithelium of the adult; the cells of the posterior wall become elongated into lens fibres, and by the forward growth of these the cavity of the vesicle is obliterated. This elongation into lens fibres is greatest at the centre of the lens, while near the equator the fibres are shorter, and here the gradual transition between the anterior epithelium and the lens fibres is seen (Fig. 663). The lens becomes enveloped in a vascular tunic, which receives its vessels from the arteria centralis retinæ and from the vessels of

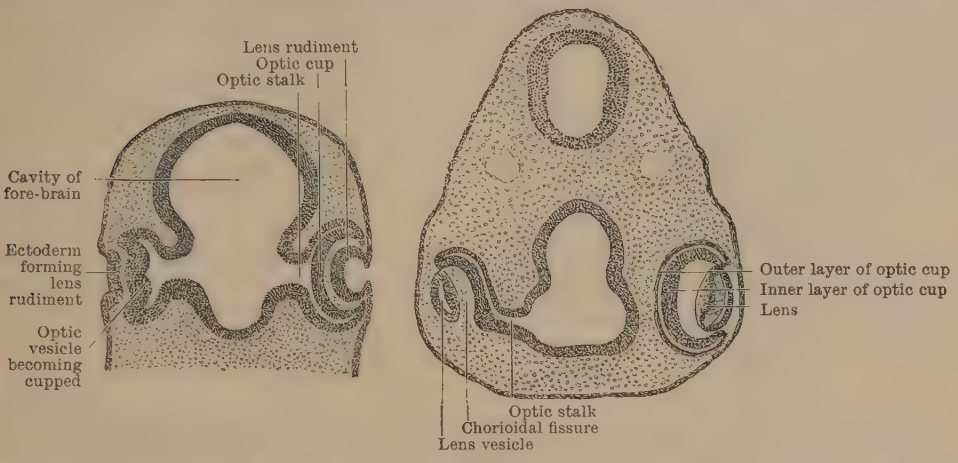

FIG. 668.—SECTIONS THROUGH PORTIONS OF THE HEADS OF FŒTAL RABBITS, to illustrate the connexion of the optic cup with the fore-brain, and the invagination of the ectoderm to form the lens.

the iris. The front part of this tunic forms the membrana pupillaris which disappears before birth (p. 808).

The hollow optic stalk becomes solid by the thickening of its walls, and, acquiring nerve-fibres, is transformed into the optic nerve. These nerve-fibres are mostly centripetal, and are the axons of the ganglionic nerve-cells of the retina; but a few are centrifugal and arise from nerve-cells in the brain. The further development of the retina resembles, in certain respects, that of the spinal medulla.

Cameron states (*Journ. Anat. and Physiol.*, vol. xxxix.) that in the early stages of the development of the inner or retinal layer of the optic cup all the structures, described by His as being present in the spinal medulla of the human embryo, are to be found, viz., (*a*) spongioblasts, (*b*) germinal cells, and (*c*) neuroblasts.

The spongioblasts undergo ramification and form a network or myelospongium, and also give rise to the inner and outer limiting membranes; the latter is next the original cavity of the optic vesicle, and therefore corresponds to the inner limiting membrane of the spinal medulla. The spongioblasts also form the groundwork of the inner and outer molecular or plexiform layers into which the processes of the neuroblasts grow and arborise.

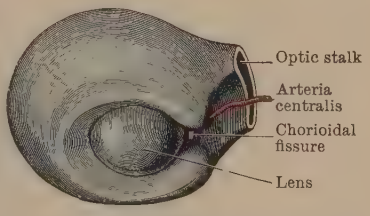

FIG. 669.—OPTIC CUP AND LENS VIEWED FROM BEHIND AND BELOW, to show formation of chorioidal fissure and enclosure of the arteria centralis retinæ (from model by Ziegler).

The germinal cells are always situated beneath the external limiting membrane, and by their division give rise to the neuroblasts. The first-formed neuroblasts are larger than those of succeeding generations, and are found in the site of the future ganglionic layer. The germinal cells in the middle of the convexity of the retinal cup cease to divide at an early stage of development, and become directly transformed into the rod and cone cells from which the rods and cones develop as processes; hence these structures appear first over the middle of the convexity of the retina.

The molecular layers make their appearance as plexuses of myelospongium. The internal molecular layer is first developed at the centre of the retinal cup. The rod and cone fibres, and the outer processes of the bipolar cells of the internal nuclear layer, grow into and arborise within the external molecular layer.

The condensed mesoderm surrounding the optic cup becomes the sclera and chorioid. In the portion of the mesoderm which lies in front of the lens a cleft appears, and divides it into a thick anterior and a thin posterior layer. The former becomes the substantia propria of the cornea; the latter, the stroma of the iris and anterior part of the vascular tunic of the lens. The fissure represents the future camera oculi anterior, and its lining cells form the endothelium of this chamber.

The **eyelids** arise as two integumentary folds above and below the cornea, each being covered on both its surfaces by the ectoderm. By the third month the edges of the folds meet and unite, the eyelids being only permanently opened shortly before birth; in many animals they are not

opened until after birth. The ectoderm forms the epithelium of the conjunctiva and the epithelium corneæ. It is also invaginated at the margins of the eyelids to form the hair-follicles and the lining cells of the tarsal glands and glands of Moll, and, at the fornix conjunctivæ superior, to form the lining cells of the alveoli and ducts of the lacrimal gland.

The **lacrimal sac** and **naso-lacrimal duct** are developed along the line of the furrow which separates the maxillary from the lateral nasal process. This furrow is lined by ectodermal cells, and these cells, after the meeting and fusion of the lips of the furrow, proliferate and form a solid rod which is embedded in the mesoderm. By the breaking down and disintegration of its central cells, this rod becomes hollowed out to form the lacrimal sac and the naso-lacrimal duct, the lower end of the latter remaining closed until near the end of fœtal life. The **lacrimal ducts** are developed as secondary buds of cells which extend lateralwards from the upper end of the solid rod, and which subsequently undergo canalisation. The **caruncula lacrimalis** is formed from a small part of the margin of the lower eyelid, which is cut off by the growth of the inferior lacrimal duct.

ORGANON AUDITUS.

The **ear** or **auditory organ** (Fig. 670) consists of three portions—external, middle, and internal; the peripheral terminations of the acoustic nerve are distributed within the internal portion.

EXTERNAL EAR.

The **external ear**[1] includes—(*a*) the auricula, attached to and projecting from the side of the head; and (*b*) the external acoustic meatus leading inwards from the most depressed part of the auricula to the tympanic membrane.

Auricula.

The **auricula** (O.T. **pinna**) (Fig. 671) forms an angle (cephalo-auricular angle) of about 30° with the side of the head. Its lateral surface is irregularly concave, but has several well-marked elevations and depressions. The deepest of the depressions, the **concha auriculæ**, is situated near the middle of the auricula; it is divided by a ridge, the **crus helicis**, into an upper, smaller portion, termed the **cymba conchæ**; and a lower, larger portion, the **cavum conchæ**; the latter leads into the external acoustic meatus. Anteriorly, the crus helicis is continuous with the **helix** or margin of the auricula, which is incurved in the greater part of its extent, and is directed at first upwards, and then backwards and downwards, to become gradually lost in the upper part of the lobule. Near the point where the helix begins to descend a small tubercle, the **tuberculum auriculæ (Darwini)**, is often seen. In front of the descending part of the helix is a second elevation, the **antihelix**, which divides superiorly into two limbs, termed the **crura**

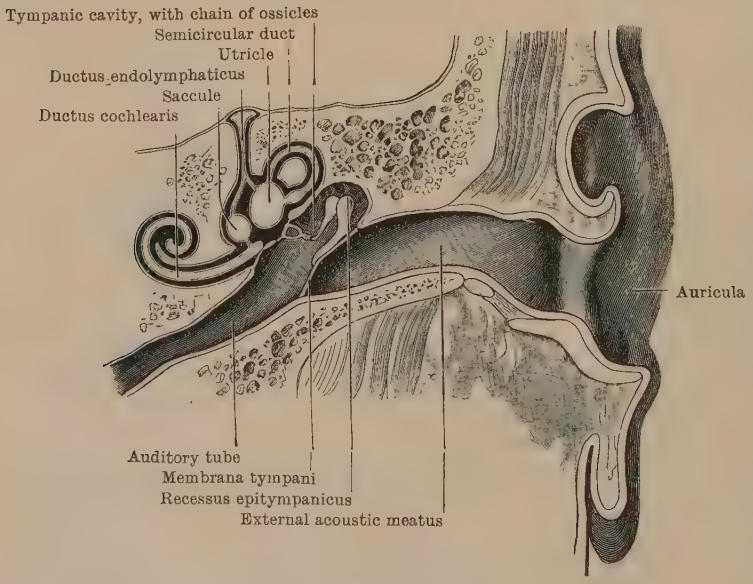

Fig. 670.—Diagrammatic View of the Organ of Hearing.

[1] Although it is usual to speak of the external, the middle, and the internal ear, it would be more correct to use the terms external, middle, and internal *portions* of the ear.

antihelicis; between the crura is a triangular depression, the **fossa triangularis**. The elongated furrow between the helix and antihelix is named the **scapha**. The concavity of the concha is overlapped in front by a tongue-like process, the **tragus**, and below and behind by a triangular projection, the **antitragus**; the notch, directed downwards and forwards between these two processes, is named the **incisura intertragica**. The tragus consists really of two tubercles, the upper of which constitutes the **tuberculum supratragicum** of His, and is separated from the helix by a groove, the **sulcus auris anterior**. The **lobule** is situated below the incisura intertragica, and is the most dependent part of the auricle.

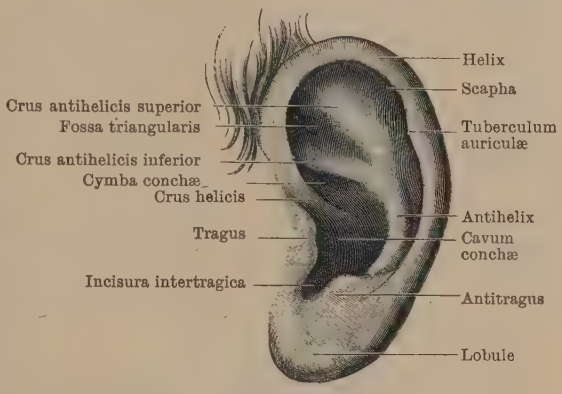

FIG. 671.—VIEW OF LATERAL SURFACE OF LEFT AURICULA (one-half natural size).

The medial or cranial surface of the auricula is also irregular, and presents elevations corresponding to the depressions on its lateral surface, *e.g.* **eminentia scaphæ, eminentia conchæ, eminentia triangularis**, etc.

The auricula, usually smaller and more finely modelled in the female than in the male, presents great variations in size and shape in different individuals. In the new-born child its length is about one-third of that of the adult; in old age it increases slightly in length and breadth.

The **cephalo-auricular angle** may be absent, as in those cases where the skin of the head passes directly on to the lateral surface of the auricula, or it may be increased to nearly a right angle, so that the lateral surface of the auricula looks directly forwards. The **tuberculum auriculæ**, the significance of which was recognised by Darwin, is a somewhat triangular prominence which projects forwards when the helix is well rolled over, but backwards and upwards when the incurving of the helix has been arrested. More frequently present in men than in women, it is of developmental interest since it is well marked at the sixth month of fœtal life, when the entire auricula resembles that of the adult macaque monkey. The **lobule** may be small and sessile or considerably elongated; it may adhere to the skin of the cheek, or its lower end may be divided.

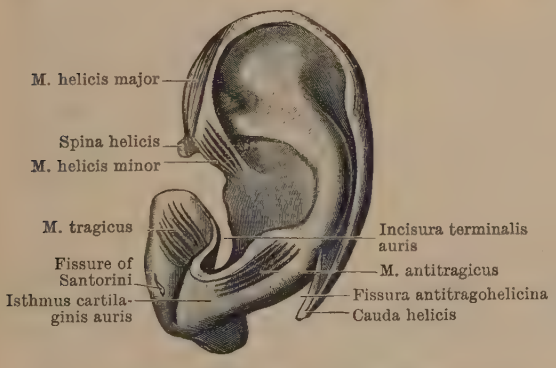

FIG. 672.—LATERAL SURFACE OF CARTILAGE OF THE AURICULA (one-half natural size).

Structure of the Auricula.—The skin covering the auricle is thin and smooth, and is prolonged, in the form of a tube, as a lining to the external acoustic meatus. On the lateral surface of the auricula, it adheres firmly to the subjacent perichondrium. Strong hairs are present on the tragus and antitragus, and also in the incisura intertragica, forming the **barbula hirci**, which guard the entrance to the concha; soft downy hairs are found over the greater part of the auricula and point towards the tuberculum auriculæ. Sebaceous glands, present on both surfaces of the auricle, are most numerous in the concha and fossa triangularis. Sudoriferous glands are found on the medial surface; few or none on the lateral surface.

The greater part of the auricula consists of a lamella of yellow fibro-cartilage, the **cartilago auriculæ**; the cartilage is, however, absent from the lobule, which is composed of fat and connective tissue. When laid bare, the cartilage (Figs. 672, 673) presents, in an exaggerated condition, all the inequalities of the auricula, and is prolonged medially to form the cartilaginous part of the external acoustic meatus. The cartilage of the helix projects anteriorly as a conical eminence, the **spina helicis**, and ends behind in a tail-like process, the **cauda helicis**, which is separated from the lower part of the antitragus by the **fissura antitragohelicina**. The cartilage of the auricula is continuous with that of the external acoustic meatus by a narrow isthmus, the **isthmus cartilaginis auris**, measuring from 8 to 9 mm. in breadth. The isthmus corresponds laterally with the deepest part of the incisura intertragica, and medially it forms the outer boundary of a deep fissure, the **incisura terminalis auris**, which separates the cartilage of the meatus from that of the concha. The upper edge of the tragus fits into an angle below the

crus helicis. Two additional fissures are usually present, one in the tragus and another behind the spina helicis.

On the cranial surface of the cartilage (Fig. 673) the eminences produced by the concha and fossa triangularis are separated by the **sulcus antihelicis transversus**, corresponding with the crus antihelicis inferior. The eminentia conchæ is crossed horizontally by a groove, the **sulcus cruris helicis**, and almost vertically by a slight ridge, the **ponticulus**; to the latter the m. auricularis posterior is attached.

Ligaments of the Auricula.—The cartilage of the auricula is fixed to the temporal bone by two extrinsic ligaments, an *anterior*, stretching from the spina helicis and tragus to the zygomatic process, and a *posterior*, from the eminentia conchæ to the mastoid portion. Small intrinsic ligaments pass between individual parts of the auricula.

Muscles of the Auricula.—The muscles of the auricula are divisible into two groups, *extrinsic* and *intrinsic*. The extrinsic muscles connect the auricula to the skull and scalp, and are described in the section on Myology. The intrinsic muscles are confined to the auricula and are six in number, four on its lateral and two on its cranial or medial surface.

(*a*) *On the lateral surface* (Fig. 672)—

1. **M. helicis major** passes upwards from the spina helicis along the ascending part of the helix. 2. **M. helicis minor** covers the crus helicis. 3. **M. tragicus**, quadrangular in shape, consists of fibres running vertically over the greater part of the tragus. Some of its fibres are prolonged upwards to the spina helicis and constitute the **m. pyramidalis**. 4. **M. antitragicus** covers the antitragus and runs obliquely upwards and backwards to the antihelix and cauda helicis.

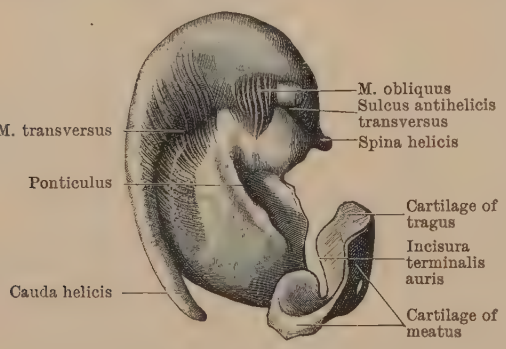

Fig. 673.—Medial Surface of the Cartilage of the Auricula (one-half natural size).

(*b*) *On the medial surface* (Fig. 673)—

1. **M. transversus auriculæ** consists of scattered fibres, which stretch from the eminentia conchæ to the eminentia scaphæ. 2. **M. obliquus auriculæ** (Tod) comprises a few fasciculi, which run obliquely or vertically across the sulcus antihelicis transversus.

A small stylo-auricularis muscle sometimes extends from the root of the styloid process to the cartilage of the meatus.

Vessels of the Auricula.—The **arteries** of the auricula are derived—(*a*) from the superficial temporal artery, which sends two or three branches to the lateral surface; and (*b*) from the posterior auricular artery, which gives three or four branches to the medial surface. From the branches of the posterior auricular artery two sets of twigs pass to the lateral surface, one turning round the free margin of the helix, and the other passing through small fissures in the cartilage. The **veins** from the lateral surface open into the superficial temporal vein; those from the medial surface chiefly join the posterior auricular vein, but some communicate with the mastoid emissary vein. The **lymph-vessels** take three directions, viz.: (*a*) forwards to the parotid lymph-glands, and especially to the anterior auricular lymph-gland in front of the tragus; (*b*) downwards to the lymph-glands which accompany the external jugular vein, and to the lymph-glands under the sterno-cleidomastoideus; and (*c*) backwards to the posterior auricular lymph-glands.

Nerves of the Auricula.—The muscles of the auricula are supplied by the facial nerve. The skin receives its sensory nerves from—(*a*) the great auricular nerve, which supplies nearly the whole of the medial surface, and sends filaments in company with the branches of the posterior auricular artery to the lateral surface; (*b*) the auriculo-temporal nerve, which supplies the tragus and ascending part of the helix; (*c*) the lesser occipital nerve, which sends a branch to the upper part of the medial surface.

Meatus Acusticus Externus.

The **external acoustic meatus** (Figs. 670, 674) is the passage leading from the concha to the membrana tympani. Its length, measured from the bottom of the concha, is about 24 mm.; from the level of the tragus it is about 35 mm. On account of the obliquity of the membrana tympani the anterior and inferior walls of the meatus are longer than the posterior and superior. The meatus consists of an external portion, the **pars cartilaginea**, about 8 mm. in length; and an internal portion, the **pars ossea**, about 16 mm. in length. The entire meatus forms a somewhat S-shaped bend (Fig. 675), and may be divided into three portions—external, intermediate, and internal; each is directed medialwards, but, in addition, the external part is inclined forwards and slightly upwards; the intermediate, backwards; and the internal, the longest, forwards and slightly downwards. On transverse section the canal is seen to be elliptical, its greatest

diameter having an inclination downwards and backwards. Widest at its lateral end, it becomes somewhat narrower at the medial end of the pars cartilaginea; once more expanding in the lateral portion of the pars ossea, it is again constricted near the medial end of the latter, where its narrowest part, or **isthmus**, is found at a distance of about 19 mm. from the bottom of the concha. The medial end of the meatus is nearly circular and is closed by the membrana tympani.

Bezold gives the diameters of the meatus as follows:—

	Greatest.	Least.
At the commencement of the pars cartilaginea . .	9·08 mm.	6·54 mm.
At the end „ „ „	7·79 mm.	5·99 mm.
At the commencement of the pars ossea . . .	8·67 mm.	6·07 mm.
At the end „ „ „ . . .	8·13 mm.	4·60 mm.

The lumen of the pars cartilaginea is influenced by the movements of the mandible, being increased when that bone is depressed. This can be verified by inserting a finger into the meatus, and then alternately opening and shutting the mouth.

The condyle of the mandible lies in front of the pars ossea; between the condyle and the pars cartilaginea a portion of the parotid gland is sometimes present. Behind the pars ossea, and separated from it by a thin plate of bone, are the mastoid air-cells.

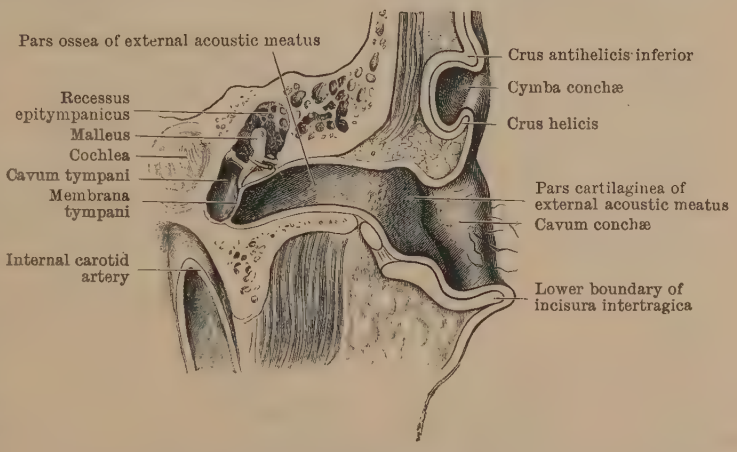

FIG. 674.—FRONTAL SECTION OF RIGHT EAR; ANTERIOR HALF OF SECTION, viewed from behind (natural size).

Structure of the Meatus.—The cartilage of the meatus, directly continuous with that of the auricula, is folded on itself to form a groove, opening upwards and backwards, the margins of which are connected by fibrous tissue. The medial end of the cartilaginous part of the meatus is firmly fixed to the lateral margin of the bony meatus; its lateral end is continuous with the cartilage of the tragus (p. 672). Two fissures exist in the anterior portion of the pars cartilaginea, and are filled by fibrous tissue. In the lateral part of the meatus the cartilage forms about three-fourths of the circumference of the tube; but near the medial end of the pars cartilaginea it forms only a part of the anterior and lower boundaries.

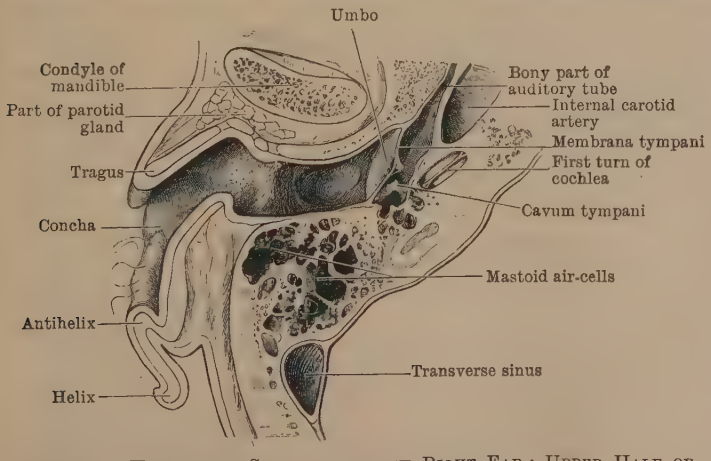

FIG. 675.—HORIZONTAL SECTION THROUGH RIGHT EAR; UPPER HALF OF SECTION, viewed from below (natural size).

The pars ossea of the external acoustic meatus is described on p. 198. In the new-born child it is represented by an incomplete ring of bone, the **annulus tympanicus**, together with a small portion of the squama temporalis, which articulates with, and bridges the interval between, the ends of the annulus superiorly. In the concavity of the annulus is a groove, the **sulcus tympanicus**,

in which the circumference of the membrana tympani is fixed. On the medial surface of the anterior part of the annulus, a little below its free end, a groove, the **sulcus malleolaris**, is directed downwards and forwards. It transmits the anterior process and the anterior ligament of the malleus, the tympanic artery, and the chorda tympani nerve. It is limited above by a ridge, the **crista spinarum** (Henle), which ends in front and behind in a spinous process (**spina tympanica anterior** et **posterior**). Below the sulcus malleolaris there is a second, less prominent ridge, the **crista tympanica** (Gruber), which subsequently unites with a process of the tegmen tympani, and so shuts off the canalis musculotubarius from the petrotympanic fissure. A **fibrous tympanic plate** (Symington) intervenes between the annulus tympanicus and the cartilage of the meatus, and into this plate the bony ring extends. The bony outgrowth does not, however, proceed uniformly from the whole of circumference of the annulus, but occurs most rapidly from its anterior and posterior parts. These outgrowths fuse about the end of the second year of life, so as to surround a foramen (**foramen of Huschke**) in the floor of the meatus; this foramen is usually closed by the fifth year, but persists until adult life in about 19 per cent. of skulls (Bürkner).

The lumen of the meatus in the new-born child is extremely small: its outer part is funnel-shaped; its inner is a mere slit, bounded below by the fibrous tympanic plate and above by the obliquely placed membrana tympani.

The external acoustic meatus is lined by skin, and the latter also covers the outer surface of the membrana tympani. The skin is thick in the pars cartilaginea, and contains fine hairs and sebaceous glands, the latter extending for some distance along the postero-superior wall of the pars ossea. In the subcutaneous tissue of the pars cartilaginea are numerous enlarged sudoriferous glands; they constitute the **glandulæ ceruminosæ** and secrete the ear wax or cerumen.

Vascular and Nervous Supply of the External Acoustic Meatus.—The external acoustic meatus receives its blood-supply from the posterior auricular and superficial temporal arteries, and from the deep auricular branch of the internal maxillary artery, the last distributing some minute twigs to the membrana tympani. The **veins** open into the external jugular and internal maxillary veins, and into the pterygoid venous plexus, while the **lymph-vessels** have a similar mode of termination to those of the auricula. **Sensory nerves** are supplied to the meatus by the auriculo-temporal branch of the trigeminal nerve and by the auricular branch of the vagus nerve.

CAVUM TYMPANI OR MIDDLE EAR.

The **tympanic cavity** is a small air-chamber in the temporal bone, between the membrana tympani and the lateral wall of the internal ear or labyrinth (Figs. 674, 676). It is lined with mucous membrane, and contains a chain of ossicles,—malleus, incus, and stapes,—which reaches from its lateral to its medial wall, and transmits the vibrations of the membrana tympani across the cavity to the internal ear. Attached to the ossicles are several ligaments and two small muscles.

The tympanic cavity consists of (*a*) the **tympanum proper**, or **atrium**, lying medial to the membrana tympani; and (*b*) the **recessus epitympanicus**, or **attic**, lying above the level of the membrana tympani and containing the greater part of the incus and the upper half of the malleus. Including the attic, the vertical and antero-posterior diameters of the cavity are each about 15 mm. The distance between its lateral and medial walls is about 6 mm. above and 4 mm. below, while at its central part, owing to the bulging of the two walls towards the cavity, it is only from 1·5 to 2 mm.

The tympanic cavity communicates, behind, with the tympanic antrum, and through this with the mastoid air-cells; in front, with the nasal part of the pharynx, through the auditory (Eustachian) tube. It is enclosed by six walls, tegmental, jugular, labyrinthic, mastoid, carotid, and membranous.

Paries Tegmentalis.—The **tegmental wall** or **roof** of the tympanic cavity (Fig. 676) is formed by a thin plate of bone, the **tegmen tympani**, constituting a portion of the anterior surface of the petrous part of the temporal bone. It extends backwards so as to cover the tympanic antrum, and forwards, to form a roof for the semicanal for the tensor tympani muscle. It separates the tympanic cavity and antrum from the middle fossa of the cranial cavity, and may contain a few air-cells, whilst occasionally it is partly deficient. In the child its lateral edge corresponds with the petro-squamous suture, traces of which can generally be seen in the adult bone.

Paries Jugularis.—The **jugular wall** or **floor** of the tympanic cavity is narrower than the tegmental wall, and consists of a thin plate of bone which separates the tympanic cavity from the fossa jugularis; anteriorly, it ascends and is continuous with the posterior wall of the carotid canal. The inner orifice of the canal which

transmits the tympanic nerve is placed near the junction of the jugular and labyrinthic walls.

Paries Labyrinthica.—The **labyrinthic** or **medial wall** of the tympanic cavity is formed by the lateral wall of the internal ear (Fig. 676). It presents—(1) a rounded eminence, the **promontory**, caused by the outward projection of the first

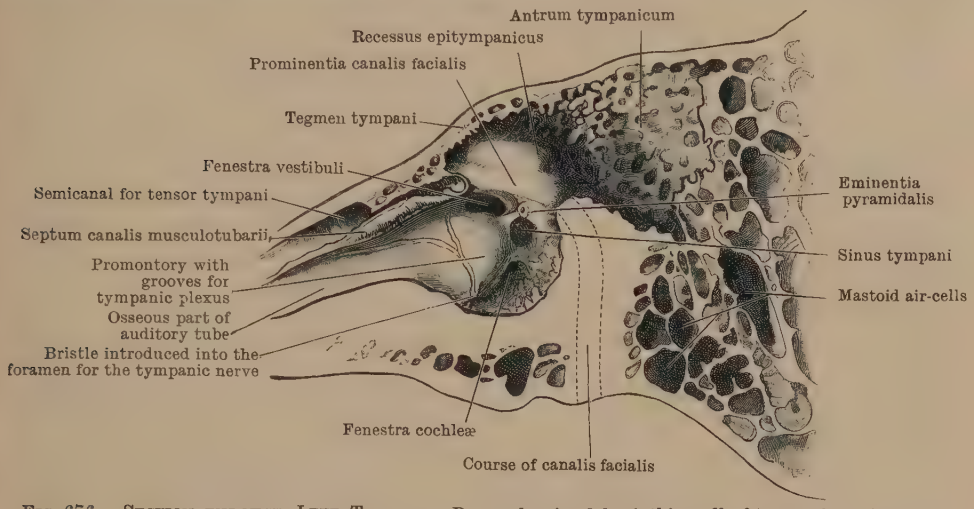

Fig. 676.—Section through Left Temporal Bone, showing labyrinthic wall of tympanic cavity, etc.

coil of the cochlea; its surface is marked by small grooves which lodge the tympanic plexus of nerves. (2) An oval or somewhat reniform opening, the **fenestra vestibuli**, which is situated above and behind the promontory, with its long axis directed antero-posteriorly; this fenestra is 3 mm. long and 1·5 mm. broad and, in the macerated bone, leads into the vestibule of the osseous labyrinth, but, in the recent state, is closed by the base or foot-plate of the stapes, surrounded by its **ligamentum annulare**. (3) An elevation, the **prominentia canalis facialis**, which is situated above the fenestra vestibuli, in the recessus epitympanicus; this elevation indicates the position of the upper part of the **canalis facialis** (O.T. **aqueduct of Fallopius**), which contains the facial nerve. (4) The **septum canalis musculotubarii** (O.T. **processus cochleariformis**), which extends backwards, above the anterior end of the fenestra vestibuli, where it makes a sharp lateral curve, and forms a pulley over which the tendon of the tensor tympani muscle plays. (5) A funnel-shaped recess, situated behind and below the promontory, and almost hidden by its overhanging edge, leads to an irregularly oval opening, termed the **fenestra cochleæ**; in the macerated bone this fenestra opens into the cochlea, but in the recent state is closed by the **membrana tympani secundaria**; this membrane is bent angularly along

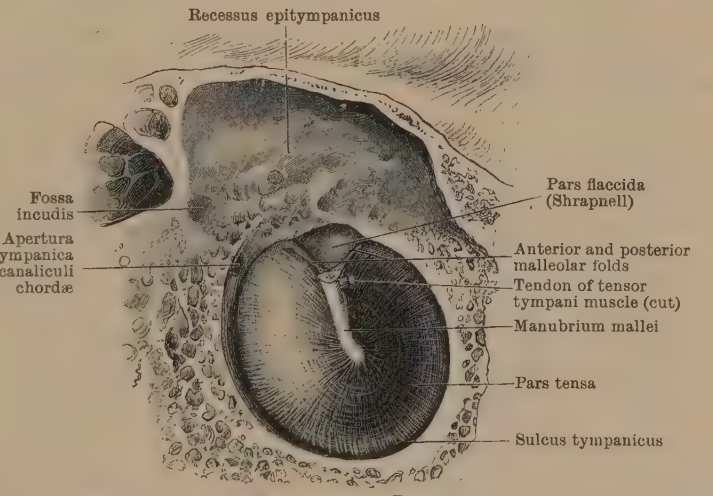

Fig. 677.—Left Membrana Tympani and Recessus Epitympanicus, viewed from within. The head and neck of the malleus have been removed to show the pars flaccida and the malleolar folds. ×3.

a line joining its antero-inferior two-thirds with the postero-superior one-third; and consists of three layers: (*a*) a *lateral* layer, continuous with the mucous lining of the tympanum, and containing a network of capillaries; (*b*) an *intermediate* fibrous layer (membrana propria); (*c*) a *medial* layer, continuous with the epithelial lining of the labyrinth. (6) Between the fenestra vestibuli and the fenestra cochleæ, and below the pyramid, is a small depression, the **sinus tympani**, which indicates the position of the ampullated end of the posterior semicircular canal, and is perforated by one or two minute foramina for blood-vessels.

Paries Mastoidea.—The **mastoid** or **posterior wall** of the tympanic cavity presents, from above downwards: (1) a round or triangular opening, which leads from the recessus epitympanicus into the **tympanic antrum** (Fig. 676); (2) a depression, the **fossa incudis**, situated in the postero-inferior part of the recessus epitympanicus (Fig. 677), for the reception of the end of the short crus of the incus; (3) a minute conical bony projection, the **eminentia pyramidalis** (Fig. 676), the summit of which is perforated by a round aperture for the passage of the tendon of the stapedius muscle. From this aperture a minute canal is continued downwards and backwards in front of the facial canal, and frequently opens, by a minute orifice, on the base of the skull in front of the stylo-mastoid foramen; it communicates with the facial canal by one or two small foramina, which transmit the vessels and the nerve to the stapedius muscle; a minute spicule of bone often unites the eminentia pyramidalis to the upper part of the promontory; (4) a small aperture, the **apertura tympanica canaliculi chordæ** (Fig. 677), which is situated close to the posterior edge of the membrana tympani, nearly on a level with the upper end of the manubrium mallei; (5) a rounded eminence, the **prominentia styloidea**, is sometimes seen below the last, and is caused by the upward and forward prolongation of the styloid process.

Paries Carotica.—The **carotid** or **anterior wall** of the tympanic cavity is narrowed in its transverse diameter by the approximation of the lateral and medial boundaries of the tympanic cavity, and in its vertical diameter by the descent of the tegmen tympani and the ascent of the carotid canal. It presents (Fig. 676) two parallel semicanals, one above the other, separated by a thin lamella of bone, the **septum canalis musculotubarii** (O.T. **processus cochleariformis**). These run forwards on the lateral wall of the carotid canal and open in the angle between the squama and the petrous part of the temporal bone. The higher and smaller semicanal is termed the **semicanalis m. tensoris tympani**, and lies immediately below the tegmen tympani. It has a diameter of about 2 mm., and extends on to the medial wall of the tympanic cavity above the anterior part of the fenestra vestibuli. The lower and larger semicanal gradually increases in diameter from before backwards, and is named the **semicanalis tubæ auditivæ**; it forms the bony part of the auditory tube. Below the orifice of the auditory tube the anterior part of the tympanic cavity is separated from the ascending portion of the carotid canal by a thin plate of bone in which there are sometimes gaps or deficiencies. This plate is perforated by the carotico-tympanic canal, which transmits the carotico-tympanic nerve from the sympathetic plexus on the carotid artery to the tympanic plexus. The auditory tube is described on p. 831.

Paries Membranacea.—The **membranous** or **lateral wall** of the tympanic cavity is formed almost entirely by the membrana tympani (Fig. 677), which closes the medial end of the external acoustic meatus, and is fixed throughout the greater part of its circumference in a groove, the **sulcus tympanicus.** The bony ring containing this sulcus is deficient superiorly, where it exhibits a small notch, the **notch of Rivinus.** On a level with the upper edge of the membrane, and in front of the ring of bone in which it is fixed, is the medial end of the **petro-tympanic fissure.** This transmits the tympanic branch of the internal maxillary artery, and lodges the anterior process and anterior ligament of the malleus. Close to the medial end of the fissure is the **iter chordæ anterius** through which the chorda tympani nerve leaves the tympanic cavity.

Membrana Tympani.—The **tympanic membrane** is an elliptical disc, its greatest diameter, 9 to 10 mm., being directed from above, downwards and forwards; its least diameter is from 8 to 9 mm. It is placed very obliquely, and forms

an angle of about 55° with the lower and anterior walls of the external acoustic meatus; it is said to be more oblique in cretins and deaf mutes, and more perpendicular in musicians.

The portion of the membrane which is fixed in the sulcus tympanicus is considerably thickened, and is named the **annulus fibrocartilagineus**. It is prolonged from the anterior and posterior ends of the notch of Rivinus to the processus lateralis of the malleus, as two ligamentous bands, the **anterior** and **posterior malleolar folds**. A small triangular portion of the membrane (Fig. 677) situated above these folds is thin and lax, and constitutes the **pars flaccida** (O.T. **membrane of Shrapnell**); whilst the main portion of the membrane is tightly stretched and is termed the **pars tensa**. A small orifice, sometimes seen in the pars flaccida, is probably either a pathological condition or has been produced artificially during manipulation. The manubrium mallei is firmly fixed to the medial surface of the membrana tympani, the central portion of which is drawn towards the tympanic cavity so that the lateral surface of the membrane is concave. The point of greatest convexity of the membrane corresponds with the lower end of the manubrium mallei, and is named the **umbo membranæ tympani**.

Structure.—The membrana tympani consists of three layers: (1) a lateral, the stratum cutaneum; (2) an intermediate, the membrana propria; (3) a medial, the stratum mucosum.

The **stratum cutaneum** is continuous with the skin of the external acoustic meatus, and consists of a thin layer of cutis covered with epidermis. The cutis is thickest near the circumference, and the epidermis near the centre, of the membrane.

The **membrana propria** consists of two sets of fibres: (*a*) a *lateral*, the stratum radiatum, situated immediately under the stratum cutaneum, and radiating from the manubrium mallei to the annulus fibrocartilagineus; (*b*) a *medial*, the stratum circulare, the fibres of which are numerous near the circumference, but scattered and few in number near the centre of the membrane (Fig. 677). The radial fibres are curved with their convexities directed towards the external acoustic meatus. Both radial and circular fibres are absent from the pars flaccida, which consists only of the cutaneous and mucous strata. In addition to the radial and circular fibres, there exists, next the stratum mucosum, a series of *dendritic* or *branched fibres* (Gruber), which are best developed in the posterior part of the membrane.

The **stratum mucosum** is continuous with the mucous lining of the tympanic cavity. It is thickest over the upper part of the membrane, and is covered with pavement epithelium.

Otoscopic Examination of the Membrana Tympani (Fig. 678).—The membrana tympani, in the living, is of a "pearl-gray" colour, but may present a reddish or yellowish tinge; the posterior segment is usually clearer than the anterior. At the antero-superior part, close to its periphery, a whitish point appears as if projecting towards the meatus; this is the processus lateralis of the malleus. Passing downwards and backwards from this point to the umbo is a ridge caused by the manubrium mallei, the lower end of which appears rounded. Two ridges, corresponding with the malleolar folds, extend from the processus lateralis of the malleus, one forwards and upwards, the other backwards and upwards. Behind, and near the lower end of the manubrium mallei, is a reddish or yellowish spot, due to the promontory of the medial wall of the tympanic cavity shining through. If the membrane is very transparent, the long crus of the incus may be visible behind the upper part of the manubrium mallei, and reaching downwards as far as its middle. From the lower end of the manubrium mallei, the "cone of light" or "luminous triangle" extends downwards and forwards, its apex being directed towards the handle; this triangle varies in size in different people.

FIG. 678.—LEFT TYMPANIC MEMBRANE (as viewed from the external acoustic meatus). × 3.

A line prolonging the manubrium downwards divides the membrane into two parts, while another, drawn at right angles to this through the umbo, subdivides it into quadrants, viz., postero-superior, postero-inferior, antero-superior, and antero-inferior; this subdivision is useful in enabling the otologist to localise and describe accurately the seat of lesions in the membrane.

Vascular and Nervous Supply of the Membrana Tympani.—The arteries of the tympanic membrane are arranged in two sets, one on the cutaneous and another on the mucous surface; they anastomose by means of small branches which pierce the membrane, especially near its periphery. The first set is derived chiefly from the deep auricular branch of the internal

maxillary artery; those on the mucous surface are small and proceed from the anterior tympanic branch of the internal maxillary artery, and from the stylo-mastoid branch of the posterior auricular artery. The **veins** from the cutaneous surface open into the external jugular vein; those from the mucous surface partly into the venous plexus on the auditory tube, and partly into the transverse sinus and veins of the dura mater. The **lymph-vessels**, like the blood-vessels, are arranged in two sets, cutaneous and mucous, which, however, communicate freely with each other. Kessel has described as lymph-vessels the spaces between the branches of Gruber's dendritic fibres. The lateral surface of the membrane receives its **nerves** from the auriculo-temporal branch of the trigeminal nerve and from the auricular branch of the vagus nerve; the medial surface, from the tympanic branch of the glossopharyngeal nerve.

Antrum Tympanicum et Cellulæ Mastoideæ.

Antrum Tympanicum.—The **tympanic antrum** (O.T. **mastoid antrum**) is an air-space situated behind the epitympanic recess. In the adult its average length is from 12 to 15 mm., its height from 8 to 10 mm., and its width from 6 to 8 mm.

Fig. 679.

Preparation to display the position and relations of the tympanic antrum. The greater part of the posterior wall of the external acoustic meatus has been removed, leaving only a bridge of bone at its medial extremity; under this a bristle is displayed, passing from the tympanic antrum to the cavity of the tympanum.

Its roof is formed by the tegmen tympani, and its floor and medial wall by the pars petrosa and pars mastoidea of the temporal bone; laterally it is closed by the part of the squama temporalis which lies below the supramastoid crest. It communicates with the epitympanic recess by a triangular or rounded opening, on the medial wall of which, immediately above and behind the canalis facialis, is a smooth convexity indicating the position of the ampullated ends of the superior and lateral semicircular canals.

At birth the lateral wall of the antrum has a thickness of only 1-2 mm., but by the ninth year this has increased to about 10 mm. Coincident with the growth of the mastoid process the mastoid air-cells are developed downwards and backwards as diverticula from the antrum, and present the greatest possible variation in different skulls.

Cellulæ Mastoideæ.—The **mastoid air-cells** may be large, comparatively few in number, and involve the whole mastoid process, in which case the compact bone surrounding them is very thin, and the innermost air-cells are separated from the transverse sinus by a transparent lamella which, in some instances, is

partly deficient. Sometimes the air-cells are small, and invade only a portion of the process, the remainder consisting of diploëtic tissue; occasionally a solid mastoid process is met with. The air-cells are not always limited to the mastoid portion of the temporal bone, but may extend forwards over the roof of the meatus, upwards towards the squama temporalis, and medially towards the temporo-occipital suture; occasionally they invade the pars jugularis of the occipital bone. The tympanic antrum and the mastoid air-cells are lined with thin mucous membrane, continuous with that of the tympanic cavity; the deep surface of the mucous membrane is fixed to the periosteum; its free surface is covered with a layer of flattened, non-ciliated epithelium.

Tuba Auditiva.

The **auditory tube** (O.T. **Eustachian tube**) leads from the tympanic cavity to the nasal part of the pharynx, and transmits air to the former, in order that the pressures on the medial and lateral surfaces of the membrana tympani may be equalised; it may also serve to convey mucous secretion from the tympanic cavity. Its **tympanic orifice** (Fig. 676) opens into the anterior part of the tympanic cavity, below the semicanal for the tensor tympani muscle. The tube is directed downwards and medialwards, and ends on the lateral wall of the nasal part of the pharynx by a wide **pharyngeal orifice** (Fig. 642, p. 797). It is about 35 mm. in length, and forms with the horizontal plane an angle of 30° to 40°, and with the sagittal plane an angle of about 45°. It consists of—(*a*) an antero-medial part, the **pars cartilaginea tubæ auditivæ**, about 25 mm. long; and (*b*) a postero-lateral part, the **pars ossea tubæ auditivæ**, about 10 mm. long. The cartilaginous part inclines downwards a little more than the osseous portion, and forms with it a wide angle. The lumen of the tube is widest at the pharyngeal orifice, narrowest at the junction of the bony and cartilaginous portions, forming here the **isthmus**; the lumen of the tube gradually increases from the isthmus to the tympanic orifice. The pars ossea occupies the angle between the tympanic and petrous parts of the temporal bone, and is separated from the tensor tympani muscle by the septum canalis musculo-tubarii; medial to it is the carotid canal. The pars cartilaginea consists partly of cartilage and partly of fibrous membrane. The cartilage is an elongated triangular plate, the apex of which is firmly attached to the medial end of the pars ossea, while the base is free, and forms a projection above and behind on the pharyngeal orifice. The upper part of this cartilaginous plate is bent lateralwards, so as to produce a furrow which is converted into a canal by the membranous lamina of the tube. On transverse section, therefore, the cartilage presents two laminæ continuous with each other superiorly (Fig. 680): (*a*) *lamina medialis*, broad and thick; and (*b*) *lamina lateralis*, thin and hook-shaped. At the pharyngeal orifice the lamina medialis forms the entire medial wall of the tube, but it gradually diminishes in breadth on approaching the isthmus tubæ. Fissures are often seen in the cartilage; sometimes it is divided into several pieces, or accessory islands may be observed in the roof, floor, or membranous lamina.

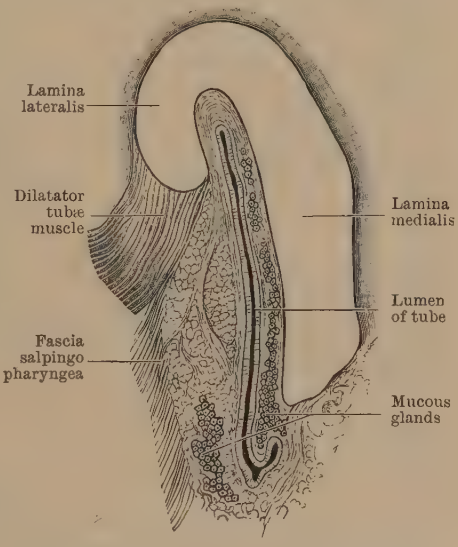

Fig. 680.—Transverse Section of the Cartilaginous Part of the Auditory Tube.

The upper and medial surfaces of the medial lamina are firmly fixed to the base of the skull, in the **sulcus tubæ auditivæ**, between the great wing of the sphenoidal bone and the petrous part of the temporal bone. Extending forwards on to the

root of the pterygoid process this sulcus ends at a projection, the **processus tubarius**, on the medial pterygoid lamina. The tensor veli palatini muscle lies on the lateral side of the tube and receives some fibres of origin from its lamina lateralis; these fibres constitute the **dilatator tubæ muscle** (Rüdinger). On the medial side of the cartilage are the levator veli palatini muscle and the mucous membrane of the pharynx. The **membranous lamina** consists of a strong fibrous membrane, stretching between the two edges of the cartilage, and so completing the lower and lateral walls of the tube. Its lower part is thickened and forms the **fascia salpingopharyngea** of Tröltsch, which gives origin to some of the fibres of the tensor veli palatini muscle. Between this fascia and the mucous lining of the tube is a layer of fatty tissue.

The **pharyngeal orifice** of the auditory tube, triangular or oval in shape, is situated on the lateral wall of the nasal part of the pharynx, the centre of the opening being on a level with the posterior end of the inferior nasal concha. It is bounded above and behind by a pad, the **torus tubarius**, produced by the base of the cartilage, which there abuts against the mucous membrane; the posterior part of the torus is very prominent and forms the anterior boundary of the **recessus pharyngeus**. Prolonged downwards from the posterior part of the torus is a fold of the mucous membrane, the **plica salpingopharyngea**, which covers the small salpingopharyngeus muscle. An indistinct fold, the **plica salpingopalatina**, extends from the upper part of the torus to the palate.

The tube is opened, during deglutition, by the dilatator tubæ and salpingopharyngeus muscles. The former springs superiorly from the lateral lamina of the tube, and blends inferiorly with the tensor veli palatini. When the dilatator tubæ contracts, the lateral lamina of the cartilage and the membranous lamina of the tube are drawn lateralwards and forwards. Some anatomists believe that the entire tensor veli palatini acts chiefly as a dilator of the tube, and Rüdinger named it the abductor tubæ. Blakeway[1] thinks that contraction of the tensor veli palatini is more likely to close than open the tube. The salpingopharyngeus muscle draws downwards and backwards the medial lamina, increasing the angle between it and the lateral lamina. Some difference of opinion exists as to the precise action of the levator veli palatini; probably it assists in opening the tube.

Mucous Membrane.—The mucous lining of the tube is continuous behind with that of the tympanic cavity, and in front with that of the nasal part of the pharynx. In the pars ossea it is thin and firmly fixed to the bony wall; in the pars cartilaginea it is loose and thrown into longitudinal folds. Numerous mucous glands open into the tube near its pharyngeal orifice, and here also there is a considerable amount of adenoid tissue, which constitutes the "tube-tonsil" of Gerlach. This adenoid tissue is continuous with that of the nasal part of the pharynx, and, like it, is especially well developed in children. The lumen of the tube is lined with ciliated columnar epithelium.

Vessels and Nerves.—The auditory tube receives its blood-supply from the ascending pharyngeal and middle meningeal arteries, and from the artery of the pterygoid canal. Its veins drain into the pterygoid venous plexus. Its sensory nerves are derived from the tympanic plexus and from the pharyngeal branch of the spheno-palatine ganglion.

The auditory tube of the child differs considerably from that of the adult; its lumen is relatively wider, its direction more horizontal, and its pars ossea relatively shorter. Kunkel states that its pharyngeal orifice is below the level of the hard palate in the fœtus; at birth it is level with the palate, whilst at the fourth year it is 3 to 4 mm., and in the adult 10 mm., above it. In the child the pharyngeal orifice forms a narrow fissure, and its cartilage projects less towards the middle line.

Ossicula Auditus.

The **auditory ossicles**, three in number, form an articulated column connecting the lateral with the medial wall of the tympanic cavity; they are named, from without inwards, the malleus, incus, and stapes. The first is attached to the medial surface of the membrana tympani; the last is fixed within the circumference of the fenestra vestibuli.

The **malleus** (Fig. 681, B, D), the largest of the three auditory ossicles, is from 8 to 9 mm. long, and consists of a head, a neck, a manubrium, and two processes, anterior and lateral.

[1] *Journal of Anatomy and Physiology*, vol. xlviii.

The head and neck are situated in the epitympanic recess; the lateral process and the manubrium are fixed to the medial surface of the membrana tympani; the anterior process is directed forwards, towards the petro-tympanic fissure, to which, in the adult, it is connected by ligamentous fibres. The **head**, somewhat rounded, is smooth and convex above and in front; on its posterior surface is a facet for

articulation with the body of the incus. This facet is more or less elliptical in form, but is constricted near the middle; an oblique ridge, corresponding with the constriction, divides the facet into two parts—an upper and larger, directed backwards, and a lower and lesser, directed medialwards. Opposite the lower part of the constriction the inferior edge of the facet is very prominent, and is continued upwards into the oblique ridge just referred to; it forms a tooth-like process, the

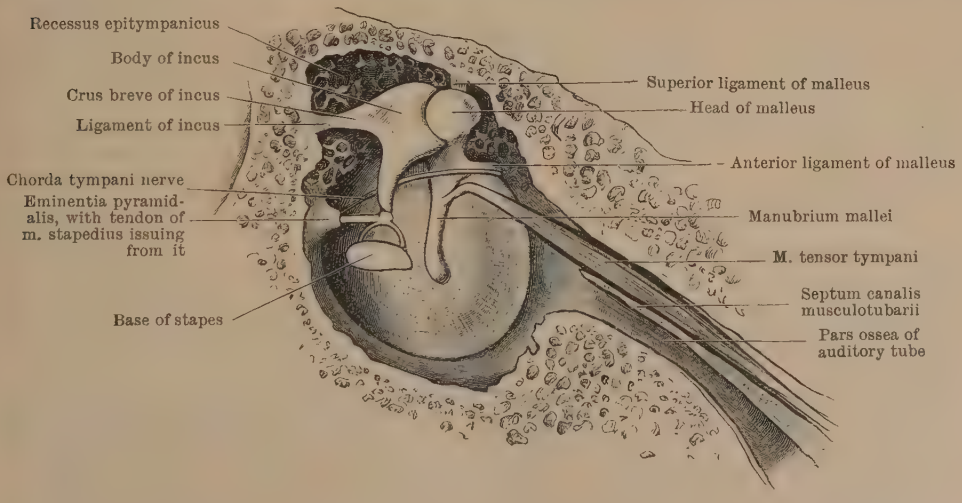

FIG. 682.—LEFT MEMBRANA TYMPANI AND CHAIN OF AUDITORY OSSICLES (seen from the medial aspect). × 3.

spur or **cog-tooth** of the malleus. On the back of the head, below this spur, is an oblique crest, the **crista mallei**, to which the lateral ligament of the malleus is attached. The **neck** is the slightly constricted portion immediately below the head. Its lateral surface is directed towards the membrana flaccida; its medial surface is crossed by the chorda tympani nerve. The **manubrium** or **handle** projects downwards, backwards, and medialwards from the neck, and forms with the long axis of the head an angle of 126° to 150°. Its upper part is flattened from before

backwards, but the lower part is twisted on itself, so that its surfaces look lateralwards and medialwards; the lower end is slightly curved, the concavity being directed forwards and lateralwards. The manubrium is fixed, by its periosteum and by a layer of cartilage to the membrana propria of the tympanic membrane. On the medial surface of the manubrium, near its upper end, is a slight projection for the attachment of the tendon of the tensor tympani muscle. The **processus anterior**, a slender spicule, springs from the front of the neck and is directed forwards, towards the petro-tympanic fissure. In the fœtus this is the longest process of the malleus, but in the adult it usually assumes the form of a small projection, since its anterior part is replaced by ligamentous tissue. The **processus lateralis** is a conical eminence, and may be looked upon as the upper end of the manubrium projected lateralwards; it is fixed to the upper part of the membrana tympani by a layer of cartilage, and to the ends of the notch of Rivinus by the anterior and posterior malleolar folds.

The **incus** (Fig. 681, A, C) resembles a premolar tooth with widely divergent roots. It consists of a body, a crus longum, and a crus breve; the crura form with each other an angle of 90° to 100°. The body and crus breve are situated in the epitympanic recess. On the **body** is a more or less saddle-shaped surface for articulation with the head of the malleus. This surface is directed forwards, and its lower part is hollowed out for the accommodation of the cog-tooth of the malleus; in front of this hollow it is prominent and spur-like. The **crus breve** is thick, pyramidal in shape, and projects horizontally backwards; its apex, covered with cartilage, is received into the fossa incudis in the postero-inferior part of the epitympanic recess. The **crus longum** projects downwards into the tympanic cavity, where it lies parallel with, but 1·25 mm. behind and medial to, the manubrium mallei. Its lower end is bent medialwards and narrowed to form a short neck, on the end of which is a small knob of bone, the **processus lenticularis**, for articulation with the head of the stapes.

The **stapes** (Fig. 681, E) consists of a head, a neck, two crura, and a base. The **head**, directed lateralwards, is concave for articulation with the processus lenticularis of the incus. The **neck** is slightly constricted, and from it the two crura spring; the tendon of the stapedius is inserted into the posterior surface of the neck. The **crus anterius** is shorter and less curved than the **crus posterius**. Diverging from each other, the crura are directed medialwards and are attached—one near the anterior, the other near the posterior end of the base. The **base** almost completely fills the fenestra vestibuli, and, like it, is somewhat oval or reniform, its anterior end being the more pointed. In the recent condition a membrane fills the arch formed by the crura and the base, the crura being grooved for its reception.

In the child the crura of the stapes are less curved than in the adult, and the opening between them and the base is nearly triangular.

Articulations of the Auditory Ossicles.—The joint between the head of the malleus and the body of the incus is diarthrodial, and may be described as one of reciprocal reception. It is surrounded by an articular capsule, from the inner surface of which a wedge-shaped meniscus projects into the joint-cavity and incompletely divides it. The joint between the processus lenticularis of the incus and the head of the stapes is of the nature of an enarthrosis and is surrounded by an articular capsule. An interarticular cartilage has been described as occurring in this joint, but some observers deny the presence of a synovial cavity and regard the articulation as a syndesmosis, the articular surfaces being held together by fibrous tissue.

Ligamenta Ossiculorum Auditus.—The malleus is attached to the walls of the tympanic cavity by anterior, superior, and lateral ligaments (Fig. 682). The **anterior ligament** consists of two portions: (*a*) the *band of Meckel*, which is attached to the base of the processus anterior, and passes forwards, through the petro-tympanic fissure, to reach the spina angularis of the sphenoidal bone; it was formerly described as the laxator tympani muscle; (*b*) a firm bundle of fibres, the *anterior ligament of Helmholtz*, which extends from the spina tympanica anterior (p. 826) to the anterior surface of the malleus, above the base of the processus

anterior. The **superior ligament** stretches from the head of the malleus to the roof of the epitympanic recess. The **lateral ligament** is short and fan-shaped; its fibres converge from the posterior half of the edge of the notch of Rivinus to the crista mallei. The posterior part of this ligament is strong and constitutes the *posterior ligament of Helmholtz*; it forms, together with the anterior ligament of the malleus, the axis around which the malleus rotates, and the two constitute what Helmholtz termed the "**axis-ligament**" of the malleus.

The posterior end of the crus breve of the incus is tipped with cartilage and fixed by means of a ligament to the fossa incudis (Fig. 677). Some observers describe this as a diarthrodial joint.

The vestibular surface, and the circumference, of the base of the stapes are covered with hyaline cartilage; that encircling the base of the stapes is joined to the circumference of the fenestra vestibuli by a ring of elastic fibres, named the **ligamentum annulare baseos stapedis**. The posterior part of this ligament is thicker and shorter than the anterior, and acts as a hinge on which the base of the stapes moves when the stapedius muscle contracts.

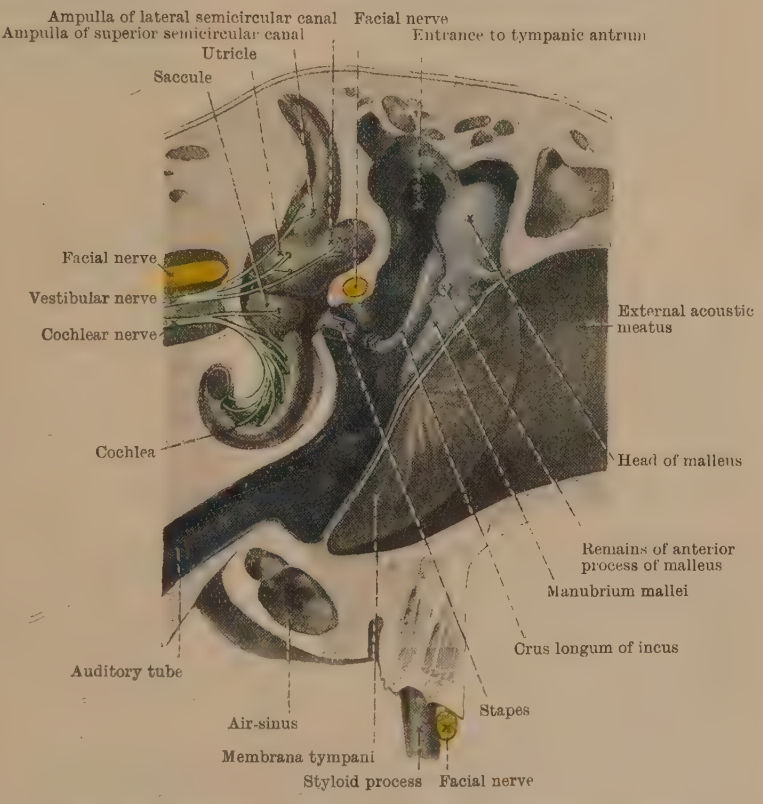

FIG. 683.—THE TYMPANIC CAVITY AND ADJACENT PARTS (SEMI-DIAGRAMMATIC).

Development of the Auditory Ossicles.—The malleus and incus are developed from the upper end of Meckel's cartilage; the stapes arises from the mesoderm in the region of the fenestra vestibuli, where it is developed around a small artery, the stapedial artery, which atrophies in man, but persists in many mammals. Ossification commences in all three bones about the third month of fœtal life. The malleus is ossified from two centres, one for the head and manubrium, and one for the processus anterior; the incus from one centre which appears in the upper part of its crus longum, and ultimately extends into the processus lenticularis; the stapes from one centre which appears in the base of the bone.

Muscles of the Tympanic Cavity.—These are the m. tensor tympani and m. stapedius.

The **m. tensor tympani**, the larger, takes origin from the roof of the cartilaginous part of the auditory tube, from the adjacent part of the great wing of the sphenoidal bone, and from the bony canal in which the muscle lies. The muscle ends in a tendon which bends lateralwards round the pulley-like posterior end of the septum canalis musculotubarii, and passes across the tympanic cavity to be inserted into the medial edge and anterior surface of the manubrium mallei, near its upper end. When the muscle contracts it draws the manubrium mallei towards the

tympanic cavity, and so renders tense the membrana tympani. It receives its nerve from the motor division of the trigeminal nerve, through the otic ganglion.

The **m. stapedius** arises within the eminentia pyramidalis, and from the canal which prolongs the hollow of this eminence downwards. Its tendon emerges from the apex of the eminence and is inserted into the posterior surface of the neck of the stapes. On contraction it draws back the head of the stapes, and so tilts the anterior part of the base towards the tympanic cavity. It is supplied by the facial nerve.

Movements of the Auditory Ossicles.—The manubrium mallei follows all the movements of the membrana tympani, while the malleus and incus move together around an axis extending forwards through the crus breve of the incus and the anterior ligament of the malleus. When the membrana tympani moves medialwards it carries with it the manubrium mallei, while the incus, moving medialwards at the same time, forces the base of the stapes towards the labyrinth. This movement is communicated to the fluid (perilymph) in the labyrinth, and causes a lateral bulging of the secondary tympanic membrane which closes the fenestra cochleæ. These movements are reversed when the membrana tympani is relaxed, unless the lateral movement of the membrane is excessive. In such a condition the incus does not follow the full movement of the malleus, but merely glides on this bone at the incudo-malleolar joint, and thus the forcible dragging of the base of the stapes out of the fenestra vestibuli is prevented. The cog-tooth arrangement, already described, on the head of the malleus and body of the incus, causes the incudo-malleolar joint to become locked during the medial movement of manubrium mallei, the joint becoming unlocked during its lateral movement.

Tunica Mucosa Tympanica.—The **mucous lining of the tympanic cavity** is continuous, through the auditory tube, with that of the nasal part of the pharynx; it extends backwards also and lines the tympanic antrum and the mastoid air-cells. Thin, transparent, and closely united with the subjacent periosteum, it covers the medial surface of the membrana tympani and is reflected over the auditory ossicles and their ligaments. It also supplies sheaths for the tendons of the tensor tympani and stapedius muscles, and forms the following **folds**: (*a*) one from the roof of the recessus epitympanicus to the head of the malleus and body of the incus; (*b*) one enveloping the chorda tympani nerve and crus longum of the incus; (*c*) two extending from the processus lateralis mallei—one to the anterior, the other to the posterior margin of the notch of Rivinus. A recess, the **pouch of Prussak**, is situated between the membrana flaccida and the neck of the malleus. This pouch communicates behind with the tympanic cavity, and may serve as a reservoir for pus or other fluid, since its opening into the tympanic cavity is above the level of its floor, a condition analogous to the opening from the maxillary air-sinus into the nasal cavity. The fold of mucous membrane which envelops the chorda tympani nerve gives rise to two pouches, one in front of, and the other behind, the manubrium mallei; these are named the **anterior** and **posterior recesses of Tröltsch.** The epithelium which lines the mucous membrane is flattened over the membrana tympani, promontory, and auditory ossicles, but ciliated and columnar over the greater portion of the rest of the cavity.

Vessels and Nerves of the Tympanic Cavity.—The **arteries** supplying the tympanic cavity are: (1) The anterior tympanic artery, a branch of the internal maxillary artery, which reaches the cavity by way of the petro-tympanic fissure. (2) The stylo-mastoid branch of the posterior auricular artery, which passes through the stylo-mastoid foramen and the facial canal; it supplies branches to the tympanic antrum and mastoid air-cells, to the stapedius muscle, to the floor and medial wall of the tympanic cavity, and forms an anastomotic circle, around the membrana tympani, with the anterior tympanic artery. (3) The middle meningeal artery sends a branch to the tensor tympani muscle, and gives off its superficial petrosal artery, which passes to the tympanic cavity through the hiatus canalis facialis; some twigs from the posterior division of the middle meningeal artery reach the tympanic antrum and epitympanic recess through the petro-squamous fissure. (4) The internal carotid artery, in its passage through the canal in the temporal bone, gives off one or two tympanic twigs. (5) A branch from the ascending pharyngeal accompanies the tympanic nerve. The **veins** drain into the pterygoid plexus, and the superior petrosal sinus. The **lymph-vessels** form a network in the mucous membrane and end mainly in the retro-pharyngeal and parotid lymph-glands. The **nerves** supplying the muscles of the tympanic cavity have already been referred to (pp. 828, 691). The mucous membrane receives its nerves from the tympanic plexus, which is described on p. 697. The chorda tympani branch of the facial nerve passes from behind, upwards, and forwards through the tympanic cavity; its course is described on p. 694.

Early Condition of Tympanic Cavity.—During the greater part of fœtal life the tympanic cavity is almost completely filled by a soft, reddish, jelly-like embryonic tissue in which there is a slit-like space lined with epithelium. Towards the end of fœtal life this tissue disappears, and at birth the cavity is filled with fluid which becomes absorbed, after the entrance of air from the nasal part of the pharynx through the auditory tube.

AURIS INTERNA.

The **internal ear** is situated in the petrous part of the temporal bone, and consists of two sets of structures, (1) a series of passages hollowed out of the bone and constituting the **osseous labyrinth**; these are continuous with each other, and

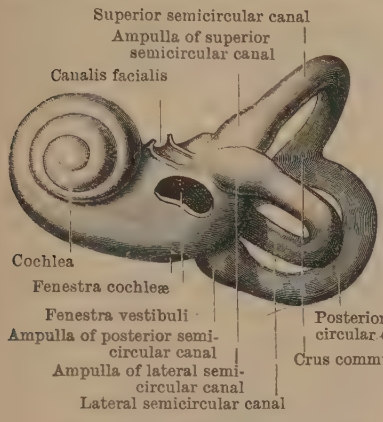

FIG. 684.—LEFT BONY LABYRINTH (viewed from the lateral aspect).

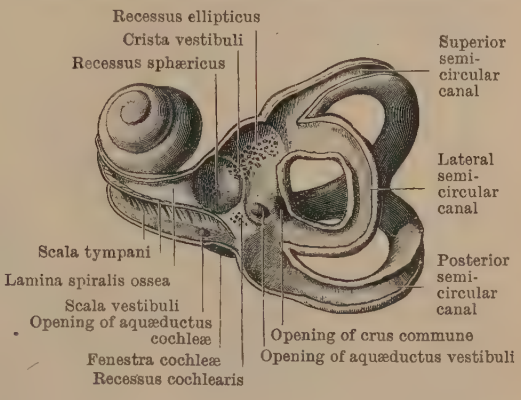

FIG. 685.—INTERIOR OF LEFT BONY LABYRINTH (viewed from lateral aspect).

are named from before backwards the **cochlea, vestibule,** and **semicircular canals** (Figs. 684, 685); (2) a complex arrangement of membranous channels (Fig. 688), situated within, but not nearly filling, the osseous labyrinth and forming the **membranous labyrinth.** These channels are named the **ductus cochlearis,** the **utricle,** the **saccule,** and the **semicircular ducts**; the utricle and saccule are lodged within the vestibule.

LABYRINTHUS OSSEUS.

Vestibulum.—The **vestibule** is the central portion of the osseous labyrinth, and communicates behind with the semicircular canals and in front with the cochlea. It is somewhat ovoid in shape, its long axis being directed forwards and lateralwards. It measures about 6 mm. antero-posteriorly, 4-5 mm. vertically, and about 3 mm. transversely. Its lateral wall is directed towards the tympanic cavity, and in it is the fenestra vestibuli, which is closed by the base of the stapes. Its medial wall corresponds with the bottom of the internal acoustic meatus, and presents, at its antero-inferior part, a circular depression, the **recessus sphæricus,** which lodges the saccule. This recess is perforated by twelve or fifteen small foramina (**macula cribrosa media**), which transmit the filaments of the acoustic nerve to the saccule. The recessus sphæricus is limited above and behind by an oblique ridge, the **crista vestibuli,** the anterior end of which is triangular in shape and named the **pyramis vestibuli.** Posteriorly this crista divides into two limbs, between which is a small depression, the **recessus cochlearis.** This recess is perforated by several small foramina, for the passage of the nervous filaments supplying the vestibular end of the ductus cochlearis. Above and behind the crista vestibuli, in the roof and medial wall of the vestibule, is an oval depression, the **recessus ellipticus,** which lodges the utricle. The pyramis vestibuli and adjacent part of the recessus ellipticus are perforated by twenty-five or thirty small foramina (**macula cribrosa superior**). The foramina in the pyramis vestibuli transmit the nerves to the utricle; those in the recessus ellipticus, the nerves to the ampullæ of the superior and lateral semicircular ducts. Behind and below the recessus ellipticus is a furrow, gradually deepening to form a canal, the **aquæductus vestibuli,** which passes backwards through the petrous part of the temporal bone, and opens, as a slit-like fissure, about midway between the internal acoustic meatus and the groove for the transverse sinus. This aqueduct is from 8 to 10 mm. long, and gives passage to the ductus endolymphaticus and a small vein. At the posterior part of the vestibule

are five circular openings leading into the semicircular canals; at its anterior part is an elliptical opening, leading into the scala vestibuli of the cochlea. This opening is bounded below by a thin osseous plate, the **lamina spiralis ossea**, which springs from the floor of the vestibule immediately lateral to the recessus sphæricus, and forms, in the cochlea, the bony part of the septum between the scala tympani and the scala vestibuli.

Canales Semicirculares Ossei.—The **osseous semicircular canals** (Figs. 684, 685), three in number, are situated above and behind the vestibule. They are distinguished from each other by their position, and are named superior, posterior, and lateral. Each forms about two-thirds of a circle, one end of which is dilated and termed the osseous ampulla. They are somewhat compressed from side to side, and their diameter is from 1 to 1·5 mm., whilst that of the ampullæ is about 2 mm. They open into the vestibule by five apertures, since the medial end of the superior, and the upper end of the posterior, join to form a common canal or crus commune.

The **superior semicircular canal**, 15 to 20 mm. long, is vertical and placed transversely to the long axis of the petrous part of the temporal bone. Its convexity is directed upwards, and its position is indicated by the arcuate eminence. Its ampullated end is the anterior and lateral, and opens into the vestibule immediately above that of the lateral canal. Its opposite end joins the non-ampullated end of the posterior canal to form the **crus commune**, which is about 4 mm. long, and opens into the upper and medial part of the vestibule. The **posterior semicircular canal**, from 18 to 22 mm. long, is also vertical. Its ampulla is placed inferiorly, and opens into the lower and posterior part of the vestibule, where there are six or eight small apertures (**macula cribrosa inferior**), for the transmission of the nerves to this ampulla. Its upper end terminates in the crus commune. The **lateral canal**, from 12 to 15 mm. long, arches nearly horizontally. Its lateral end is ampullated, and opens into the vestibule immediately above the fenestra vestibuli, close to the ampullary end of the superior canal.

Crum Brown (*Journ. Anat. and Physiol.*, London, vol. viii.) pointed out that the lateral canal of one ear is very nearly in the same plane as that of the other; while the superior canal of one ear is nearly parallel to the posterior canal of the other.

Cochlea.[1]—When freed from its surroundings the **cochlea** assumes the form of a short cone (Fig. 684); the central part of its **base** corresponds with the bottom of the internal acoustic meatus, whilst its apex or **cupula**, directed forwards and lateralwards, is in close relation with the semicanal for the tensor tympani muscle. It measures about 9 mm. across the base and about 5 mm. from base to apex, and consists of a spirally arranged tube, which forms from $2\frac{1}{2}$ to $2\frac{3}{4}$ coils around a central pillar, termed the **modiolus**. The length of the tube is from 28 to 30 mm., and its diameter, near the base of the cochlea, 2 mm. Its coils are distinguished by the terms basal, central, and apical; the basal coil gives rise to the promontory on the labyrinthic wall of the tympanic cavity.

The modiolus is about 3 mm. in height, and its diameter diminishes rapidly from the base to the apex; the latter ends about 1 mm. from the cupula. Its **base** corresponds with the **area cochleæ** on the fundus of the internal acoustic meatus, and exhibits the **tractus spiralis foraminosus**, which transmits the nerves for the basal and central coils of the cochlea and the **foramen centrale**, which gives passage to the nerves for the apical coil. The foramina of the tractus spiralis foraminosus traverse the modiolus, running at first parallel to its long axis, and then bending outwards to reach the attached edge of the lamina spiralis ossea, where they expand and form by their apposition a spiral canal, the **canalis spiralis cochleæ**, which lodges the **ganglion spirale cochleæ**. From this spiral canal numerous small canals, for the transmission of vessels and nerves, pass outwards to the free edge of the lamina spiralis ossea.

The **lamina spiralis ossea**, a thin, flat shelf of bone, winds round the modiolus like the thread of a screw, and, projecting about half-way into the cochlear tube,

[1] In the following description the cochlea is supposed to be placed on its base.

incompletely divides it into two passages, an upper, the **scala vestibuli**, and a lower, the **scala tympani**. The lamina spiralis ossea begins at the floor of the vestibule, near the fenestra cochleæ, and ends near the cupula of the cochlea in a sickle-shaped process, the **hamulus laminæ spiralis**, which assists to bound an aperture named the **helicotrema**. In the basal coil the upper surface of the lamina spiralis ossea forms almost a right angle with the modiolus, but the angle becomes more and more acute on ascending the tube. In the lower half of the basal coil a second smaller bony plate, the **lamina spiralis secundaria**, projects from the outer wall of the cochlea

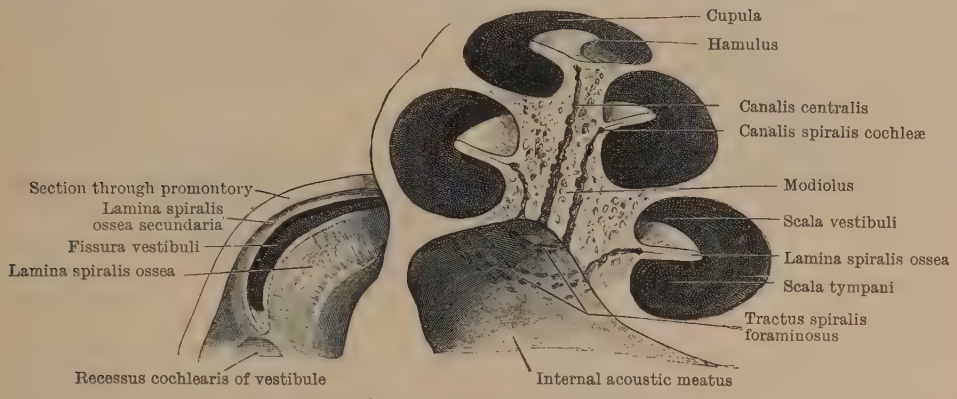

FIG. 686.—SECTION OF BONY COCHLEA.

towards the lamina spiralis ossea, without, however, reaching it. If viewed from the vestibule a slit-like fissure, the **fissura vestibuli**, is seen between the two laminæ, which are continuous with one another round the posterior end of the fissure. A membrane, the **membrana basilaris**, stretches from the free edge of the lamina spiralis ossea to the outer wall of the cochlea, and completes the septum between the scala vestibuli and scala tympani, but the two scalæ communicate with each other through the opening of the helicotrema at the cupula of the cochlea. The scala tympani begins at the fenestra cochleæ, which is closed by the secondary tympanic membrane (p. 827). At the commencement of the scala tympani a crest, termed the **crista semilunaris**, stretches from the attached margin of the lamina spiralis ossea towards the orifice of the fenestra cochleæ. Close to this crest is seen the inner orifice of the **aquæductus cochleæ**, a canal measuring from 10 to 12 mm. in length, and opening on the under surface of the petrous part of the temporal bone in front of the fossa jugularis. This aqueduct establishes a communication between the scala tympani and the subarachnoid cavity, and transmits a small vein to join the inferior petrosal sinus. The scala vestibuli, the higher of the two passages, begins in the vestibule; in the basal coil its diameter is less than that of the scala tympani, but in the upper coils it exceeds it.

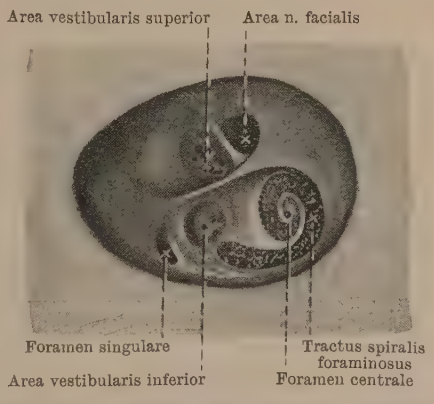

FIG. 687. — BOTTOM OF INTERNAL ACOUSTIC MEATUS DIVIDED INTO UPPER AND LOWER AREAS BY THE CRISTA TRANSVERSA.

The **fundus** of the **internal acoustic meatus** has been referred to as forming the medial wall of the vestibule and the base of the modiolus. It is divided by a transverse ridge, the **crista transversa**, into a **fossula superior** and a **fossula inferior**. In the anterior part of the fossula superior is a single large opening for the transmission of the facial nerve; the posterior part of this fossula is named the **area vestibularis superior**, and is perforated by the nerves of the utricle and the ampullæ of the superior and lateral semicircular ducts. The anterior part of the fossula inferior is termed the **area cochleæ**: in it are the **canalis centralis** of the modiolus and the surrounding **tractus spiralis**

foraminosus, for the passage of the nerves to the cochlea. Behind the area cochleæ, and separated from it by a ridge, is the **area vestibularis inferior**, which is pierced by the nerves to the saccule; behind this area is the **foramen singulare**, which gives passage to the nerves of the ampulla of the posterior semicircular duct.

LABYRINTHUS MEMBRANACEUS.

The **membranous labyrinth** (Fig. 688) is contained within the bony labyrinth, but does not nearly fill it. It contains a fluid termed **endolymph**, while the interval between it and the bony labyrinth is named the **perilymphatic space**, and is occupied by a fluid termed **perilymph**. The perilymphatic space in the vestibule is continuous behind with that of the semicircular canals, and opens in front into the scala vestibuli; at the apex of the cochlea it is continuous, through the helicotrema, with the scala tympani, which is shut off from the tympanic cavity by the secondary tympanic membrane. Through the aquæductus cochleæ the perilymphatic space communicates with the subarachnoid cavity. The ductus semicirculares and the ductus cochlearis follow the course and lie along the inner surfaces of the outer walls of the corresponding bony tubes. The bony vestibule, on the other hand, contains two membranous sacs, the **utricle** and **saccule**. The former receives the ends of the semicircular ducts, whilst the latter communicates with the ductus cochlearis. Moreover, the cavities of the utricle and saccule are indirectly connected, and thus all parts of the membranous labyrinth communicate with each other.

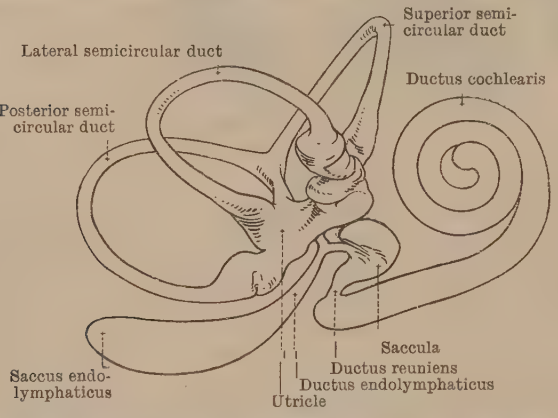

FIG. 688.—DIAGRAMMATIC REPRESENTATION OF THE DIFFERENT PARTS OF THE MEMBRANOUS LABYRINTH. (Milne-Dickie.)

(From a model made by Dr. J. H. M. Dickie, and sections made by Dr. J. S. Fraser.)

Utriculus.—The **utricle** is larger than the saccule, and (Fig. 683) occupies the postero-superior portion of the vestibule. Its highest part, or **recessus utriculi**, lies in the recessus ellipticus, and the ampullæ of the superior and lateral semicircular ducts open into it. The non-ampullated end of the lateral semicircular duct opens into the central part of the utricle, and this part is prolonged upwards and backwards as the **sinus superior**, into which the crus commune of the superior and posterior semicircular ducts open. The ampulla of the posterior semicircular duct opens into the lower and medial part, or **sinus inferior**. The floor and anterior wall of the recessus utriculi are thickened to form the **macula acustica utriculi**, to which the utricular fibres of the acoustic nerve are transmitted through the foramina in the pyramis vestibuli. Whitish in colour, and of an oval or nearly rhombic shape, this macula measures 3 mm. in length and 2·3 mm. in its greatest breadth.

Sacculus.—The **saccule** occupies the recessus sphæricus, in the lower and anterior part of the vestibule (Fig. 683). It is of an oval shape and measures 3 mm. in its longest, and about 2 mm. in its shortest diameter. It presents anteriorly an oval, whitish thickening, the **macula acustica sacculi**. This has a breadth of about 1·5 mm., and to it the saccular fibres of the acoustic nerve are distributed. The upper end of the saccule is directed upwards and backwards, and forms the **sinus utricularis sacculi**, which comes into contact with the utricle, and here the utricle and saccule are separated by a common wall (Milne Dickie[1]). From the lower part of the saccule a short canal, the **ductus reuniens (Henseni)**, descends and

[1] *Journal of Laryngology, Rhinology, and Otology*, vol. xxxv.

gradually widens into the vestibular end of the ductus cochlearis. A second small channel, the **ductus endolymphaticus**, is continued from the posterior part of the saccule, and is joined by a small canal, the **ductus utriculosaccularis**, which arises from the medial side of the utricle. The ductus endolymphaticus then enters and traverses the aquæductus vestibuli and ends, under the dura mater on the posterior surface of the petrous part of the temporal bone, in a dilated blind pouch, termed the **saccus endolymphaticus**; this, according to Rüdinger, is perforated by minute foramina, through which the endolymph may pass into the meningeal lymphatics.

The vestibule also contains the vestibular extremity of the ductus cochlearis, which lies immediately below the saccule in the recessus cochlearis.

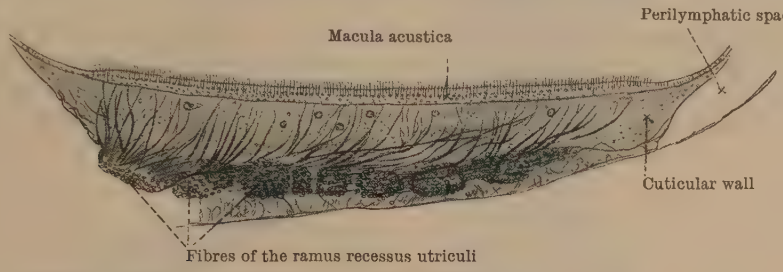

FIG. 689.—VERTICAL SECTION OF THE WALL OF THE RECESSUS UTRICULI WITH THE MACULA ACUSTICA AND THE BUNDLES OF NERVE FIBRES.

Structure.—The walls of the utricle and saccule are composed of (*a*) an external layer of connective tissue which blends with the periosteal lining of the vestibule, (*b*) an intermediate transparent layer or tunica propria, and (*c*) an internal layer of pavement epithelium. The walls are thickened at the maculæ acusticæ; towards the periphery of the maculæ the epithelium is cubical, while on them it is columnar.

In the maculæ of the utricle and saccule two kinds of cells are found, (*a*) supporting cells, and (*b*) hair-cells. The **supporting cells** are somewhat fusiform, each containing, near its middle, a nucleus. Their branched, deep ends are attached to the membrana propria; their free ends lie between the hair-cells and form a thin inner limiting cuticle. The **hair-cells** are flask-shaped and do not reach the membrana propria, their rounded ends lying between the supporting cells. Each hair-cell contains, in its deepest part, a large nucleus, the rest of the cell being granular and pigmented. From the free end of each there projects a stiff, hair-like process, which, on the application of reagents, splits into several finer filaments. The nerve-fibres pierce the membrana propria, and ramify around the deep ends of the hair-cells (Fig. 691). A collection of small crystals of carbonate of lime, termed **otoconia**, adheres to each of the maculæ.

Ductus Semicirculares.—The **semicircular ducts** are elliptical on transverse section (Fig. 690), and are attached to the walls of the bony canals. The convex wall of each duct is fixed to the periosteal lining of the canal, whilst the opposite part is connected by delicate fibrous bands to the bony wall. Like the bony canals, each of the semicircular ducts is dilated at one end into an ampulla; these ampullæ nearly fill the corresponding portions of the bony tubes, but the diameter of the semicircular ducts is only about one-fourth of that of the osseous canals.

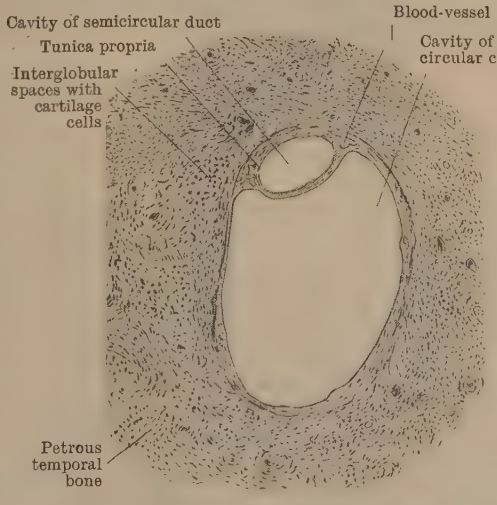

FIG. 690.—SECTION OF A SEMICIRCULAR CANAL AND DUCT.

(From a section made by Dr. J. S. Fraser.)

Structure.—Each semicircular duct consists of three layers, (*a*) an outer vascular and partly pigmented **fibrous stratum** which fixes the duct to the bony wall; (*b*) an intermediate, transparent

tunica propria, presenting a number of papilliform elevations which project towards the lumen. The fibrous layer and tunica propria are thinnest along the attached surface of the duct, and in this region also the papilliform elevations are absent; (*c*) an internal **epithelial layer**, composed of pavement cells. In each ampulla the tunica propria is thickened, and projects into the cavity as a transverse elevation, termed the **septum transversum**, which, when seen from above, is somewhat fiddle-shaped; the most prominent part of this septum is named the **crista ampullaris**. The cells covering the crista ampullaris consist of **supporting cells** and **hair-cells**, and are similar in their arrangement to those in the maculæ of the utricle and saccule; the hairs of the hair-cells are, however, considerably longer, and project as far as the middle of the ampullary lumen. In fresh specimens they appear to end free, but in hardened preparations are seen to terminate in a soft, clear, dome-like structure, the **cupula terminalis**, which is radially striated. The nerves form arborisations around the bases of the hair-cells.

In most mammals a ridge (*crista quarta*) projects into the posterior end of the lateral semicircular duct, and to this crista nerve-filaments have been traced.

Ductus Cochlearis.—The **ductus cochlearis** (O.T. **membranous cochlea** or **scala media**) is a spirally arranged canal inside the bony cochlea. Its lower end occupies the recessus cochlearis of the vestibule and communicates with the saccule through the ductus reuniens; its upper end is closed, and is named the **lagena**, or **cæcum**

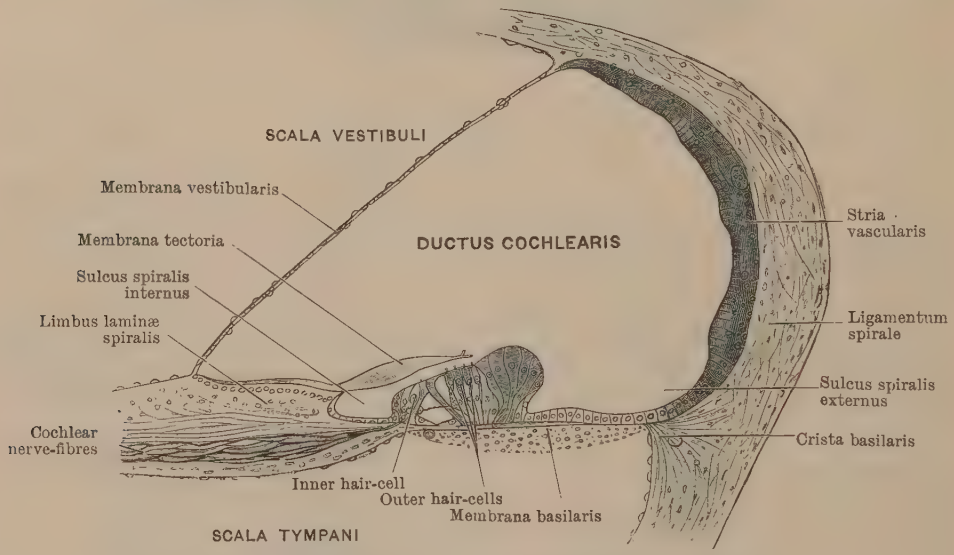

FIG. 691.—SECTION ACROSS THE DUCTUS COCHLEARIS. (Retzius.)

cupulare; it is fixed to the cupula of the cochlea, and partly bounds the helicotrema. As already stated (p. 839) the membrana basilaris stretches from the free edge of the lamina spiralis ossea to the outer wall of the cochlea. A second, more delicate membrane, the **membrana vestibularis** (O.T. **membrane of Reissner**), stretches from the thickened periosteum covering the upper surface of the lamina spiralis ossea to the outer wall of the cochlea, some distance above the external attachment of the membrana basilaris. A canal is thus enclosed between the underlying scala tympani and membrana basilaris, and the overlying scala vestibuli, and constitutes the **ductus cochlearis**. Triangular on transverse section, the ductus cochlearis possesses a roof, an outer wall, and a floor; it is lined throughout with epithelium and filled with endolymph. On its floor the epithelium is greatly modified, and there the endings of the cochlear nerve are found.

The **roof** or **vestibular wall** of the ductus cochlearis is formed by the membrana vestibularis, a delicate, nearly homogeneous membrane, covered on both surfaces by a layer of epithelium. Its entire thickness is about 3 μ.

The **outer wall** of the ductus cochlearis (Fig. 691) consists of the periosteal lining of the bony cochlea, which, however, is thickened and greatly modified to form the **ligamentum spirale cochleæ**. This ligament projects inwards inferiorly as a triangular crest, the **crista basilaris**, to which the outer edge of the membrana basilaris is attached. In the upper part of the ligamentum spirale the periosteum

is of a reddish-yellow colour, and contains, immediately under its epithelial lining, numerous small blood-vessels and capillary loops, forming the **stria vascularis**. The lower limit of this stria is bounded by a prominence, the **prominentia spiralis**, in which is seen a vessel, the **vas prominens**, and between this prominence and the crista basilaris is a concavity, the **sulcus spiralis externus**. The height of the outer wall of the ductus cochlearis diminishes towards the apex of the cochlea.

The **floor** or **tympanal wall** of the ductus cochlearis is formed by the periosteum covering that portion of the lamina spiralis ossea which is situated on the outer side of the membrana vestibularis, and by the **membrana basilaris**, which stretches from the free edge of the lamina spiralis ossea to the crista basilaris. On the inner part of the membrana basilaris the complicated structure termed the **organon spirale** (O.T. **organ of Corti**) is situated. The lamina spiralis ossea consists of two plates of bone, between which are placed the canals for the branches of the cochlear nerve. On the upper plate the periosteum is thickened and modified to form the **limbus laminæ spiralis**, the outer border of which is concave, and appears, in radial sections, as a C-shaped indentation, the **sulcus spiralis internus** (Fig. 691). The portions of the limbus which project above and below this concavity are termed respectively the **labium vestibulare** and **labium tympanicum**. The latter is perforated by about 4000 small apertures, the **foramina nervosa**, for the transmission of the cochlear nerves, and is continuous with the membrana basilaris. The upper surface of the labium vestibulare presents a number of furrows crossing each other nearly at right angles, and intersecting a series of elevations which, at the free margin of the labium, form a row of tooth-like structures, about 7000 in number, the **auditory teeth of Huschke**. Covering the limbus is a layer of apparently squamous epithelium; the deeper protoplasmic portions of the cells, however, with their contained nuclei, lie in the intervals between the elevations and auditory teeth. This layer of epithelium is continuous above with that covering the under surface of the membrana vestibularis and below with that which lines the sulcus spiralis internus.

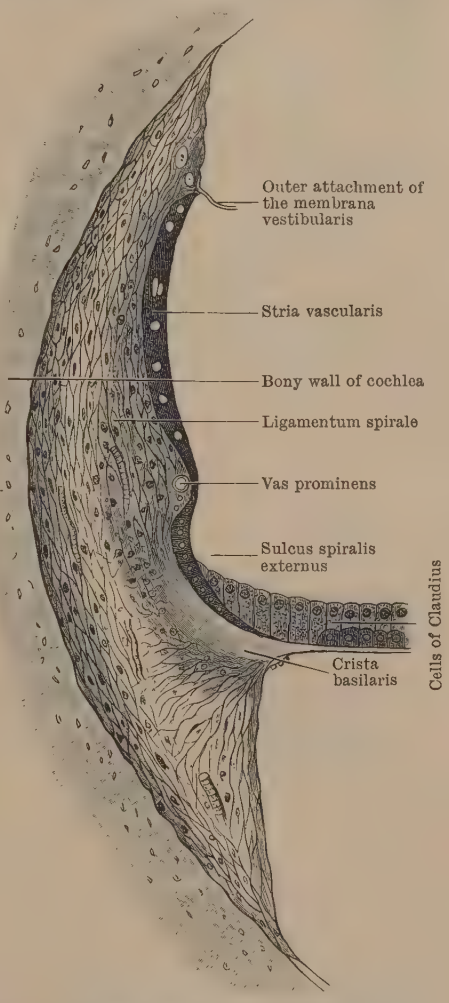

FIG. 692.—TRANSVERSE SECTION THROUGH OUTER WALL OF DUCTUS COCHLEARIS. (Schwalbe.)

Membrana Basilaris.—The basilar membrane stretches from the tympanic lip of the lamina spiralis ossea to the crista basilaris. Its inner part is thin, and supports the organon spirale; it is named the **zona arcuata**, and reaches as far as the foot-plate of the outer rod of Corti. Its outer part is thicker and distinctly striated, and is termed the **zona pectinata**. The substantia propria of the membrane is almost homogeneous, but exhibits, in its deeper part, numerous fibres. These fibres are most distinct in the zona pectinata, and number, according to Retzius, about 24,000. Covering the under surface of the membrana basilaris is a layer of connective tissue, containing, in its inner part, small blood-vessels; one of these is larger than the others and lies below the tunnel of Corti, and is named the vas

spirale. The width of the membrana basilaris increases from 0·21 mm. in the basal coil to 0·36 mm. in the apical coil.

Organon Spirale (O.T. **Organ of Corti**) (Fig. 693).—Placed upon the zona arcuata or inner portion of the membrana basilaris, the organon spirale consists of an epithelial eminence which extends along the entire length of the ductus cochlearis, and comprises the following structures: (1) Corti's rods or pillars, (2) hair-cells (inner and outer), (3) supporting cells of Deiters, (4) the cells of Hensen and Claudius, (5) the lamina reticularis, and (6) the membrana tectoria.

The **rods of Corti** form two rows, **inner** and **outer**, of stiff, pillar-like structures, and each rod presents a base or foot-plate, an intermediate elongated portion, and an upper end or head. The bases of the rods are planted on the membrana basilaris, those of the inner row at some little distance from those of the outer. The intermediate portions of the rods incline towards each other and the heads come into contact, so that, between the two rows and the membrana basilaris, a triangular tunnel, the **tunnel of Corti**, is enclosed; this tunnel increases both in height and width on passing towards the apex of the cochlea. The **inner rods** number nearly 6000, and the head of each resembles somewhat the proximal end of the ulna, presenting externally a deep concavity for the reception of a corresponding convexity on the head of the outer rod. The part of the head which overhangs this

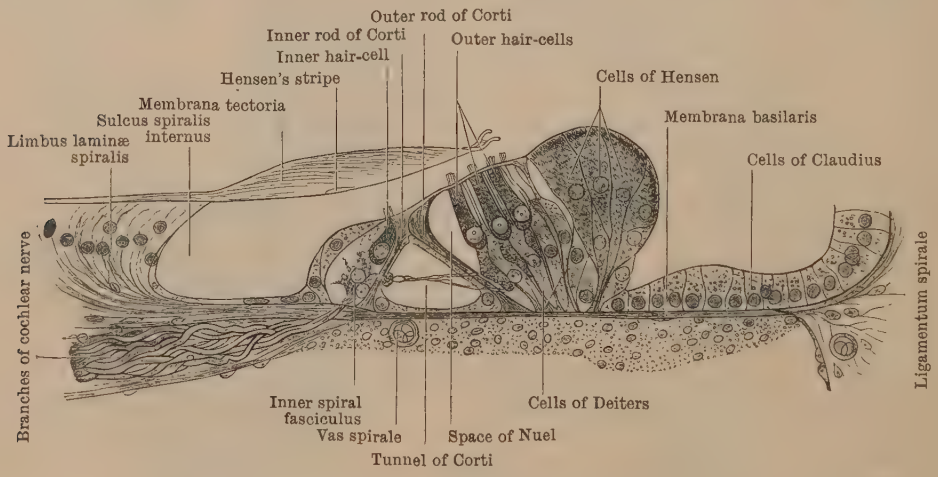

Fig. 693.—Transverse Section of the Organon Spirale from the Central Coil of the Ductus Cochlearis. (Retzius.)

concavity is prolonged outwards, under the name of the **head-plate**, and overlaps the head of the outer rod. The expanded bases of the inner rods are placed immediately on the outer side of the foramina nervosa of the labium tympanicum; the intermediate parts of these rods are sinuously curved, and form with the membrana basilaris an angle of about 60°. The **outer rods** number about 4000, and are longer than the inner, especially in the upper turns of the cochlea. They are more inclined towards the membrana basilaris, and form with it an angle of about 40°. The head of each is convex internally, to fit the concavity on the head of the inner rod, and is prolonged outwards as a plate, the **phalangeal process**, which becomes connected with the lamina reticularis; in the head is an oval body which has an affinity for certain reagents. The main part of each rod consists of a nearly homogeneous material, which is finely striated. At the base of each rod, on the surface next Corti's tunnel, is a nucleated mass of protoplasm which reaches as far as the head of the rod, and covers also a part of the tunnel floor; this protoplasm may be regarded as the undifferentiated part of the cell from which the rod was developed. Slit-like intervals, for the transmission of nerves, exist between the intermediate portions of adjacent rods.

Hair-cells.—These, like Corti's rods, form two sets, **inner** and **outer**; the former consists of a single row lying immediately internal to the inner rods—the latter of three, or, it may be, four rows placed to the outer side of the external rods. The **inner hair-cells** are about 3500 in number; the diameter of each is greater than that of an inner rod, and so each inner hair-cell is supported by more than one rod. The free end of each hair-cell is surmounted by about twenty fine hair-like processes, arranged in the form of a crescent, with its concavity directed inwards. The deep end of the cell

contains a large nucleus and is rounded; it reaches only about half-way down the rod, and is in contact with the arborisations of the nerve terminations. To the inner side of this row of hair-cells are two or three rows of elongated columnar cells, which act as supporting cells, and are continuous with the low columnar cells lining the sulcus spiralis internus. The **outer hair-cells** number about 12,000, and form three rows in the basal coil and four rows in the upper two coils, although in the higher coils the rows are not so regularly arranged. The rounded free end of each hair-cell supports about twenty hairlets arranged in the form of a crescent, opening inwards; the deep end reaches about half-way to the membrana basilaris, and is in contact with the nerve arborisations.

Alternating with the rows of the outer hair-cells are the rows of **Deiters' supporting cells**, the lower ends of which are expanded on the membrana basilaris, whilst their upper ends are tapered; the nucleus is placed near the middle of each cell, and, in addition, each cell contains a bright, thread-like structure called the **supporting fibre**. This fibre is attached by a club-shaped base to the membrana basilaris, and expands, at the free end of the cell, to form one of the phalanges of the membrana reticularis.

The **cells of Hensen**, or outer supporting cells, consist of about half a dozen rows, immediately outside Deiters' cells, and form a well-marked elevation on the floor of the ductus cochlearis. Their deep extremities are narrow and attached to the membrana basilaris, whilst their free ends are expanded; each cell contains a nucleus and some pigment granules. The columnar cells, situated externally to the cells of Hensen, and covering the outer part of the zona pectinata, are named the **cells of Claudius**. A space, the **space of Nuel**, exists between the outer rods of Corti and the neighbouring row of hair-cells; it communicates with Corti's tunnel, and extends outwards between the outer hair-cells as far as Hensen's cells.

The **lamina reticularis** is a thin cuticular structure which lies over the organon spirale, and extends from the heads of the outer rods as far as Hensen's cells. It consists of two or three rows of structures, named **phalanges**, which are elongated cuticular plates resembling in shape the digital phalanges. The innermost row is formed by the phalangeal processes of the heads of the outer row of Corti's rods; the succeeding row, or rows, represent the expanded upper ends of Deiters' supporting cells. The number of rows of phalanges, therefore, varies with the number of rows of outer hair-cells and the alternating cells of Deiters. The free ends of the hair-cells occupy the circular apertures between the constricted middle portions of the phalanges.

The **membrana tectoria** (Fig. 693) is an elastic membrane overlying the sulcus spiralis internus and the organon spirale. Attached, by its inner border, to the limbus laminæ spiralis, near the lower edge of the membrana vestibularis, it reaches outwards as far as the outer row of hair-cells. Its inner portion is thin and overlies the auditory teeth of Huschke. Its outer part is thickened, but becomes attenuated near its external border, which, according to Retzius, is attached to the outer row of Deiters' cells. The hairs of the hair-cells project into the under surface of the membrane, and on this surface, opposite the interval between the inner and outer rows of hair-cells, is a clear, spirally arranged band, named **Hensen's stripe**.

Hardesty[1] is of opinion that the lateral border of the membrana tectoria is free, and is finely and irregularly scalloped. He describes the membrane as consisting of multitudes of delicate fibrils embedded in a transparent matrix of a soft, collagenous, semi-solid character with marked adhesiveness. The fibres run in curves from the vestibular lip and from the upper surface of the membrane to its under surface where, by their interlacement, they produce the appearance known as Hensen's stripe. Hardesty also describes a thin *accessory tectorial membrane*, lying along the under surface of the outer zone of the principal membrane, and attached to the latter by its outer border.

Nervus Acusticus (Fig. 694).—The **acoustic nerve** divides within the internal acoustic meatus into an anterior or cochlear and a posterior or vestibular nerve.

Nervus Cochleæ.—The **cochlear nerve** is distributed to the hair-cells of the organon spirale, the branches for the basal and middle coils entering the foramina in the tractus spiralis foraminosus, those for the apical coil running in the canalis centralis of the modiolus. The nerve-fibres traverse the bony canals of the modiolus, and then radiate outwards between the lamellæ of the lamina spiralis ossea. Contained in the spiral canal of the modiolus, near the attached margin of the lamina, is a ganglion of bipolar nerve-cells, named the **ganglion spirale** (O.T. **ganglion of Corti**) (Fig. 695); the fibres of the nerve arise from the cells of this ganglion. Beyond the ganglion spirale the nerve-fibres extend outwards, at first

[1] Irving Hardesty, *American Journal of Anatomy*, vol. viii.

in bundles, and then in a more or less continuous sheet, from the outer edge of which they are again collected into bundles, which pass through the foramina nervosa of the labium tympanicum. Beyond this they appear as naked axis-cylinders, and, turning in a spiral manner (**inner** or **first spiral fasciculus**), send

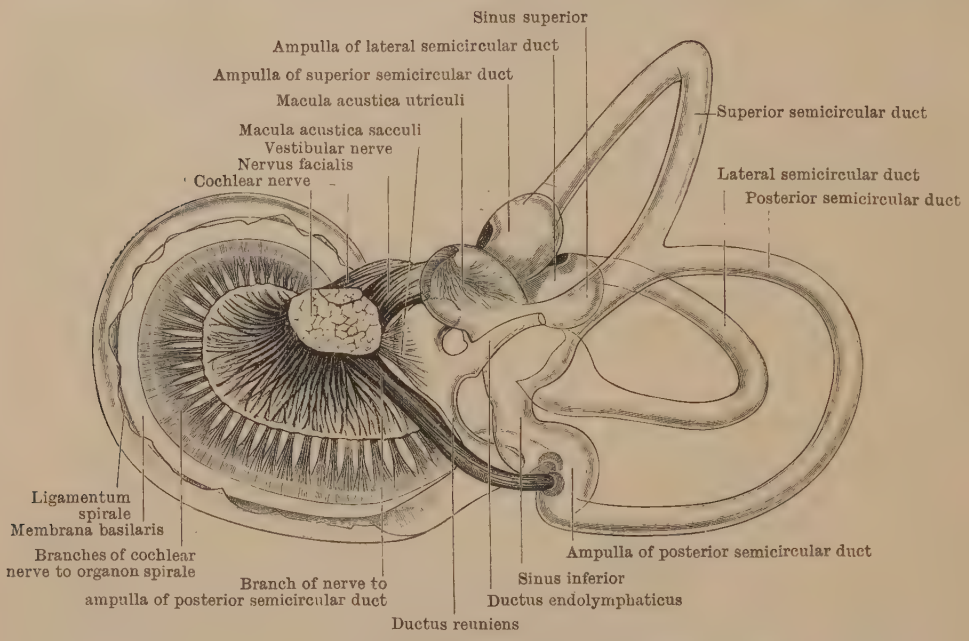

Fig. 694.—Membranous Labyrinth of a Five Months' Fœtus, viewed from its postero-medial aspect. (Retzius.)

fibrillæ towards the inner row of hair-cells. Other fibrils run between the inner rods and form a **second spiral fasciculus** in Corti's tunnel, from which fibrils extend outwards across the tunnel, and, passing between the outer rods, enter Nuel's space. They form a spiral fasciculus on the inner aspect of each row of Deiters' cells, and fibrillæ pass from these fasciculi towards the bases of the outer hair-cells.

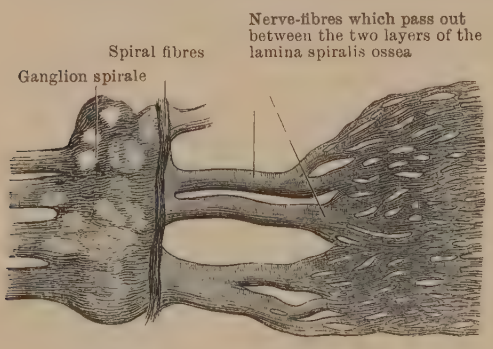

Fig. 695.—Part of Cochlear Nerve, highly magnified. (Henle.)

The hair-cells in the basal and middle coils of the cochlea are more richly supplied with nerves than those in the apical coil.

The cochlear nerve gives off a vestibular branch, the terminal filaments of which go through the foramina in the recessus cochlearis and are distributed to the hair-cells of the vestibular end of the ductus cochlearis. On this vestibular branch there is a minute ganglion (Bœttcher).

Nervus Vestibuli.—The **vestibular nerve** is distributed to the utricle, the saccule, and the ampullæ of the semicircular ducts. It divides into three branches, superior, inferior, and posterior, and each of these splits into filaments which pass through foramina in the fundus of the internal acoustic meatus. The filaments from the superior branch go through the foramina in the area vestibularis superior and supply the macula of the utricle and the cristæ ampullares of the superior and lateral semicircular ducts; those from the inferior branch run through the foramina in the area vestibularis inferior to the macula of the saccule. The posterior branch passes through the foramen singulare, and its filaments, six to eight in

number, are distributed to the crista ampullaris of the posterior semicircular duct. On the trunk of the vestibular nerve, within the internal acoustic meatus, is a ganglion, the **vestibular ganglion**, of bipolar nerve cells, from which the fibres of the nerve take origin. Sometimes the vestibular nerve divides on the proximal side of the ganglion and the latter is then split into three parts, one on each of the three branches of the nerve.

Vessels of the Internal Ear.—The arteries of the internal ear are the internal auditory artery, a branch of the basilar artery, and the stylo-mastoid artery, a branch of the posterior auricular artery. The internal auditory artery enters the internal acoustic meatus and divides into vestibular and cochlear branches. The vestibular branch supplies the soft tissues in the vestibule and semicircular canals, each canal receiving two arteries, which, starting from the ends of the canal, anastomose on the summit of the arch. The cochlear branch divides into numerous twigs, which enter the foramina in the tractus spiralis foraminosus, and run outwards in the lamina spiralis ossea to reach the soft structures; the largest of these arteries runs in the canalis centralis. The stylo-mastoid artery also supplies some minute branches to the cochlea. The **veins** from the cochlea and vestibule unite, at the bottom of the internal acoustic meatus, with the veins from the semicircular canals to form the **internal auditory vein**, which may open either into the posterior part of the inferior petrosal sinus or into the transverse sinus. A small vein passes through the aquæductus cochleæ and opens into the inferior petrosal sinus or into the internal jugular vein. Another small vein traverses the aquæductus vestibuli and ends in the superior petrosal sinus.

Development of Labyrinth (Figs. 696, 697).

The epithelial lining of the labyrinth is derived from an invagination of the cephalic ectoderm, termed the **auditory pit**, which appears opposite the hind brain immediately above the first visceral cleft. The mouth of the pit is closed by the growing together of its margins, and the pit then assumes the form of a hollow vesicle, the **otic vesicle**, which severs its connexion with the ectoderm and sinks into the subjacent mesoderm. The vesicle soon becomes pear-shaped; and from its middle part a diverticulum is given off which later forms the ductus and saccus

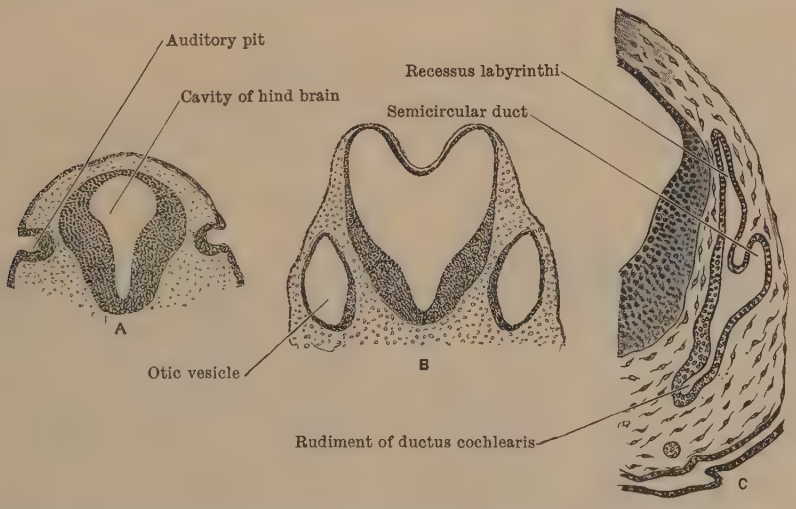

Fig. 696.—Sections through the Region of the Hind Brain of Fœtal Rabbits (to illustrate the development of the labyrinthine epithelium).

In A the ectoderm is invaginated to form the auditory pit; in B the auditory pit is closed to form the otic vesicle which is detached from the ectoderm; in C a further stage in the development of the vesicle is shown.

endolymphaticus.[1] About the fifth week the anterior part of the vesicle is prolonged forwards as a diverticulum, the future ductus cochlearis. This is at first short and straight, but it elongates and curves on itself, so that at the twelfth week all three coils of the ductus cochlearis are differentiated. From the upper part of the vesicle the three semicircular ducts are developed, and appear as hollow, disc-like evaginations; the central parts of the walls of each disc coalesce and disappear, leaving only the peripheral ring or canal. The three ducts are free about the beginning of the second month, and are developed in the following order, viz.: superior, posterior, and lateral. The intermediate part of the otic vesicle is divided by a constriction into an anterior

[1] See p. 55.

part, the saccule, communicating with the ductus cochlearis, and a posterior part, the utricle, communicating with the semicircular ducts. The constriction extends for some distance into the ductus endolymphaticus, and thus the utricle and saccule are connected by a Y-shaped tube. Another constriction makes its appearance between the saccule and the vestibular end of the ductus cochlearis and forms the **canalis reuniens**. The epithelial lining is at first columnar, but becomes cubical throughout the whole labyrinth, except opposite the terminations of the acoustic nerve, where it forms the columnar epithelium of the maculæ of the utricle and saccule, of the cristæ ampullares, and of the organon spirale. On the floor of the ductus cochlearis two ridges appear, of which the inner forms the limbus laminæ spiralis, whilst the cells of the outer become modified to form the rods of Corti, the hair-cells, and the supporting cells of Deiters and Hensen.

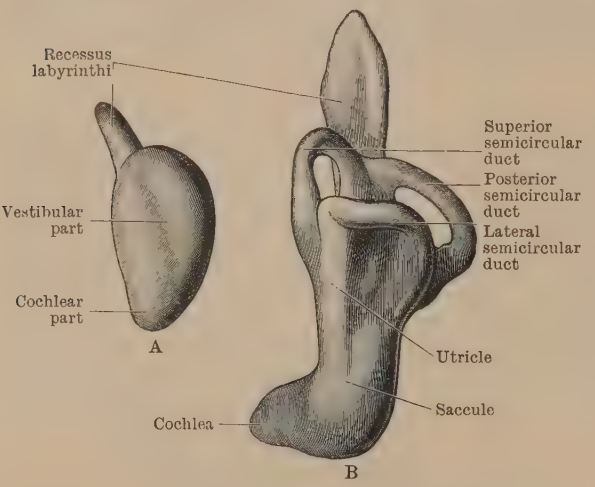

Fig. 697.

A, Left labyrinth of a human embryo of about four weeks; B, Left labyrinth of a human embryo of about five weeks. (From W. His, jun.)

The mesoderm surrounding the otic vesicle is differentiated into: (1) a fibrous layer, the wall of the membranous labyrinth; (2) a cartilaginous capsule, the future bony labyrinth; and (3) an intervening layer of gelatinous tissue, which is ultimately absorbed, leaving the perilymphatic space between the bony and membranous labyrinths.

The development of the external and middle parts of the ear are described on pp. 57, 58.

ORGANON GUSTUS.

The peripheral **gustatory organ** consists of groups of modified epithelial cells, termed **calyculi gustatorii** or **taste-buds**, found on the tongue and in its immediate neighbourhood.

Taste-buds are present in large numbers around the circumference of the

Fig. 698.

A, Section through a papilla vallata of human tongue. B, Section through a part of the papilla foliata of a rabbit.

1. Papilla. 2. Vallum. 3. Taste-buds. 4. Papillæ. 5. Taste-buds. 6. Duct of a serous gland.

papillæ vallatæ, while some are found also on their opposing walls (Fig. 698). They are very numerous over the folia linguæ, which correspond with the papillæ foliatæ of the tongue of the rabbit, and are found also over the posterior part and sides of the tongue, either on the papillæ fungiformes or throughout the stratified epithelium. They exist, also, on the oral surface of the velum palatinum and on the posterior surface of the epiglottis.

Structure of Taste-buds (Fig. 699).—The taste-buds are oval or flask-shaped, and occupy nests in the stratified epithelium of the regions mentioned. The deep extremity of each is expanded and rests upon the corium; the free end is perforated by a minute pore, termed the **gustatory pore.** They consist of two kinds of epithelial cells—(*a*) supporting cells, and (*b*) gustatory cells (Fig. 700). The **supporting cells** are elongated, nucleated spindles, and are mostly arranged like the staves of a cask to form the outer envelope of the taste-bud; but some are found in the interior amongst the gustatory cells. The **gustatory cells** occupy the centre

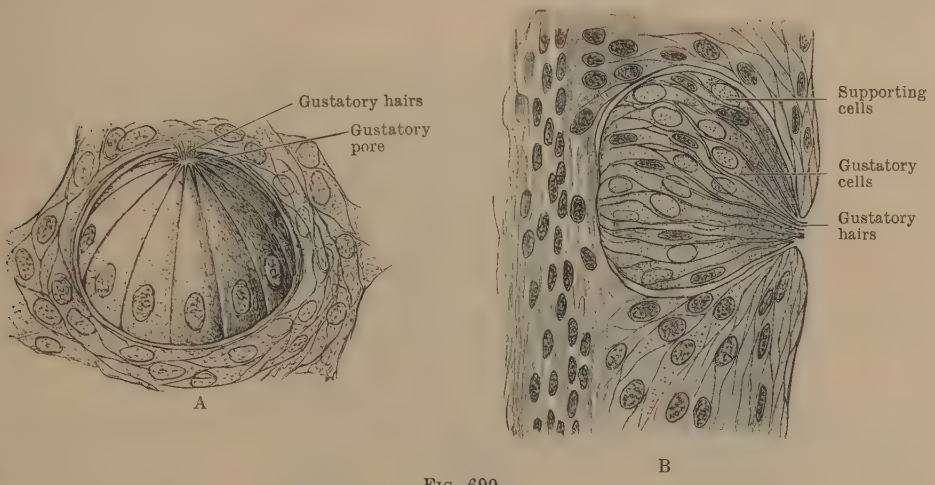

FIG. 699.

A, Three-quarter surface view of a taste-bud from the papilla foliata of a rabbit (highly magnified).

B, Vertical section of a taste-bud from the papill foliata of a rabbit (highly magnified).

of the taste-bud, and each consists of a nucleated cell-body, prolonged into a peripheral and a central process. The peripheral process is rod-like and almost hyaline, and terminates at the gustatory pore in a slender filament, the **gustatory hair.** The central process passes towards the deep extremity of the taste-bud, where it ends in a single or branched varicose filament.

Nerves of Taste.—The nerve supplying the taste-buds over the anterior part of the tongue is the chorda tympani, which is derived from the sensory root of the facial nerve; that for the posterior part is the glosso-pharyngeal. The nerve-fibrils, having lost their medullary sheaths, ramify partly between the gustatory cells and partly amongst the supporting cells of the taste-buds.

FIG. 700.—ISOLATED CELLS FROM THE TASTE-BUD OF A RABBIT. (Engelmann.)

a, Supporting cells. *b*, Gustatory cells.

The ducts of Ebner's glands open into the bottom of the valleys surrounding the papillæ vallatæ, and the serous-like secretion of these glands probably washes the free hair-like extremities of the gustatory cells, and so renders them ready to be stimulated by successive substances.

The development of the tongue is described on pp. 50-51.

INTEGUMENTUM COMMUNE.

The **integument** or **skin** covers the body, and is continuous, at the orifices on its surface, with the mucous lining of the alimentary and other canals. It contains the peripheral terminations of many of the sensory nerves, and serves as an organ

of protection to the deeper tissues. It plays an important part in regulating the body temperature, and, by means of its sudoriferous and sebaceous glands, acts as an excretory structure. Its superficial layers are modified in certain situations to form appendages in the shape of hairs and nails.

The skin is very elastic, and its colour, determined partly by its own pigment and partly by that of the blood, is deeper on exposed parts and in the regions of the genitals, axillæ, and mammary areolæ, than elsewhere. The colour varies also with race and age, and the different races of the world are roughly classified, according to the colour of their skin, into the three groups of white, yellow, and black. The skin is pinkish in colour in childhood, but it assumes a yellowish tinge in old age. In certain diseases (*e.g.* icterus and melasma Addisonii) the colour undergoes marked alteration.

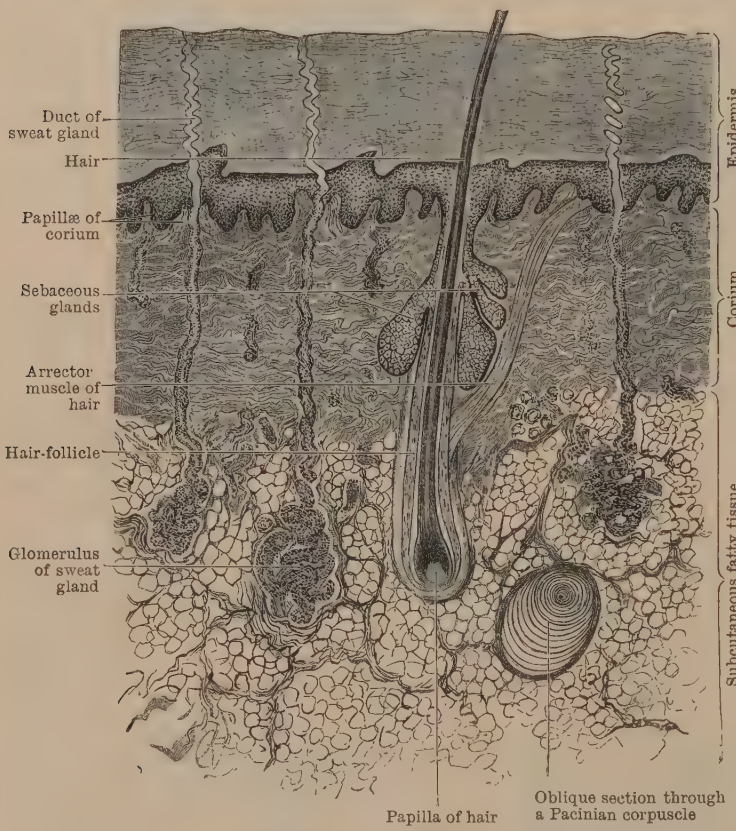

FIG. 701.—VERTICAL SECTION OF THE SKIN (schematic).

The surface of the skin is perforated by the hair-follicles and by the ducts of the sudoriferous and sebaceous glands, and on the palms, soles, and flexor surfaces of the digits it presents numerous permanent ridges, the **cristæ cutis**, which correspond with rows of underlying papillæ. Over the terminal phalanges these ridges form distinctive patterns, which are retained from youth to old age, and may be utilised for purposes of identification. Retinacula of the skin are seen in the neighbourhood of the joints, and it can be thrown into wrinkles by the contraction of the subcutaneous muscles, where those exist. Over the greater part of the body it is freely movable; but on the scalp and lateral surfaces of the auriculæ, as well as on the palms and soles, it is bound down to the subjacent tissues.

Structure.—The skin consists of a deep stratum, the corium, and a superficial, the epidermis (Fig. 701).

The **corium** or **cutis vera** is derived from the embryonic mesoderm, and consists essentially of a felted interlacement of connective tissue and elastic fibres. In the deeper layer, or **stratum reticulare** of the corium, the fibrous bundles are coarse and form an open network, in the meshes of which are vessels, nerves, pellets of fat, hair-follicles, and glands. This reticular stratum passes, as a rule, without any line of demarcation, into the panniculus adiposus or subcutaneous fatty tissue, but in some parts it rests upon a layer of striped or unstriped muscular fibres—the latter in the case of the scrotum. In the superficial layer, or **stratum papillare**, of the corium, the connective tissue-bundles are finer and form a close network. Projecting from the superficial surface of this stratum are numerous finger-like, single, or branched elevations, termed **papillæ** (Fig. 702), which are received into corresponding depressions on the deep surface of the epidermis. These papillæ vary in size, being small on the eyelids, but large on the palms and soles, where they may attain a length of 225 μ, and produce the permanent ridges already referred to. Each

ridge usually contains two rows of papillæ, between which the ducts of the sudoriferous glands pass to open on the surface. The papillæ consist of fine connective tissue and elastic fibres, mostly arranged parallel to the long axis of the papillæ; the majority contain capillary loops, but some contain the terminations of nerves. The superficial surface of the corium is covered with a thin, homogeneous basement-membrane.

The **epidermis** or **cuticle** is derived from the embryonic ectoderm and covers the corium. Its thickness varies in different parts of the body and ranges from 0·3 mm. to 1 mm. or more; it is thickest on the palms of the hands and soles of the feet, and thinnest on the eyelids and penis. It is non-vascular and consists of stratified epithelium; its superficial layers are modified to form the **stratum corneum**, which may be separated by maceration or blistering from the deeper, softer portion, or **stratum mucosum** (**Malpighi**). The epidermis consists from within outwards of the following five strata (Fig. 702):—

1. The **stratum germinativum** is a single stratum of nucleated columnar cells planted by denticulated ends on the basement-membrane of the corium.

2. The **stratum mucosum** consists of six or eight layers of polygonal, nucleated "prickle-cells," the finger-like processes of which join those of adjacent cells. Between the cells of this layer are minute channels, in which leucocytes or pigment granules may be seen. The cells of the stratum mucosum are characterised by the presence of numerous epidermic fibrils, which are coloured violet by hæmatoxylin and red by carmine. These fibrils are unaffected by boiling, but swell up under the action of acids and alkalies, and form the filaments of union between adjacent cells. On account of their presence, L. Ranvier has named this layer the **stratum filamentosum**. The dark colour of the negro's skin is caused by the presence of numerous pigment granules in the deeper layers of the stratum mucosum; the pigment—of which *melanin* forms an important constituent—is absent from the more superficial layers of the epidermis.

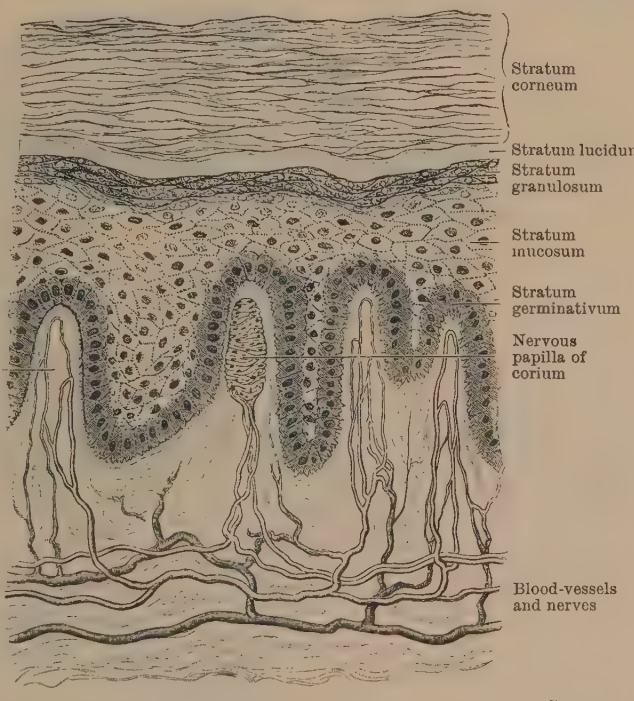

Fig. 702.—Vertical Section of Epidermis and Papillæ of Corium (highly magnified).

3. The **stratum granulosum** comprises two or three layers of horizontally arranged, flattened cells. Scattered around the nuclei of these cells are elliptical or spherical granules of *eleidin*, a substance staining deeply with carmine and hæmatoxylin, and probably representing an intermediate stage between the protoplasm of the cells of the deeper strata and the keratin of the cells of the superficial layers.

4. The **stratum lucidum** consists of several strata of squamous cells, which contain granules or droplets of *keratohyalin*, a hyaline substance, staining less deeply than eleidin.

5. The **stratum corneum** is made up of several layers of flattened non-nucleated squames, the more superficial of which assume the form of horny scales, and are from time to time removed by friction. The deeper cells contain granules of a fatty material having the consistency and plasticity of beeswax, and staining with osmic acid. The peripheral parts of the cells consist of **keratin**, a highly resistant substance which is unaffected by mineral acids, and is indigestible in pepsin-hydrochloric acid.

L. Ranvier has pointed out that the **stratum lucidum** is really double, and has named the deeper of its two layers the **stratum intermedium**; this he describes as consisting of two or three layers of clear cells with atrophied nuclei, while in the cell-walls the epidermic fibrils "are rolled up like the threads of a cocoon."

Regeneration of the epidermis is generally regarded as taking place by cell proliferation in the stratum germinativum, the young cells gradually passing through the polyhedral and granular stages, and ultimately becoming the flattened squames of the stratum corneum, while the eleidin granules of the stratum granulosum are converted into the keratin of the stratum corneum.

Vessels and Nerves of the Skin.—In the subcutaneous tissue the **arteries** form a plexus from which branches extend into the corium, where they supply the hair-follicles and glands,

and form a second plexus under the papillæ, to which small loops are given. The **veins** and the **lymph-vessels** commence in the papillæ, and, after forming subpapillary plexuses, open into their respective subcutaneous vessels.

The **nerves** of the skin vary in number in different parts of the body; they are extremely numerous where the sense of touch is acute, *e.g.* on the palmar surfaces of the terminal phalanges, whilst in the skin of the back, where the sensibility is less, they are fewer in number. Their different modes of ending are described on pp. 856-859.

Appendages of the Skin.

The appendages of the skin are the nails, the hairs, the sebaceous glands, and the sudoriferous or sweat glands.

Ungues.—The **nails** (Figs. 703, 704) are epidermal structures, and represent the hoofs and claws of the lower animals. The **root** of the nail is hidden

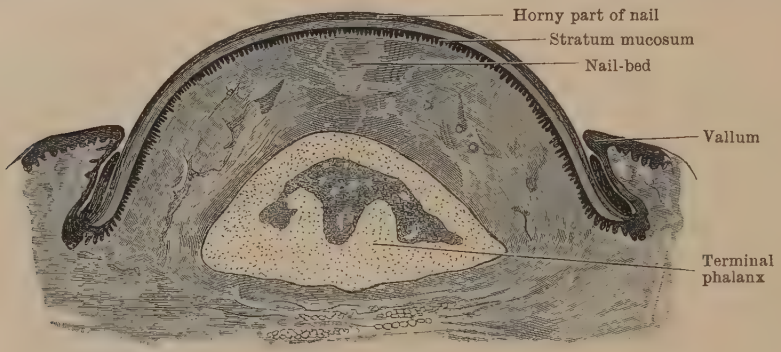

Fig. 703.—Transverse Section of a Nail.

from view and embedded in a fold of skin; the **body**, or uncovered part, rests on the corium and ends in a **free margin**. The greater part of the lateral margin of the nail is overlapped by a duplicature of skin, termed the **vallum unguis** or **nail-wall**. The nails are pink in colour, with the exception of small semilunar areas near their roots, which are more opaque than the rest, and are named the

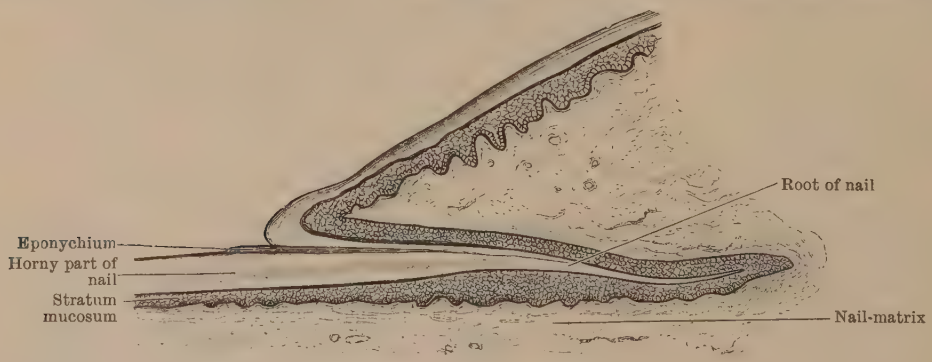

Fig. 704.—Longitudinal Section through Root of Nail.

lunulæ. The lunulæ diminish in size from the thumb towards the little finger, whilst the thickness of the nail diminishes towards its root and lateral margins. The corium under the nail is highly vascular and sensitive, and presents, especially under the anterior part of the body, numerous longitudinally arranged ridges. The part of the corium under the body is termed the **nail-bed**; that under the root, the **nail-matrix**. The deep part of the nail consists of the stratum germinativum and stratum mucosum, while its superficial horny portion is constituted by a greatly thickened stratum lucidum, and consists of nucleated, keratinised squames. The stratum corneum is represented by the thin cuticular fold overlapping the lunula, and termed the **eponychium**, while the stratum granulosum can be traced only as far forwards as the nail-root.

Pili.—Hairs are well developed on the external genitals, scalp, and margins of the eyelids, in the axilla, the vestibule of the nose, and at the entrance to the concha, and also on the face of the male. Those on the genitals and face appear about puberty. Rudimentary over the greater part of the body, hairs are absent from the flexor surfaces of the hands and feet, the dorsal surfaces of the terminal phalanges, the glans penis, the inner surface of the prepuce, and medial surfaces of the labia. Marked variations, individual and racial, exist as to the colour of the hair, and also as to the manner of its growth; hence the terms straight, curly, woolly, etc., are used to designate it. Straight hairs are coarser than curly ones, and have, moreover, a circular or oval outline on transverse section, curly hairs being flat and riband-like.

The **root of the hair** is embedded in a depression of the skin, termed the **hair-follicle** (Fig. 705); the free portion of the hair is named the **scapus** or **shaft**, and consists from without inwards of cuticle, cortex, and medulla. The *cuticle* is

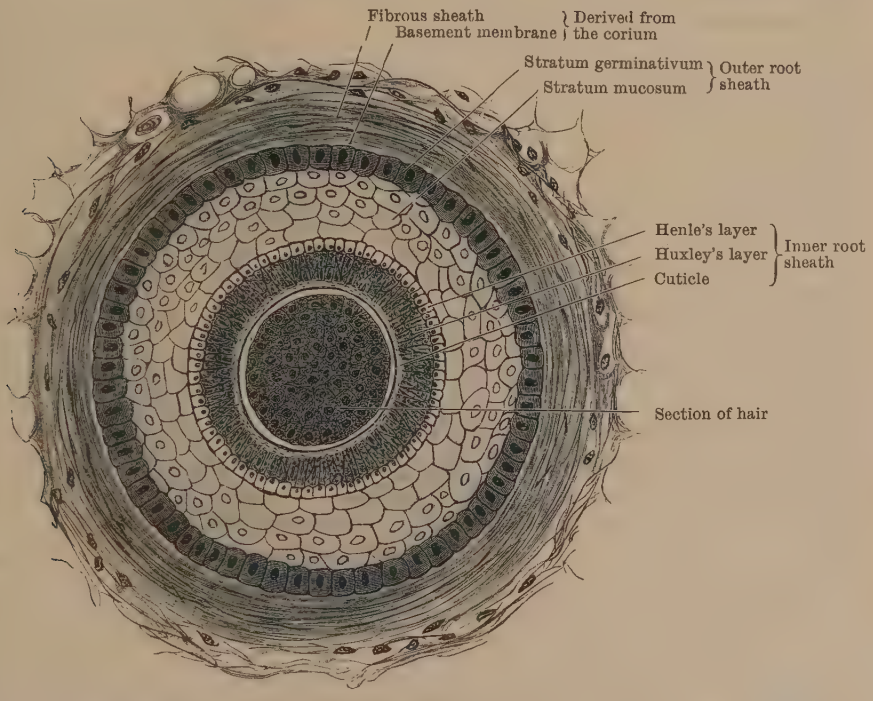

Fig. 705.—Transverse Section of a Hair-Follicle with a contained Hair (highly magnified).

formed by a layer of imbricated scales which overlap one another from below upwards. The *cortex* consists of longitudinally arranged fibres made up of elongated, closely applied, fusiform cells, which contain pigment and sometimes air-spaces, the latter especially in white hairs. The *medulla*, absent from the fine hairs of the body generally and from the hairs of young children, forms a central core, which appears black by transmitted, and white by reflected, light, and is composed of polyhedral nucleated cells containing pigment, fat-granules, and air-spaces.

The **hair-follicle** is an oblique or curved—the latter in curly hairs—invagination of the epidermis and corium, and in the case of large hairs extends into the subcutaneous tissue (Fig. 701); the ducts of the sebaceous glands open into the hair-follicles a short distance below their orifices. The dermic coat or portion of the follicle derived from the corium consists of a fibrous sheath of external longitudinal and internal circular connective tissue fibres, the latter being lined by a hyaline layer directly continuous with the basement-membrane of the corium. The parts of the follicle derived from the epidermis are named the **inner** and **outer root-sheaths**. Below the orifices of the sebaceous gland-ducts the outer root-sheath is formed by the stratum germinativum and stratum mucosum, while above these orifices all the

epidermal strata contribute to it. The inner root-sheath surrounds the cuticle of the hair, and comprises from without inwards—(*a*) *Henle's layer*, a layer of nucleated cubical cells; (*b*) *Huxley's layer*, one or two layers of polyhedral nucleated cells; and (*c*) *a delicate cuticle*, composed of a layer of flattened imbricated cells, with atrophied nuclei. The bottom of the hair-follicle is moulded on a vascular **papilla**, derived from the corium and capped by the **bulb of the hair** or expanded part of the hair-root. The cells of the bulb are continuous with those of the outer root-sheath, and form the different parts of the hair, as well as its inner root-sheath. The vessels form capillary loops in the papilla of the hair, and send twigs into the outer layer of its fibrous sheath; the inner and outer root-sheaths and the hair are non-vascular. The nerves end in longitudinal and annular fibrils below the level of the sebaceous glands and outside the hyaline layer of the follicle.

Glandulæ Sebaceæ.—**Sebaceous glands** exist wherever there are hairs, and their ducts open into the superficial parts of the hair-follicles (Fig. 701); the number of glands associated with each follicle varies from one to four. On the labia minora and mammary areolæ they open on the surface of the skin independently of hair-follicles, and in the latter situations undergo great enlargement during pregnancy. The deep end of each gland expands into a cluster of oval or flask-shaped **alveoli**, which are surrounded by a basement-membrane, and filled with polyhedral cells containing oil droplets. By the breaking down of the superficial cells, their oily contents are liberated as the *sebum cutaneum* and discharged into the hair-follicle, whilst the deeper cells undergo proliferation. The size of the glands bears no proportion to that of the hairs, the glands being very large in the minute hair-follicles of the fœtus and new-born child, and also in the follicles of the rudimentary hairs of the nose and certain parts of the face.

Bundles of non-striped muscular fibres are associated with the hair-follicles, and are named the **mm. arrectores pilorum**. Attached to the deep part of the hair-follicle, and forming with it an acute angle, they pass outwards close to the sebaceous glands, and end in the papillary layer of the corium. They are situated on the side towards which the hair slopes, so that, on contraction, they diminish the obliquity of the hair-follicle and render the hair more erect, and, at the same time, compress the sebaceous glands and expel their contents. The condition of "goose-skin" is caused by the contraction of these slender muscles.

Arthur Thomson suggests that the condition of curly hair is produced by the contraction of the mm. arrectores pilorum. Straight hair is thick and cylindrical; curly hair is flat and ribbon-like. When the arrector muscle contracts, the thick rounded hair resists the tendency of the muscle to bend it, while the flat hair, not sufficiently strong to resist the strain of the muscle, becomes bent, and this is probably the explanation why the follicle assumes the curved form characteristic of the scalp of a bushman. The sebaceous gland lies in the concavity of the bend between the follicle and the muscle, and forms a mass of greater resistance, around which the follicle may be curved by the contraction of the muscle. The cells at the root of the hair accommodate themselves to the curved follicle, and, becoming more horny as they advance to the surface, retain the form of the follicle in which they are moulded.

Glandulæ Sudoriferæ.—**Sudoriferous** or **sweat glands** are found in the skin of nearly every part of the body; they are relatively few in number on the back of the trunk, but are very plentiful on the palms and soles, where they open on the summits of the curved ridges. Each consists of an elongated tube; the deeper portion of the tube forms its secretory part, and is coiled in the subcutaneous tissue or deep part of the corium in the form of an ovoid or spherical ball, termed the **corpus glandulæ sudoriferæ** (O.T. **glomerulus**) (Fig. 701). The superficial part of the tube, or **ductus sudoriferus**, extends through the corium and epidermis, and opens on the surface by a funnel-shaped orifice, the **porus sudoriferus**; where the epidermis is thick the duct is spirally coiled. The corpora glandulæ, as a rule, vary in diameter from 0·1 to 0·5 mm., but in the axillæ they measure from 1 to 4 mm. Each is surrounded by a capillary network and by a capsule of connective tissue, inside which is a homogeneous basement-membrane. The lumen of the tube is lined by a layer of nucleated, granular, and striated, columnar, epithelial cells, between the deep ends of which and the basement-membrane is a layer of non-striped muscular

fibres, the long axis of the fibres being more or less parallel with that of the tube. The excretory ducts are devoid of muscular fibres, and consist of a basement-membrane lined by two or three layers of polyhedral cells, which are covered, next the lumen of the duct, with a thin cuticle.

The **glandulæ ciliares**, at the margins of the eyelids, and the **glandulæ ceruminosæ** of the external acoustic meatus, are modified sudoriferous glands; the former are, however, not coiled, while the cell-protoplasm of the latter contains yellowish pigment, and their gland-ducts, in the fœtus, open into hair-follicles.

Development of the Skin and its Appendages.

Skin.—The vascular and sensitive corium is developed from the mesoderm, the cells of which, immediately underlying the ectoderm, have, by the second month of fœtal life, become aggregated together and flattened parallel to the surface of the embryo. By the third month they form two layers, the superficial of which becomes the corium, and the deeper the subcutaneous tissue; the papillæ of the corium make their appearance in the fourth month. The epidermis, nails, hairs, sudoriferous and sebaceous glands are of ectodermal origin.

The epidermis at first consists of a single layer of cells, but by the end of the second month two layers are present, a superficial, of irregular cells, and a deeper, of more or less cubical cells. By the third month three strata are seen; the deep layer consists of a layer of cubical cells—the future stratum germinativum; the middle comprises two or three layers of irregular cells—the future stratum mucosum; and the superficial, a double stratum of large cells. This superficial layer appears to be homologous with a thin membrane, termed the *epitrichium*, first described as covering the embryo of the sloth and overlying its hairs, but since shown to be present also in birds and mammals. Over the hairy parts of the body the epitrichium disappears about the sixth month; but over the free edges and the roots of the nails, and on the palms and soles, it develops into several layers of cells, which, in these parts, probably persist to form the thick stratum corneum. The part which persists over the roots of the nails is termed the *eponychium*, and covers the proximal parts of the lunulæ (p. 852, Fig. 704).

Nails.—The rudiments of the nails are seen about the beginning of the third month of fœtal life, and consists of thickenings of the epitrichium over the ends of the digits. Owing to the greater growth of the volar surfaces of the digits, the nail rudiments come to be placed dorsally, and, at the proximal edge of each, an ingrowth of the stratum mucosum occurs to form its root, while the future nail is limited behind and at the sides by a groove. The superficial cells of the stratum mucosum are keratinised to form a thick stratum lucidum, the future nail proper, over the greater part of which the epitrichium disappears. The latter persists in the adult as the eponychium across the root of the nail, and, until the fifth month, also forms a thick mass over the distal edge of the nail, and is continued into the stratum corneum over the end of the digit. The future distal edge of the nail, at this stage, is continuous with the stratum lucidum in front of it; but this continuity is lost, and by the seventh month the nail presents a free border. The nails grow in length, and are renewed, in case of removal, by a proliferation of the cells of the stratum mucosum at the roots of the nails, while an increase in their thickness takes place from the stratum mucosum underlying the lunulæ.

Hairs.—The hair-rudiments appear about the third month of fœtal life as solid downgrowths of the stratum mucosum, which pass obliquely into the subjacent corium. The deep end of each downgrowth of cells expands to form the hair-bulb, and is moulded on a papilla derived from the corium; the epidermis immediately overlying the papilla is differentiated into the hair and its inner root-sheath, while the peripheral cells form its outer root-sheath. The surrounding corium is condensed to form the fibrous sheath of the hair-follicle, the hyaline layer of which is continuous with the basement-membrane covering the corium. The hair gradually elongates, and, reaching the neck of the follicle, its extremity lies at first under the epitrichium, but becomes free on the disappearance of the latter about the fifth month of fœtal life. The first crop of hairs constitutes the *lanugo*, and is well developed by the seventh month; it consists of very delicate hairs, some of which are shed before, the remainder shortly after birth—the last to drop out being those of the eyelashes and scalp—and are replaced by stronger hairs. Shedding and renewal of the hairs take place during life; prior to the shedding of a hair active growth and proliferation of the cells of the hair-bulb cease, and the papilla becomes atrophied, while the hair-root, gradually approaching the surface, at last drops out. New hairs arise from epidermic buds, which extend downwards from the follicle, and their development is identical with that of the original hairs.

Sebaceous Glands.—These appear about the fifth month of fœtal life as solid outgrowths from the sides of the hair-follicles, and consist of epidermal offshoots continued from the cells of the outer root-sheath. Their deep ends become enlarged and lobulated, to form the secreting part of the gland, while the narrow neck connecting this with the follicle forms its duct. The sebaceous secretion, together with the cast-off epidermal cells, is collected on the surface of the body during the last months of intra-uterine life, and forms a layer of varying thickness, termed the *vernix caseosa* or *smegma embryonum*.

Sudoriferous Glands.—These, like the hairs, arise as solid downgrowths of the stratum mucosum. They descend, however, perpendicularly, instead of obliquely, and are of a yellowish colour; they appear on the palms and soles early in the fifth month of fœtal life, but much later

over the hairy parts of the body. The downgrowths extend through the corium, and, on reaching the subcutaneous tissue, become coiled up to form the body or secreting part of the gland. The ducts of the glands do not open on the surface until the seventh month.

ENDINGS OF NERVES OF GENERAL SENSATIONS.

Under this heading will be described the terminations of those sensory nerves which are widely distributed throughout the body and are associated with the muscular sense and the senses of pressure, heat, cold, and pain. These nerves may end (*a*) as fine ramifications of the naked axis-cylinders lying *free* amongst the tissues, or (*b*) in *special end-organs* where the terminations of the axis-cylinders are surrounded by connective tissue capsules.

FREE NERVE-ENDINGS.

Free nerve-endings are found chiefly in the epithelium covering the skin or the mucous membranes, and constitute the peripheral pain end-organs. The nerve-fibres, after subdividing in the sub-epithelial connective tissue, lose successively their medullary and primitive sheaths and are continued as naked axis-cylinders, which, if stained with gold chloride, are seen to consist of fine varicose filaments. The axis-cylinders subdivide and form primary and secondary plexuses, and from the latter numerous fibrillæ pierce the sub-epithelial basement-membrane and ramify between the overlying epithelial cells where they end in minute knobs or flattened discs. In the epidermis the nerve-fibrillæ are limited to the stratum mucosum, but in the cornea they reach the surface layers of epithelium (Fig. 706). Free nerve-endings also occur around the sudoriferous glands, in the papillæ and root-sheaths of the hair-follicles, in the sub-epithelial and intermuscular connective tissues, and in serous membranes.

a, *b*, primary plexus in connective tissue of cornea; *c*, branch passing to sub-epithelial plexus *d*; *e*, intra-epithelial plexus; *f*, terminations of fibrils.

Modifications of free nerve-endings are seen in the *tactile discs* or *cells of Merkel*; here the neuro-fibrillæ end in the deeper layers of the epidermis in crescentic or cup-shaped expansions, in contact with large, modified epithelial cells. These tactile discs are well marked in the pig's snout (Fig. 707).

SPECIAL END-ORGANS.

The special end-organs vary greatly in size and form, but in all of them the termination of the axis-cylinder is enclosed within a connective tissue capsule or sheath of varying thickness. The following are the more important special end-organs.

(1) **End-bulbs of Krause** (Fig. 709).—These are minute cylindrical or oval bodies which are found in the conjunctiva, in

the mucous membrane of the lips, and in the skin of the glans penis and glans clitoridis. Each consists of a thin connective tissue capsule enclosing a core of homogeneous or nucleated semifluid substance. As the nerve-fibre pierces the capsule, it loses its medullary sheath, and the axis-cylinder is continued into the core of the bulb where it may pursue a somewhat tortuous course, but more frequently divides into minute varicose fibrils which form an intricate plexus. The end-bulbs of the glans penis and glans clitoridis are named *genital corpuscles* and differ from those just described in that they are larger and possess thicker capsules. Similar endings, termed *articular bulbs*, are found in the synovial membranes of certain joints, *e.g.* those of the fingers.

Fig. 708.—Grandry's Corpuscles from the Duck's Tongue (Izquiardo). (From Quain's *Anatomy*.)

A, composed of three cells with two interposed discs, into which the axis-cylinder of the nerve-cell is observed to pass. In B there is but one tactile disc enclosed between two tactile cells.

(2) **Corpuscles of Grandry** (Fig. 708).—These are seen in the skin covering the beaks of aquatic animals, and in the mucous membrane of the duck's palate. Each consists of two or more flattened epithelial cells enclosed within a capsule, and the axis-cylinder ends in flattened "tactile discs" which lie between the cells.

(3) **Corpuscles of Pacini** (Fig. 709).—These are widely distributed and consist of small oval bodies which measure from 2 to 3 mm. in length and about 1 mm. in width. They are found on the cutaneous nerves of the hand and foot, on the infra-orbital and intercostal nerves, on the cutaneous nerves of the neck, nipple, and

mamma, and on the nerves of the solar plexus. They are present in the parietal peritoneum and on the nerves of the joints, and are very plentiful in the mesentery of the cat. The capsule of the corpuscle consists of a number of connective tissue tunics arranged concentrically around a central core of more or less clear protoplasm; the deeper tunics are closely applied to each other, but those towards the circumference of the corpuscle are here and there separated by narrow lymph-spaces. Each corpuscle is attached to a nerve trunk by a narrow pedicle composed of a single medullated nerve-fibre which pierces the capsule and, on reaching the

core, loses its medullary sheath. The axis-cylinder is continued into the core as far as its distal end and there terminates in one or more enlargements in which the neuro-fibrillæ form a dense plexus. The **corpuscles of Herbst** (Fig. 710), which are found in the skin of birds, differ from the Pacinian corpuscles in that their cores consist of nucleated cells, between which the axis-cylinder extends as a single or branched process.

(4) **Corpuscles of Golgi and Mazzoni.**—These are present in the subcutaneous tissue of the pulp of the fingers and also in other parts of the skin. Their capsules are

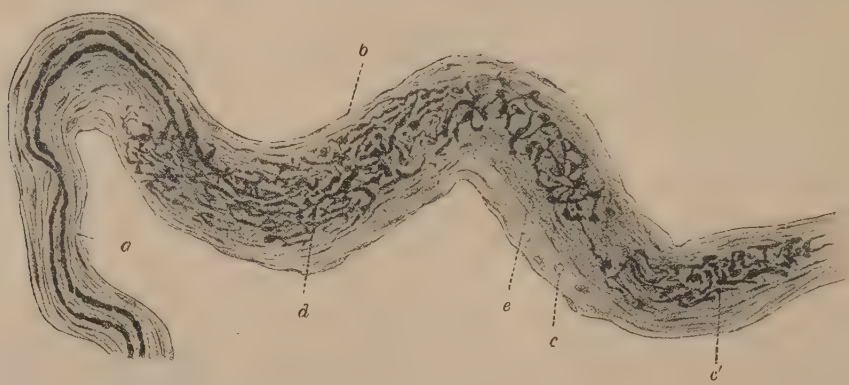

Fig. 711.—An Organ of Ruffini from the Subcutaneous Tissue. (From Quain's *Anatomy*.)

a, Entering nerve-fibres ; *b*, *d*, endings of their axis-cylinders ; *e*, *c*, capsule of organ ; *c'*, core.

thinner and their cores thicker than those of the Pacinian corpuscles, while their axis-cylinders undergo a greater degree of ramification and their terminal filaments end in somewhat flattened expansions.

(5) **Tactile Corpuscles of Wagner and Meissner** (Fig. 709).—These are plentifully distributed in the papillæ of the corium of the hand, foot, and front of the forearm. They are found also in the skin of the lips, in the mucous membrane of the tip of the tongue, in the palpebral conjunctiva and the skin of the nipple. They are

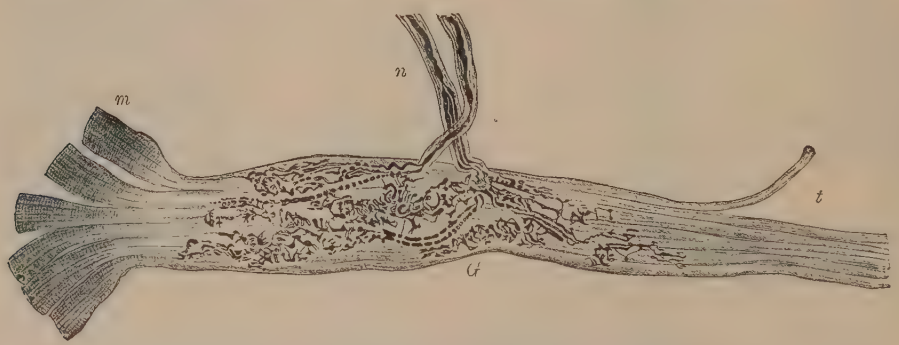

Fig. 712.—Organ of Golgi from the Human Tendo Calcaneus, Chloride of Gold Preparation (Ciaccio). (From Quain's *Anatomy*.)

m, Muscular fibres ; *t*, tendon bundles ; G, Golgi's organ ; *n*, two nerve-fibres passing into it.

oval in shape, and their length varies from ·04 mm. to ·15 mm., and their thickness from ·03 mm. to ·06 mm. One or more nerve-fibres pierce the capsule of the corpuscle, losing, at the same time, their medullary sheaths. The axis-cylinders, which are frequently varicose, assume a spiral or convoluted course and end in terminal enlargements. From the deep surface of the capsule imperfect membranous septa are continued inwards between the nerve ramifications.

(6) **Organs of Ruffini** (Fig. 713).—These were found by Ruffini in the subcutaneous connective tissue of the fingers. They are of considerable size, and their shape is oval or fusiform. One or more nerve-fibres penetrate the side of the capsule, within which they pursue a curved course and then lose their medullary sheaths.

The axis-cylinders break up into a close-meshed network which lies between, or partly encircles, the smaller fasciculi of connective tissue.

(7) **Neuro-tendinous Spindles** (Fig. 712).—These were first described by Golgi in 1878. They consist of long spindle-shaped bodies, and are usually found near the junctions of the tendons with their muscles. Each is surrounded by a capsule which encloses a number of *intrafusal* tendon fasciculi. The nerve-fibres pierce the side of the capsule and then lose their medullary sheaths; the axis-cylinders subdivide, and their terminal branches ramify between, or partly encircle, the smaller tendon bundles and end in plate-like expansions.

(8) **Neuro-muscular Spindles.**—These are widely distributed throughout the voluntary muscles but are more numerous in the muscles of the limbs than in those of the trunk, and are plentifully found in the muscles of the hand and foot. They have not yet been seen in the intrinsic muscles of the tongue, and only a few are present in the ocular muscles. They lie in the connective tissue between the muscular bundles, and each consists of a lamellated capsule enclosing a fasciculus of striped muscular fibres (*intrafusal fibres*), together with minute blood-vessels and three or four medullated nerve-fibres. These intrafusal muscular fibres display many of the characteristics of embryonic muscle; they are smaller both in length and diameter than ordinary muscular fibres; they contain numerous nuclei near the centre of the spindle where their cross striation is less distinct; they also possess more protoplasm than ordinary muscular fibres. The nerve-fibres pierce the side of the capsule, inside which they lose their medullary sheaths and undergo subdivision; they are then prolonged in a spiral or annular manner around the individual muscular fibres and end in flat or oval enlargements.

Fig. 713.—Ending of Nerve-fibres in Muscle Spindle (Ruffini). (From Quain's *Anatomy*.)

Three intrafusal muscular fibres are shown: *x*, nerve-fibres entering spindle; *a*, axis-cylinders terminating around and between the intrafusal fibres in *b*, ring-like; *c*, spiral; and *d*, irregularly ramified endings.

THE VASCULAR SYSTEM.

By the late Alfred H. Young,
Professor of Anatomy, Victoria University, Manchester,
and
Arthur Robinson,
Professor of Anatomy, University of Birmingham.

Revised and partly rewritten by Arthur Robinson, M.D.,
Professor of Anatomy in the University of Edinburgh.

All the tissues of the body require that food and other materials necessary for their growth, maintenance, and work shall be carried to them in a fluid form, and that the products of their work shall be removed, also in a fluid form, either to the tissues by which they can be used or, if they are residual or effete and would be dangerous if they accumulated in the body, to places where they can be eliminated.

It is to meet these necessities that the tubular vascular system is provided. It is filled with the media used for the transport of materials to and from the tissues which are corpuscle-laden fluids called **blood** and **lymph.**

It consists of the **heart, arteries, veins,** and **lymph vessels.**

The heart is a rhythmically contractile muscular pump, and it is divided into receiving and ejecting chambers. During the intervals between its rhythmical contractions blood flows into its receiving chambers, which are termed **atria,** from vessels called **veins.** As soon as the receiving chambers are full they contract and force their contents into ejecting chambers called **ventricles,** then the ventricles contract and project the blood into efferent vessels known as **arteries.**

The two stem arteries into which the blood is projected are necessarily large, but they break up into branches, which again branch, and so, by repeated branchings, the arteries rapidly become smaller as they approach the tissue areas they supply. Ultimately the smallest branches, which are called **arterioles,** end in plexuses of vessels of extremely small calibre which are known as **capillaries.**

Capillary networks, whose meshes vary in size and form in different regions, are found in all tissues except cartilage. They are drained by vessels called **veins,** which gradually unite with one another to form larger and larger trunks, and through the terminal and largest trunks the blood is returned to the atria of the heart.

As the blood passes through the parts of the capillary plexuses into which the arterioles open, some of its fluid portion, which is termed **blood plasma,** passes through the thin walls of the capillaries and permeates the tissues, from which part re-enters the capillaries towards their venous ends, and so is returned to the heart.

The remaining part is passed from the tissues into a set of capillary vessels called **lymph capillaries.** The lymph capillaries join larger vessels, **lymph vessels,** which unite together, like the smaller veins, to form still larger vessels, and ultimately all the lymph is passed into two terminal lymph vessels, one on the right and one on the left side, which end in the great veins at the root of the neck; thus the fluid which irrigates the tissues is eventually passed on to the heart.

It is, however, a well-known fact that much fluid containing effete products is

removed from the body by the action of the kidneys as urine. The fluid exudes from the renal blood capillaries and is transmitted through the walls of the renal tubules into their cavities, and so by way of the ureter and urinary bladder to the exterior. A large quantity of fluid is also given off from the skin and in the breath from the lungs as watery vapour. The fluid thus passed out of the body is replenished by fluid taken in by the mouth and passed, after it becomes food-laden, through the walls of the abdominal part of the alimentary canal, into the blood and lymph capillaries which lie in the tissues of those walls.

An indispensable necessity for the proper performance of tissue work, other than food in the ordinary sense, is **oxygen**, and one of the effete products which must be discharged is **carbonic acid.**

The lowest vertebrates obtain their oxygen from water, by means of capillary plexuses in their gills through which the blood passes on its way from the heart to the tissues. In fishes, therefore, the heart is essentially a single tube, divided mainly into a single receiving and a single rejecting chamber.

Gills are not, however, well adapted for obtaining oxygen from air; therefore as land animals were evolved from fish other means for obtaining oxygen had to be adopted, and special organs called lungs were developed.

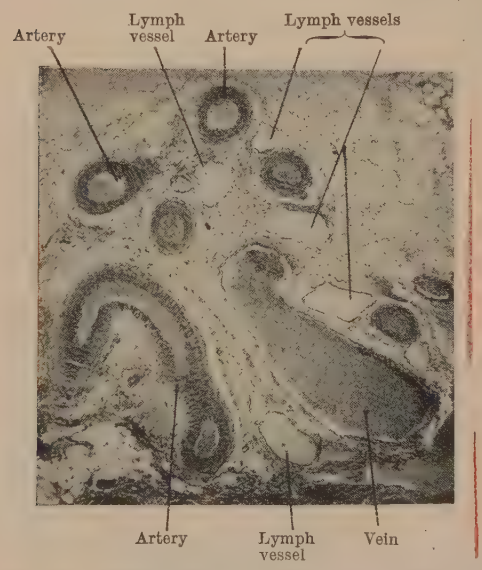

FIG. 714.—PHOTOGRAPH OF A SECTION OF ARTERIES, A VEIN, AND LYMPH VESSELS.

Since a certain amount of moisture is necessary for all active tissues, obviously the gills were ill adapted for transformation into lungs. They were placed too superficially and their surface epithelium, which would have had to play an active part, could not have been easily and regularly kept in a sufficiently moist and warm condition.

Another organ, the swim-bladder of certain fishes, was available. It was deeply situated and therefore could be kept warm and moist; further, it developed as a diverticulum from the alimentary canal and consequently could be kept in communication with the external air through the mouth and nose. It was supplied, however, by branches of the aorta which contained oxygenated blood; consequently, its adoption for transformation into lungs necessitated an alteration of the circulation, whereby it should be possible for the venous blood, returned to the heart by the veins, to be sent first through the lungs, where it could lose its carbonic acid and obtain oxygen, and then through the body generally.

The process of evolution whereby this object was attained was gradual during the period of transition from fish to mammal. It was fully achieved by the complete division of the single longitudinal tube of the primitive heart into right and left halves, by the formation of septa, and by the connexion of the right ventricle with arteries passing to the lungs and the left atrium with the veins returning blood from the lungs, whilst the left ventricle was connected with the arteries supplying the body generally and the right atrium with the veins returning blood from the body. In this way two circulations were established, the pulmonary and the systemic; the arteries and veins of the lung circulation constituting the **pulmonary system of blood-vessels**, and those of the body generally the **systemic system of blood-vessels**, which are subdivisions of the blood vascular system.

There is in addition the system of vessels called lymph vessels which return some of the fluid from the tissues to the systemic veins. They constitute the **lymph vascular system.**

THE TISSUES OF THE VASCULAR SYSTEM.

The tissues of which the various parts of the vascular system are composed are, endothelium, areolar tissues, white fibrous tissue, elastic tissue, unstriped muscle, and cardiac muscle, and of these endothelium alone is found in all parts of the system. It lines the cavities of the heart, the arteries, the arterioles, the veins, and the lymph vessels, and it is the only constituent of the walls of the majority of the capillaries.

The Tissues of the Heart.—The heart consists mainly of cardiac muscle with a certain amount of areolar tissue, white fibrous tissue and elastic tissue, and its cavities are lined with a single layer of endothelial cells.

The cardiac muscle is peculiar, inasmuch as its cells are striated like voluntary muscle, but they are devoid of a cell membrane. They branch and anastomose

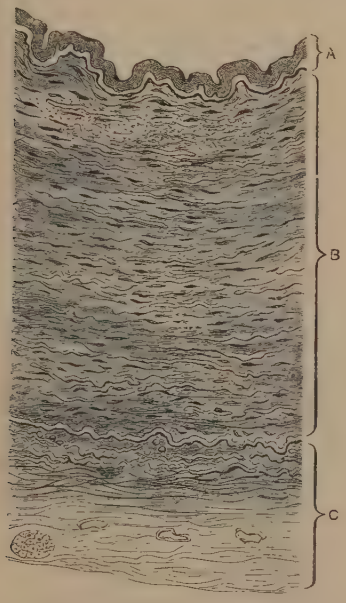

FIG. 715.—TRANSVERSE SECTION THROUGH THE WALL OF A LARGE ARTERY.

A, Tunica intima. B, Tunica media. C, Tunica externa.

FIG. 716.—PHOTOGRAPH OF A LONGITUDINAL SECTION OF A SMALL ARTERY.

with one another, their nuclei are central, and they are not under the control of the will; that is, they are involuntary.

The contractions of the muscle provide the main propulsive force which drives the blood through the blood-vessels.

The tissues of the arteries are unstriped muscle, areolar tissue, white fibrous tissue, elastic tissue, and endothelium. All the arteries are lined by a single layer of endothelial cells, but the other tissues are present in different amounts in different vessels.

In vessels of the largest size elastic tissue predominates, so that by their distension, as blood is suddenly forced into them by the contractions of the heart, the smaller vessels may be preserved from sudden great strain, whilst the elastic reaction of the distended walls keeps up a steady onflow of blood in the arteries, in the intervals between the contractions of the heart.

All parts of the body are not equally active at the same time, and it is obvious that an active part will require, during its activity, more blood than it does when it is quiescent. Therefore it is necessary that the flow of blood to any particular tissue or organ shall be capable of regulation. The regulation is obtained by means of unstriped muscle, which predominates in the arteries of medium and small size.

The muscle consists of spindle-shaped cells which, for the main part, are

arranged in spiral bundles in the middle parts of the walls of the arteries, where they form, with a little intermingled areolar, elastic and white fibrous tissue, the **tunica media** or middle coat of the artery.

The muscle fibres are not under control of the will, that is they are involuntary, but they are under control of the nervous system. Therefore when there is a call from any area for more blood they are relaxed, the calibres of the arteries are enlarged and more blood is permitted to flow through them, whilst when less blood is required they are contracted and the lumina of the arteries are diminished.

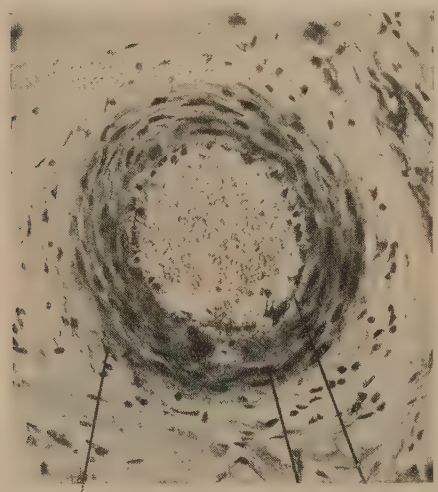

FIG. 717.—PHOTOGRAPH OF A TRANSVERSE SECTION OF A SMALL ARTERY.

The tunica media, above spoken of, intervenes between the two other coats of the arteries, which are termed respectively the **tunica intima** and the **tunica externa.**

The Tunica Intima.—The constituent parts of the tunica intima, as it exists in arteries of medium size, are the endothelial lining, a thin layer of fine connective tissue fibres and cells called *subendothelial connective tissue,* and a layer of elastic fibrils, running more or less longitudinally, or an elastic fenestrated membrane called the *elastic lamina.*

In the smaller arteries the subendothelial tissue disappears. The smallest arteries are devoid of the elastic lamina also.

In the larger arteries, on the other hand, the subendothelial tissue increases in amount and is intermingled with elastic fibrils which merge into the elastic lamina so that the boundary between the two is lost, whilst in the largest arteries the combined subendothelial tissue and elastic lamina are blended with the tunica media, which itself consists mainly of layers of elastic fibrils.

The Tunica Media.—In typical arteries, that is, arteries of medium size, the middle coat consists mainly of unstriped muscle fibres bound together and into more or less spiral strata, by fine connective tissue intermingled with the elastic fibrils.

As the arteries become smaller, and the tunica media is reduced, the muscular strata become fewer and fewer until only a single layer of scattered fibrils remains (Fig. 718). In the largest arteries the muscle fibres disappear and are replaced by increase of the elastic fibrils.

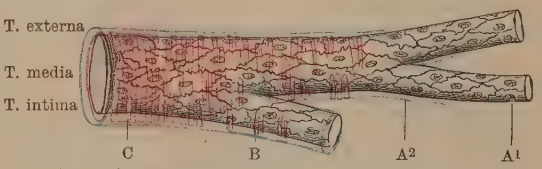

FIG. 718.—STRUCTURE OF BLOOD-VESSELS (diagrammatic).

A^1, Capillary—with simple endothelial walls. A^2, Larger capillary—with connective tissue sheath, "adventitia capillaris." B, Capillary arteriole—showing muscle cells of middle coat, few and scattered. C, Artery—muscular elements of the tunica media forming a continuous layer.

Tunica Externa. — The outer tunic of an artery consists almost entirely of fibrillated connective tissue, in which lie many connective tissue corpuscles. In all but the smallest arteries numerous elastic fibres are also present. The elastic element is specially strong near the middle coat in small and medium-sized vessels, and is sometimes described as an external elastic membrane. In some arteries longitudinally arranged unstriped muscular fibres are also found in the external coat.

The external coat is the strongest and least friable coat of the artery. It disappears on the smallest arteries as the muscle fibres disappear, but is very strong around small, medium, and large arteries.

Vagina Vasis.—In addition to the three tunics above described, arteries

are enclosed in a **sheath** of the surrounding connective tissue, and are more or less connected with it by fine strands of fibrillated connective tissue.

The Tissues of Capillaries.—Capillaries measure from 8 μ to 12·5 μ in diameter, and about ·75 mm. in length. Their walls are simple, and, in the smallest capillaries, consist of elongated elastic endothelial cells, with sinuous edges, pointed extremities, and oval nuclei. The cells are cemented to one another, along their margins, by intercellular cement, which readily stains with nitrate of silver. Here and there the cement substance appears to accumulate, forming minute spots indicative of the less perfect apposition of the edges of the cells. Such spots, when small, form the so-called **stigmata**; when larger they are known as **stomata.**

The larger capillaries are invested by a connective tissue sheath consisting of branched cells which are united together and to the endothelial cells of the capillary wall. This sheath is termed the **tunica externa capillaris.**

Capillaries are arranged in networks, the nature and character of which differ in different tissues. The small arteries which end in them are known as **capillary arterioles**, and the venous radicles which commence from them are appropriately termed **capillary veins.**

Exchanges between the blood and lymph and the tissues take place through the walls of the capillaries, but only where they consist of endothelium alone.

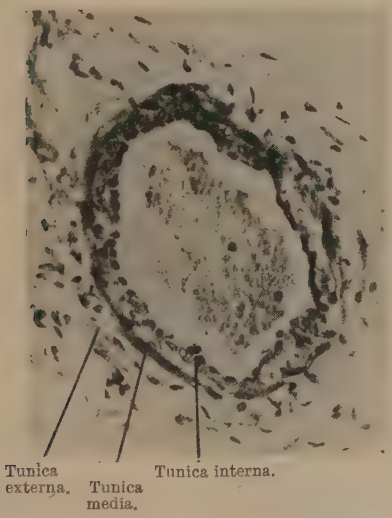

FIG. 719.—PHOTOGRAPH OF A TRANSVERSE SECTION OF A SMALL VEIN.

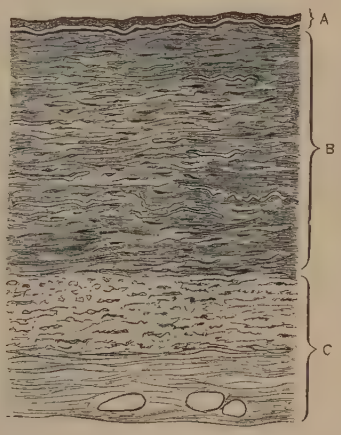

FIG. 720.—TRANSVERSE SECTION OF THE WALL OF A VEIN.

A, Tunica intima. B, Tunica media. C, Tunica externa.

The Tissues of Veins.—The walls of veins are similar in structure to those of arteries; they are, however, thinner, so much so, that, although veins are cylindrical tubes when full of blood, they collapse when empty and their lumina almost disappear. The structural details of the three tunics vary somewhat in different veins; in most the innermost tunic is marked by folds which constitute valves. Like the arteries, the veins are enclosed in connective tissue sheaths.

Tunica Intima.—In the majority of the veins the tunica intima includes an internal endothelial layer, a middle layer of subendothelial connective tissue, and an outer layer of elastic tissue. The innermost tunic of a vein is less brittle than the inner coat of an artery, and is more easily peeled off from the middle coat. The subendothelial tissue is a fine fibrillated connective tissue, less abundant than in the arteries, and in many cases it is absent. The elastic layer consists of lamellæ of elastic fibres which are arranged longitudinally; it rarely has the appearance of a fenestrated membrane.

One of the chief peculiarities of the tunica intima is the presence of folds of its substance which constitute **valves.** The cusps of the valves are of semilunar shape, and they are usually arranged in pairs. Their convex borders are continuous with the vessel wall, and their free borders are turned towards the heart; whilst,

therefore, they do not interfere with the free flow of blood from the periphery, they prevent any backward flow towards it, and they help to sustain the column of blood in all vessels in which there is an upward flow. Each valve cusp consists of a fold of the endothelial layer, strengthened by a little connective tissue. As a general rule, the wall of the vein is dilated on the cardiac side of each valve into a shallow pouch or sinus; consequently, when the veins are distended they assume a nodulated appearance. The valves are more numerous in the deep than in the superficial veins, and in the veins of children than in the veins of adults.

Tunica Media.—The middle tunic is much thinner than the corresponding tunic of an artery, and it contains a smaller amount of muscular and a larger amount of ordinary connective tissue; indeed, so much does the latter preponderate that it separates the muscular fibres into a number of bands, which are isolated from one another by strands of connective tissue; therefore the muscle fibres do not form a continuous layer. In some of the veins the more internal muscular fibres do not retain the transverse direction which is usually met with both in arteries and veins; on the contrary, they run longitudinally. This condition is met with in the branches of the mesenteric veins, in the femoral and iliac veins, and in the umbilical veins. The middle tunic is absent in the thoracic part of the inferior vena cava; it is but slightly developed in many of the larger veins, whilst in the jugular veins its muscular tissue is very small in amount.

Tunica Externa.—This tunic consists of white fibrous and elastic tissue. In many of the larger veins a considerable amount of muscular tissue is also present; this is the case in the iliac and axillary veins, the abdominal part of the inferior vena cava, the azygos and hemiazygos veins, and in the renal, spermatic, splenic, superior mesenteric, portal, and hepatic veins. The striped muscle fibres of the heart are prolonged into it at the terminations of the venæ cavæ. The external tunic is frequently thicker than the middle tunic, and the two are not easily separable from one another.

Vascular and Nervous Supply of Arteries and Veins.—**Blood-vessels.**—The walls of the blood-vessels are supplied by numerous small arteries, called *vasa vasorum*, which are distributed to the outer and middle tunics. They arise either from the vessels they supply or from adjacent arteries, and after a short course enter the walls of the vessels in which they end. The blood is returned by small venæ vasorum.

Lymphatics.—Although the cell spaces in the middle and inner tunics may be regarded as the commencement of lymphatics, definite lymphatic vessels are limited to the outer tunic.

Nerves.—Arteries and veins are well supplied with nerves, which form a coarse network in the outer tunic. Branches from this network enter the tunica media, where they form a finer network which supplies twigs to the muscle fibres and sends fine filaments into the inner coat.

COR.

The **heart** is a hollow muscular organ. It receives blood from the veins, and propels it into and along the arteries. The cavity of the fully developed heart is completely separated into right and left halves by an obliquely placed longitudinal septum, and each half is divided into a posterior receiving chamber, the **atrium**, and an anterior ejecting chamber, the **ventricle**. The separation of the atria from the ventricles, however, is not complete. Externally a comparatively shallow constriction, running transversely to the long axis of the organ, indicates the distinction between the atria and ventricles; internally a wide aperture is left between the atrium and ventricle of each side. Each **atrio-ventricular aperture** is provided with a valve which allows the free passage of blood from the atrium to the ventricle, but effectually prevents its return.

The **shape** of the heart is that of an irregular and somewhat flattened cone; and a base, an apex, two surfaces (inferior or diaphragmatic and antero-superior or sterno-costal), and three borders (right, left, and inferior) are distinguishable.

An oblique groove, the **sulcus coronarius**, runs transversely to the long axis of the organ; it separates the postero-superior or atrial portion from the antero-inferior or ventricular part. The separation of the atrial portion into right and left chambers is marked, externally, at the base of the heart only, where an indistinct interatrial groove exists. The division of the ventricular part into right and left ventricles is more definitely marked on the surface by anterior and an inferior longitudinal sulcus which meet at the inferior border to the right of the apex.

The heart lies in the middle mediastinum. It rests below on the diaphragm, and is enclosed in a fibro-serous sac, called the pericardium, which intervenes between it and the neighbouring structures. Its long axis, from base to apex, runs obliquely from behind forwards, downwards, and to the left.

Basis Cordis.—The base, which is formed by the atria, and almost entirely by

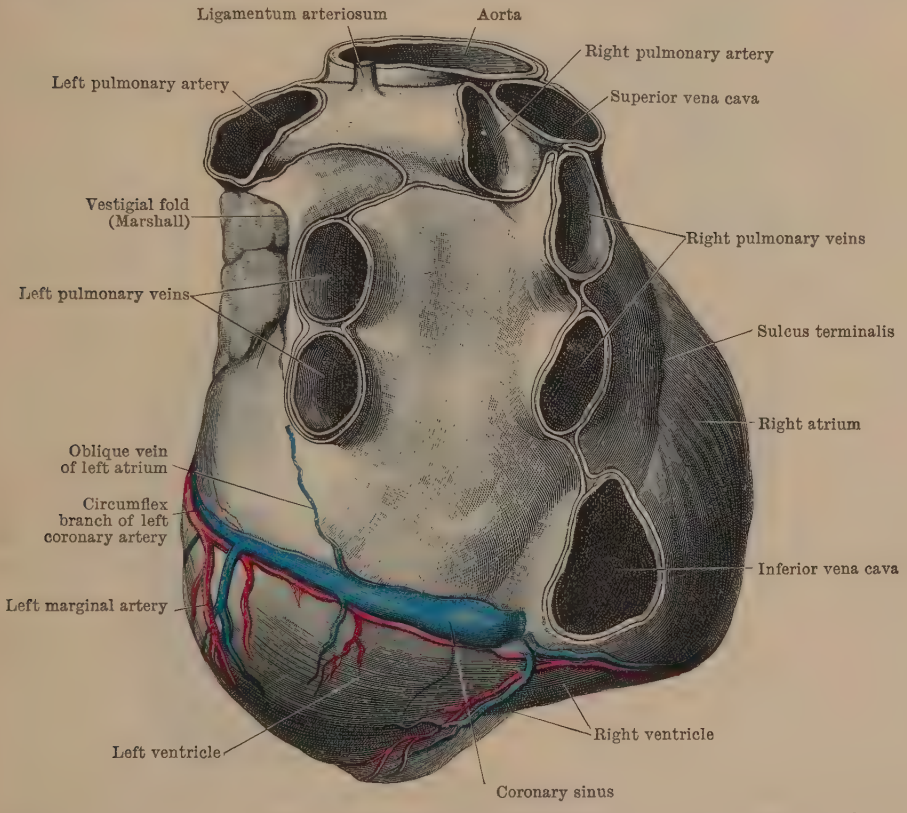

FIG. 721.—THE BASE AND DIAPHRAGMATIC SURFACE OF THE HEART, showing the openings of the great vessels and the line of reflexion of the serous pericardium in a formalin-hardened preparation.

the left atrium, is directed upwards, posteriorly, and to the right. It lies anterior to the descending thoracic aorta, the œsophagus, and the lower right pulmonary vein, which separate it from the bodies of the sixth, seventh, and eighth thoracic vertebræ.

On the whole the base is somewhat flattened. It is irregularly quadrilateral in outline, and the terminations of the superior and inferior venæ cavæ and the four pulmonary veins pass through it. The opening of the superior vena cava is situated at the upper right angle, that of the inferior cava occupies the lower angle on the right side; between and a little to the left of those openings are the orifices of the two right pulmonary veins, and immediately to the right of the latter is the indistinct posterior interatrial sulcus, which descends to the left of the orifice of the inferior vena cava. The openings of the two left pulmonary veins are situated near the left border of the base. The portion of the surface which lies between the right and left pulmonary veins forms the anterior boundary of a section of the pericardial cavity called the great oblique sinus.

The base is limited below by the inferior part of the coronary sulcus, in which the coronary sinus lies; its upper border is in relation with the pulmonary arteries. A fold of pericardium, the *vestigial fold*, descends, near the left border of the base, from the left branch of the pulmonary artery, above, to the left superior pulmonary vein below. It contains the ligamentum v. cavæ sinistræ, and from its lower end a small vein, *the oblique vein of the left atrium*, passes below the orifice of the lower left pulmonary vein, and descends to the coronary sinus. Further, it is from the base that the visceral layer of the pericardium, which elsewhere completely invests the heart, is reflected to the fibrous layer, the lines of reflexion corresponding with the orifices of the great vessels.[1]

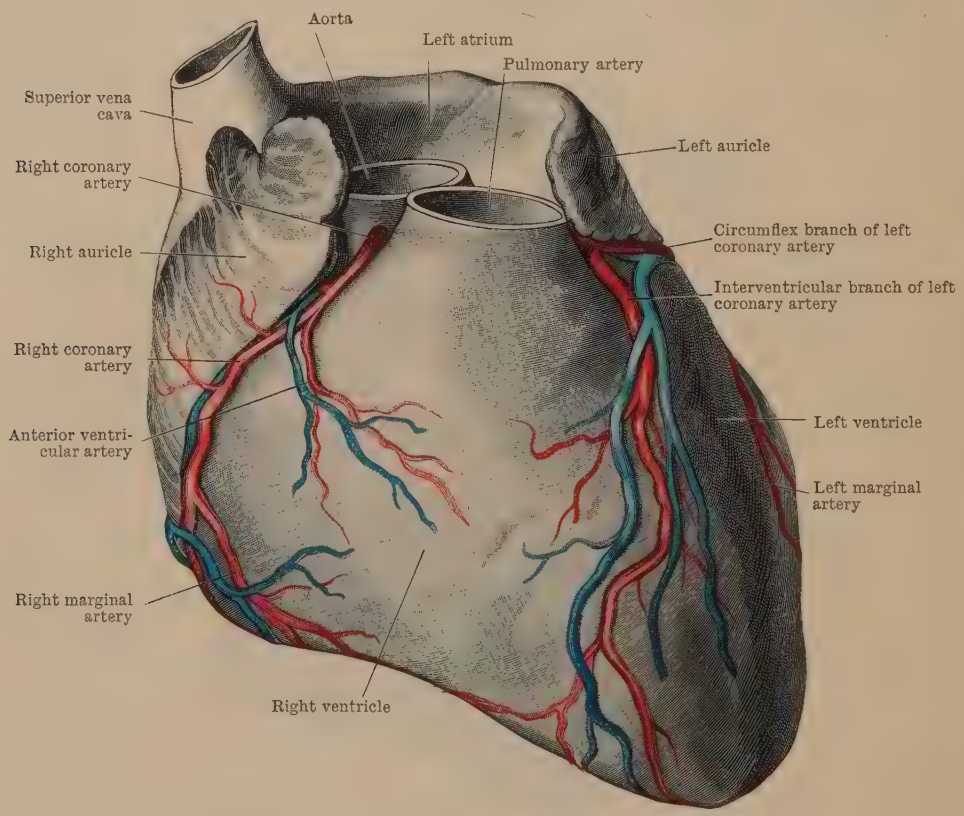

FIG. 722.—THE STERNO-COSTAL SURFACE OF FORMALIN-FIXED HEART.

The *apex*, bluntly rounded, is formed entirely by the left ventricle. It is directed downwards, anteriorly, and to the left, and is situated, under cover of the anterior borders of the left lung and pleura, behind the fifth left intercostal space, or behind the sixth rib, three and a half inches from the anterior median line.

The *diaphragmatic surface* is formed by the ventricular part of the heart. It rests upon the diaphragm, chiefly on the central tendon, but, upon the left side, on a small portion of the muscular substance also, and it is divided into two areas —a smaller to the right side and a larger to the left side—by an oblique antero-posterior groove, the **inferior interventricular sulcus**. It is separated from the base by the posterior or inferior portion of the coronary sulcus.

The *sterno-costal surface* is directed upwards, anteriorly, and to the left. It lies posterior to the body of the sternum and the medial extremities of the cartilages of the third, fourth, fifth, and sixth ribs of the right side, and a greater extent of the corresponding cartilages of the left side. This surface is separated into upper and lower sections by the anterior portion of the

[1] In the fœtus and young child the atrial portion of the heart forms not only the base, but also the posterior part of the inferior or diaphragmatic surface.

coronary sulcus, which runs obliquely from above downwards, and from left to right, from the level of the third left to that of the sixth right costal cartilage. The upper section of the surface, which is concave anteriorly, is formed by the atria; it is separated from the sternum by the ascending aorta and the pulmonary artery, and is continuous laterally with the auricles of the atria which, projecting forwards, embrace the great vessels. The lower section of the sterno-costal surface is convex; it is formed by the ventricular part of the heart, and is divided, by an anterior interventricular sulcus, into a smaller left and a larger right part. At the junction of the atrial and ventricular parts of this surface are the orifices of the pulmonary artery and the aorta, the former lying anterior to the latter.

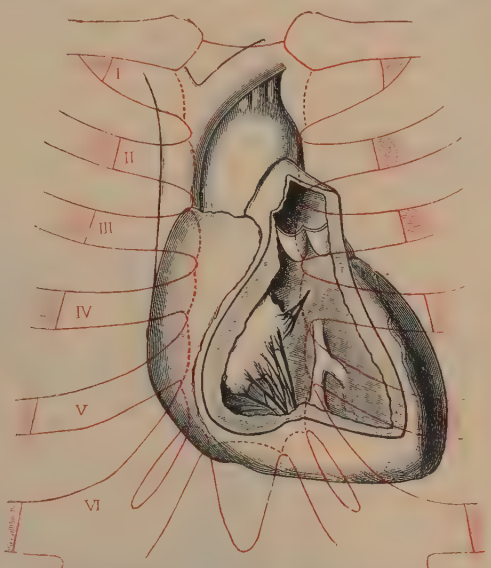

Fig. 723.—The Relation of the Heart to the Anterior Wall of the Thorax.

I, II, III, IV, V, VI, the upper six costal cartilages.

The *right margin* of the heart is formed by the right atrium. It lies posterior to the cartilages of the third, fourth, fifth, and sixth ribs on the right side, about half an inch from the margin of the sternum; it is in relation with the right pleura and lung, the phrenic nerve with its accompanying vessels intervening, and it is marked by a shallow groove—the *sulcus terminalis*—which passes from the front of the superior vena cava to the front of the inferior vena cava. The *inferior margin* of the sterno-costal surface is sharp, thin, and usually concave corresponding with the curvature of the anterior part of the diaphragm; it is formed mainly by the right ventricle and only near the apex by the left ventricle. It lies, almost horizontally, in the angle between the diaphragm and the anterior wall of the thorax, passing from the sixth right costal cartilage, posterior to the lower part of the body of the sternum, or the xiphoid process, and the cartilages of the sixth and seventh ribs on the left side, to the apex of the heart.

The *left margin* is formed mainly by the left ventricle, and only to a small extent by the left atrium; it is thick and rounded. It lies in relation with the left pleura and lung, the phrenic nerve and its accompanying vessels intervening, and it passes from just above the third left costal cartilage, about an inch from the sternum, to the apex of the heart, descending obliquely and with a convexity to the left.

THE CHAMBERS OF THE HEART.

Atria.—The **atrial** or basal portion of the heart is cuboidal in form. Its long axis, which lies transversely, is curved, with the concavity of the curve forwards. Its cavity is divided into two chambers—the right and left atria—by a septum which runs from the anterior wall backwards and to the right, so obliquely that the right atrium lies anterior and to the right, and the left atrium posterior and to the left.

Each atrium is also somewhat cuboidal in form, the long axes of both being vertical, and each possesses a well-marked, ear-shaped, forward prolongation, known as the **auricle**, which projects from its anterior and upper angle.

Atrium Dextrum.—The **right atrium** receives, posteriorly, the superior vena cava above and the inferior vena cava below. Between them, and a little above its middle, it is crossed posteriorly by the lower right pulmonary vein. It is separated by the pericardium from the posterior part of the right lung and pleura. It is continuous below and anteriorly with the right ventricle, at the atrio-ventricular

aperture. Above and anteriorly it is in relation with the ascending aorta, and from the junction of this aspect with the right lateral boundary the right auricle is prolonged anteriorly and to the left. Its right side forms the right margin of the heart, and is in relation with the right phrenic nerve and its accompanying vessels, and with the right pleura and lung, the pericardium intervening. On the left the right atrium is limited by the oblique septum which separates it from the left atrium. The **sulcus terminalis** is a shallow groove on the surface of the right atrium, which passes from the front of the superior vena cava to the front of the inferior vena cava. It indicates the junction of the primitive sinus venosus (see p. 72) with the atrium proper.

The interior of the right atrium is lined with a glistening membrane, the **endocardium**; its walls are smooth, except anteriorly and in the auricle where

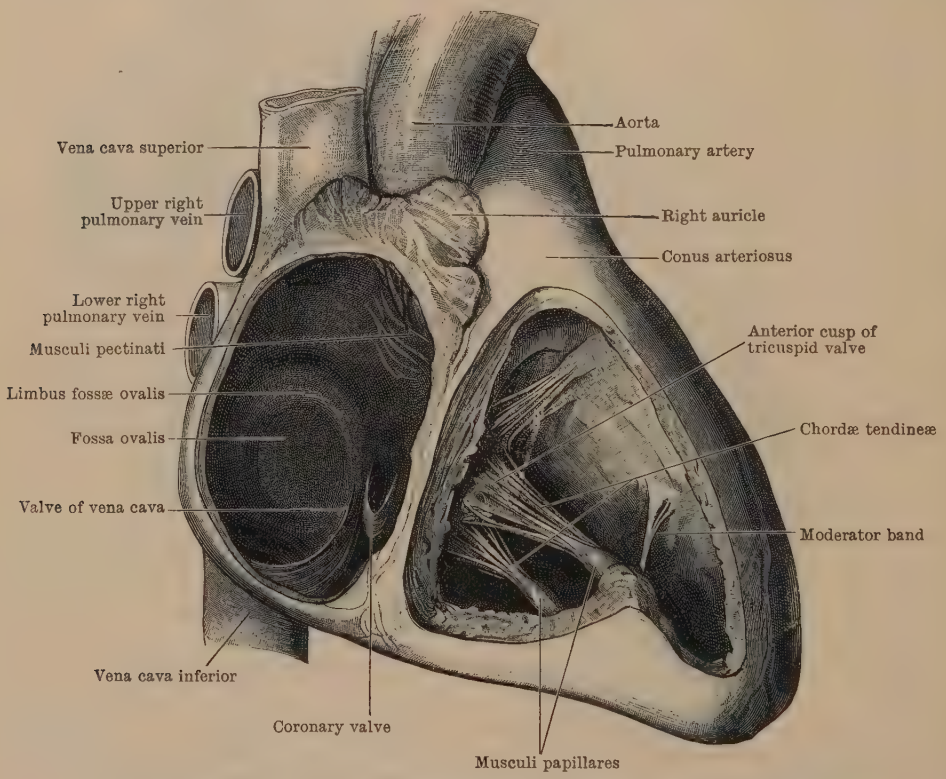

FIG. 724.—THE CAVITIES OF THE RIGHT ATRIUM AND RIGHT VENTRICLE OF THE HEART.
From a formalin-fixed heart.

muscular bundles, the **musculi pectinati**, form a series of small vertical columns. The musculi pectinati terminate, posteriorly, in a crest, the **crista terminalis**, which corresponds in position with the sulcus terminalis on the external surface.

At the upper and posterior part of the cavity is the opening of the superior vena cava, devoid of a valve. At the lower and posterior part is the orifice of the inferior vena cava, bounded, anteriorly, by the rudimentary **valve of the vena cava** (O.T. Eustachian); and immediately anterior and to the left of this valve, between it and the atrio-ventricular orifice, is the opening of the coronary sinus, guarded by the unicuspid **coronary valve**. The atrio-ventricular aperture, guarded by a tricuspid valve, is known as the **tricuspid orifice**. It is situated in the inferior part of the anterior boundary, and admits three fingers. A number of small fossæ, foramina venarum minimarum, are scattered over the walls, and into some of them the **venæ cordis minimæ** open. In the septal wall is an oval depression, the **fossa ovalis**, bounded, above and anteriorly, by a raised margin, the **limbus fossæ ovalis**, which is continuous, inferiorly, with the valve of the vena cava; the fossa is the remains of an aperture, the **foramen ovale**, through which the two atria

communicated with one another before birth. Even in the adult a portion of the aperture persists at the upper part of the fossa in about one in five cases. Between the apertures of the superior and inferior venæ cavæ, and posterior to the upper part of the fossa ovalis, a small eminence may be distinguished, which is called **the tuberculum intervenosum**; it probably directs the blood from the superior vena cava to the tricuspid orifice, during fœtal life.

The **valvula venæ cavæ inferioris** is a thin and sometimes fenestrated fold of endocardium and subendocardial tissue, which extends from the anterior and lower margin of the orifice of the inferior vena cava to the anterior part of the limbus ovalis. It varies very much in size, and is usually of falciform shape; its apex is attached to the limbus fossæ ovalis and its base to the margin of the inferior caval orifice. It is an important structure in the fœtus, directing the blood from the inferior vena cava through the foramen ovale into the left atrium.

The **valvula sinus coronarii** is usually a single fold of endocardium which is placed at the right margin of the orifice of the coronary sinus. It is almost invariably incompetent.

Atrium Sinistrum.—The **left atrium** is in relation posteriorly with the

descending thoracic aorta and the œsophagus, but is separated from them by the pericardium and the oblique sinus of the pericardium. Below and anteriorly it is continuous with the left ventricle. Its sterno-costal surface is concave, and lies in close relation to the ascending aorta, the pulmonary artery, and the left coronary artery. Its right side, formed by the interatrial septum, is directed anteriorly and to the right. Its left side forms a very small portion of the left margin of the heart, and from it, at its junction with the antero-superior surface, the long and narrow left auricle is prolonged, forwards, round the left side of the ascending portion of the aorta and the trunk of the pulmonary artery.

The four pulmonary veins enter the upper part of the posterior surface, two on each side.

The **interior of the left atrium** is lined with endocardium, and its walls are smooth, except in the auricle, where musculi pectinati are present, and on the septum, in a position corresponding with the upper part of the fossa ovalis on the right side, where there are several musculo-fibrous bundles radiating anteriorly and upwards. These septal bundles are separated at their bases by small semilunar depressions, in the largest of which remains of the foramen ovale may be found. Foramina venarum minimarum, and the apertures of venæ cordis minimæ, are scattered irregularly over the inner aspect, whilst in the inferior

part of the anterior boundary is the atrio-ventricular aperture or mitral orifice. The orifice is oval in form; its long axis is placed obliquely antero-posteriorly, and from left to right, and is capable of admitting two fingers. It is guarded by a valve formed of two large cusps, known as the **mitral valve.**

Ventriculi.—The **ventricular portion** of the heart is conical and somewhat flattened. The base, directed upwards and posteriorly, is partly continuous with the atrial portion and partly free. It is perforated by four orifices, the two atrio-ventricular, the aortic, and the pulmonary. The atrio-ventricular orifices are placed, one on each side, inferiorly and posteriorly; anteriorly and between them is the aortic orifice, whilst the orifice of the pulmonary artery is still more anterior, and slightly to the left of the aortic orifice.

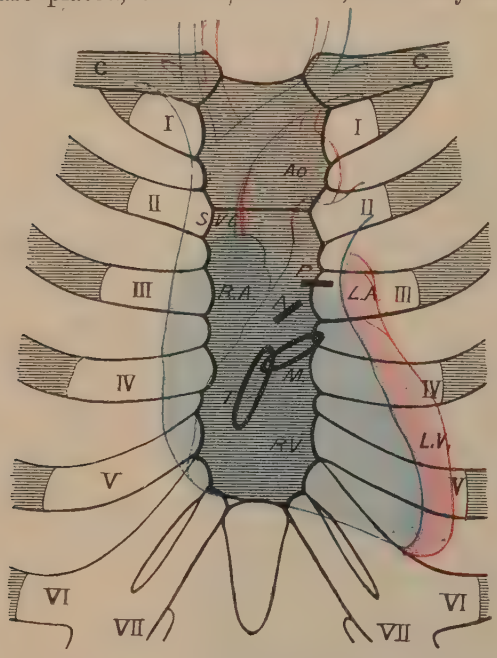

FIG. 726.—THE RELATIONS OF THE HEART AND THE ATRIO-VENTRICULAR, AORTIC, AND PULMONARY ORIFICES TO THE ANTERIOR THORACIC WALL.

I to VII, Costal cartilages.
A, Aortic orifice.
Ao, Aorta.
C, Clavicle.
LA, Left atrium.
LV, Left ventricle.
M, Mitral orifice.
P, Pulmonary orifice.
RA, Right atrium.
RV, Right ventricle.
SVc, Superior vena cava.
T, Tricuspid orifice.

In the triangle between the atrio-ventricular and the aortic orifices is embedded a mass of dense fibrous tissue which is the representative of the os cordis of the ox. It is continuous with the upper part of the interventricular septum, and with fibrous rings which surround the apertures at the bases of the ventricles.

The diaphragmatic surfaces and the sterno-costal surfaces of the two ventricles constitute respectively the greater portions of the corresponding surfaces of the heart; the former rest upon the diaphragm, whilst the latter are directed upwards and anteriorly towards the sternum and the costal cartilages of the left side. The apex of the left ventricle forms the **apex** of the heart.

The inferior margin of the ventricular region, which is thin, forms the inferior margin of the heart; and the left margin, which is thick and rounded, forms the greater part of the left margin of the heart.

The ventricular portion of the heart is divided into right and left chambers by the **ventricular septum**, which is placed obliquely, with one surface directed anteriorly and to the right, and the other posteriorly and to the left; it bulges into the right ventricle, and its lower margin lies to the right of the apex of the heart, which is formed entirely by the left ventricle. The margins of the septum are indicated on the two surfaces of the ventricular part of the heart by anterior and inferior interventricular sulci.

Ventriculus Dexter.—The **right ventricle** is triangular in form. Its base is directed upwards and to the right, and, in the greater part of its extent, it is continuous with the right atrium, with which it communicates by the atrio-ventricular orifice; but its left and anterior angle is free from the atrium, and gives origin to the pulmonary artery. Its inferior wall rests upon the diaphragm. The sterno-costal wall lies posterior to the lower part of the left half of the sternum and the cartilages of the fourth, fifth, and sixth ribs of the left side. The left or septal wall, which is directed posteriorly and to the left, bulges into its interior, and on that account the transverse section of the cavity has a semilunar outline. The cavity itself is a bent tube consisting of an inferior portion or **body** into which the atrio-ventricular orifice opens, and of an antero-superior part, the **infundibulum** or **conus arteriosus,** which terminates in the pulmonary artery.

In the angle between the two limbs is a thick ledge of muscle, the **supra-ventricular crest**.

The **right atrio-ventricular orifice** is guarded by a **tricuspid valve**. The three cusps are an *anterior*, which intervenes between the atrio-ventricular orifice and the infundibulum, a *medial* or *septal*, and an *inferior*. Each cusp consists of a fold of endocardium, strengthened by a little intermediate fibrous tissue. The bases of the cusps are generally continuous with one another at the atrio-ventricular orifice, where they are attached to a fibrous ring, but they may be separated by small intermediate cusps which fill the angles between the main segments. The apices of the cusps project into the ventricle. The margins, which are thinner than the central portions, are notched and irregular. The atrial surfaces are smooth. The ventricular surfaces are roughened, and, like the margins and apices, they give attachment to fine tendinous cords, the **chordæ tendineæ**. The opposite extremities of the chordæ tendineæ are attached to muscular bundles, the **musculi papillares**, which project from the wall into the cavity of the ventricle (Fig. 724).

The **pulmonary orifice**, which lies anterior and to the left of the tricuspid orifice, is guarded by a **pulmonary valve** composed of three semilunar segments, two of which are placed anteriorly and one posteriorly. The convexity or outer border of each semilunar segment is attached to the wall of the pulmonary artery. The inner border is free, and it presents at its centre a small nodule, the **nodulus valvulæ semilunaris**. On each side of the nodule there is a small, thin marginal segment, of semilunar form, the **lunule**. Each segment of the valve is formed by a layer of endocardium on its ventricular surface, an endothelial layer of the inner coat of the artery on its arterial surface, and an intermediate stratum of fibrous tissue. Both the attached and the free margins of the cusps are strengthened by fibrous bands, and strands of condensed fibrous tissue radiate from the outer border of each cusp to the nodule, but they do not enter the lunulæ. When the valve closes the noduli are closely apposed, the lunulæ of the adjacent segments of the valve are pressed together, and both noduli and lunulæ project vertically upwards into the interior of the artery.

The cavity of the right ventricle is lined with endocardium; the walls are smooth in the conus arteriosus, but are rendered rugose and sponge-like in the body by the inward projection of numerous muscular bundles, the **trabeculæ carneæ**. The fleshy trabeculæ are of two kinds: the simpler are merely columns raised in relief on the wall of the ventricle; those of the other class are rounded bundles, free in the middle, but attached at each end to the wall of the ventricle. One special bundle of the second group, called the **moderator band**, is attached by one extremity to the septum, and by the other to the sterno-costal wall, at the base of the anterior papillary muscle; it tends to prevent over-distension of the cavity. In addition to the trabeculæ carneæ conical muscular eminences, the **musculi papillares**, project into the cavity of the ventricle. The bases of the papillary muscles are continuous with the wall of the ventricle, and their apices terminate in numerous chordæ tendineæ which are attached to the apices, the borders, and ventricular surfaces of the cusps of the tricuspid valve.

The musculi papillares of the right ventricle are—(1) a large anterior muscle, from which the chordæ pass to the anterior and inferior segments of the valve; (2) a smaller and more irregular inferior muscle, sometimes represented by two or more segments, from which chordæ pass to the inferior and medial cusps; and (3) a group of muscular bundles, varying in size and number, which spring from the septum and are united by chordæ to the anterior and medial cusps.

The walls of the right ventricle, the septal excepted, are much thinner than those of the left, but the trabeculæ carneæ are coarser and less numerous in the right than in the left ventricle.

Ventriculus Sinister.—The **left ventricle** is a conical chamber, and its cavity is oval in transverse section. The base is directed upwards and posteriorly, and in the greater part of its extent it is continuous with the corresponding atrium, with which it communicates through the mitral orifice; but anteriorly and to the

right of its communication with the atrium it is continued into the ascending aorta.

The **mitral orifice** is oval; its long axis runs obliquely from above downwards and to the right, and it is guarded by a valve consisting of two cusps, which is known as the **bicuspid** or **mitral valve.** The two cusps of the valve are triangular and of unequal size. The smaller of the two is placed to the left and inferiorly; and the larger, placed to the right and anteriorly, between the mitral and aortic orifices, is known as the **aortic cusp.** The bases of the cusps are either continuous with one another, at their attachments to the fibrous ring around the mitral orifice, or they are separated by small intermediate cusps of irregular form and size. The apices of the cusps project into the cavity of the ventricle. The atrial surfaces are smooth; the ventricular surfaces are roughened by the attachments of the chordæ tendineæ, which are connected also with the irregular and notched margins and with the apices. The structure is the same as that of the cusps of the tricuspid valve, but the ventricular surface of the anterior cusp is relatively smooth; therefore the blood flow into the aorta is not impeded.

The **aortic orifice** is circular; it lies immediately anterior and to the right of the mitral orifice, from which it is separated by the anterior cusp of the mitral valve, and it is guarded by the **aortic valve,** formed of three semilunar segments, one of which is placed anteriorly and the other two posteriorly. The structure and attachments of the cusps of the aortic valve are similar to those of the cusps of the pulmonary valve (see p. 873).

The cavity of the left ventricle is separable, like that of the right, into two portions, the body and the aortic vestibule; the latter is a small section placed immediately below the aortic orifice; its walls are non-contractile, consisting of fibrous and fibro-cartilaginous tissue. The wall of the cavity is lined by endocardium. The inferior wall and the apex are rendered sponge-like by numerous fine trabeculæ carneæ, whilst the upper part of the sterno-costal wall and the septum are relatively smooth.

There are two papillary muscles of much larger size than those met with in the right ventricle—an anterior and an inferior; each is connected by chordæ tendineæ with both cusps of the mitral valve.

The walls of the left ventricle are three times as thick as those of the right ventricle, and they are thickest in the region of the widest portion of the cavity, which is situated about a fourth of its length from the base. The muscular portion of the wall is thinnest at the apex, but the thinnest portion of the boundary lies at the upper part of the septum, and it consists entirely of fibrous tissue; this part is occasionally deficient, and an aperture is left through which the cavities of the two ventricles communicate.

The **ventricular septum** is a musculo-membranous partition. It is placed obliquely, so that one surface looks anteriorly and to the right, and bulges into the right ventricle, whilst the other looks posteriorly and to the left and is concave towards the left ventricle. Its sterno-costal and inferior margins correspond respectively with the anterior and the inferior portions of the interventricular sulcus, and it extends from the right of the apex to the interval between the pulmonary, the aortic, and the atrio-ventricular orifices. The main part of its extent is muscular, and is developed from the wall of the ventricular part of the heart; but its upper and posterior portion, the **pars membranacea,** which is developed from the septum of the truncus arteriosus, is entirely fibrous, and constitutes the thinnest portion of the ventricular walls. The pars membranacea lies between the aortic vestibule of the left ventricle, on the left, and the upper part of the right ventricle and the lower and left part of the right atrium, on the right.

Structure of the Heart.

The walls of the heart consist mainly of peculiar striped muscle, the **myocardium,** which is enclosed between the visceral layer of the pericardium, or **epicardium,** externally, and the **endocardium** internally. The muscular fibres differ from those of ordinary voluntary striped

muscle in several ways: they are shorter, many of them being oblong cells, with forked extremities which are closely cemented to similar processes of adjacent cells; they form a reticulum, and the nuclei lie in the centres of the cells. Moreover, still more peculiar fibres, the **fibres of Purkinje**, are found immediately beneath the subendocardial tissue. The fibres of Purkinje are large cells which unite with one another at their extremities; their central portions consist of granular protoplasm, in which sometimes one but more frequently two nuclei are embedded, and the peripheral portion of each cell is transversely striated. These cells, in short, present, in a permanent form, a condition which is transitory in all other striped muscle cells.

The reticulating cardiac muscle cells are grouped in sheets and strands which have a more or less characteristic and definite arrangement in different parts of the heart; they are separated and at the same time bound together by intervening lamellæ of fine connective tissue in which elastic fibrils are present; by careful dissection, and after special methods of preparation, it is possible to recognise many layers and bundles, some of which are, however, probably artificially produced.

In the **atria** the muscular fasciculi fall naturally into two groups: (*a*) superficial fibres common to both atria; (*b*) deep fibres special to each atrium.

The **superficial fibres** are most numerous on the sterno-costal aspect and in the neighbourhood of the coronary sulcus. They run transversely across the atria and a few of them dip into the interatrial septum.

The deep fibres are—(1) looped fibres. The extremities of the looped fibres are attached to the fibrous rings around the atrio-ventricular orifices and the fibres pass antero-posteriorly over the atria. (2) Annular fibres which surround (*a*) the extremities of the large vessels which open into the atria; (*b*) the auricles; (*c*) the fossa ovalis.

In the **ventricles** the muscular fasciculi form more or less definite V-shaped loops which commence from and end at the fibrous rings which surround the large orifices at the bases of the ventricles. In their courses the loops embrace the cavities of either one or both ventricles, one stem of each loop lying on the outer surface of the heart and the other in the interior, and some of the loops possess very acute whilst others have very open bends.

The superficial fibres on the sterno-costal surface pass towards the left, those on the inferior surface towards the right. At the apex all are coiled into a whorl or *vortex* through which they pass into the interior of the ventricular walls and run towards the base, some in the septum and others in the papillary muscles. The various bundles which have been described can, according to Mall, be resolved into two main systems. One system arises from the conus arteriosus and the root of the aorta, that is from the remains of the primitive aortic trunk: it is called the "bulbo-spiral" system. The other springs from the region of the primitive venous sinus and is termed the "sino-spiral." Both systems are separable into superficial and deep portions, and the general plan of more or less spirally curved V-shaped loops is retained in each, but the details of the arrangement are too complicated for consideration within the limits of an ordinary text-book (see *Amer. Journ. of Anat.* vol. ii., 1910–1911).

The **Atrio-Ventricular Bundle.**—It would appear from the preceding description that the muscle-fibres of the atria and the ventricles are entirely separated from one another by the fibrous rings which surround the atrio-ventricular orifices; that, however, is not the case, for the two groups are connected together by a bundle of muscle fibres of pale colour and rudimentary structure, which lies immediately adjacent to the endocardium and constitutes the atrio-ventricular bundle.

The bundle commences in a nodular enlargement which lies in the lower part of the wall of the right atrium, close to the base of the medial cusp of the tricuspid valve. From that point the bundle runs along the posterior and lower borders of the membranous part of the ventricular septum to the upper and posterior part of the muscular portion of the septum, where it divides into right and left branches. The right branch runs along the right side of the ventricular septum to the moderator band, along which it passes into the anterior papillary muscle of the right ventricle. The left branch runs along the left side of the septum and both branches give off numerous ramifications, by means of which the main bundle is associated with all parts of the walls of the two ventricles.

Both the function and the origin of the atrio-ventricular bundle are uncertain. After the discovery of the bundle it was asserted that impulses were conveyed from the atria to the ventricles by the muscle fibres of the atrio-ventricular bundle and by them alone; more recently it has been shown that minute nerve fibrils are intimately intermingled with the muscle fibres of the bundle, and it has yet to be decided whether the impulses which pass from the atria to the ventricles, for the purpose of maintaining the proper sequence of the movements of the chambers, travel by the nerve fibrils or the muscle fibres or by both.

The atrio-ventricular bundle is probably a remnant of the muscular continuity which existed in the early stages of development between the atrial and ventricular chambers of the heart, but it may be, wholly or in part, a new formation.

The **epicardium**, or visceral portion of the pericardium, consists of white connective and of elastic tissue, the latter forming a distinct reticulum in the deeper part. The surface which looks towards the pericardial cavity is covered with flat polygonal endothelial plates.

The **endocardium** lines the cardiac cavities and is continuous with the inner coats of the vessels which enter and leave the heart. It is much thinner than the epicardium. It consists, like the tunica intima of the blood-vessels, of an inner lining of flat endothelial cells, a layer of fine subendothelial connective tissue, and an external elastic layer which usually assumes the form of a fenestrated membrane. The endocardium rests externally on a layer of fine sub-

endocardial connective tissue which is continuous with the connective tissue lamellæ between the muscle layers of the heart. It contains blood-vessels and nerves which are absent from the endocardium.

Size of the Heart.—The heart is about 125 mm. (five inches) long, 87 mm. (three and a half inches) broad; its greatest depth from its sterno-costal to its diaphragmatic surface is 62 mm. (two and a half inches), and it is roughly estimated as being about the same size as the closed fist. The size, however, is variable, the volume increasing at first rapidly, and then gradually, with increasing age, from 22 cc. at birth to 155 cc. at the fifteenth year, and to 250 cc. by the twentieth year. From that period to the fiftieth year, when the maximum volume (280 cc.) is attained, the increase is much more gradual, and after fifty a slight decrease sets in. The volume is the same in both sexes up to the period of puberty, but thereafter it preponderates in the male.

Weight.—The average weight of the heart in the male adult is 310 grms. (11 ounces), and in the female adult 255 grms. (9 ounces); but the weight varies greatly, always, however, in definite relation to the weight of the body, the relative proportions changing at different periods of life. Thus at birth the heart weighs 24 grms. (13½ drachms), and its relation to the body weight is as 1 to 130, whilst in the adult the relative proportion is as 1 to 205. The heart is said to increase rapidly in weight up to the seventh year, then more slowly up to the age of puberty, when a second acceleration sets in; but after the attainment of adult life the increase, which continues till the seventieth year, is very gradual.

The above changes affect the whole heart, but the several parts also vary in their relation to one another at different periods of life. During fœtal life the right atrium is heavier than the left; in the first month after birth the two become equal; at the second year the right again begins to preponderate, and it is heavier than the left during the remainder of life. In the latter part of fœtal life the two ventricles are equal; after birth the left grows more rapidly than the right, until, at the end of the second year, a position of stability is gained, when the right is to the left as 1 to 2, and this proportion is maintained until death.

Capacity.—During life the capacity of the ventricles is probably the same, and each is capable of containing from three to four ounces of blood, whilst the atria are a little less capacious. After death the cavity of the right ventricle appears larger than that of the left.

Vascular Supply of the Heart.—The walls of the heart are supplied by the **coronary arteries** (p. 884), the branches of which pass through the interstitial tissue to all parts of the muscular substance and to the subendocardial and subepicardial tissues; the endocardium and the valves are devoid of vessels. The capillaries, which are numerous, form a close-meshed network around the muscular fibres. Sometimes the valves contain a few muscular fibres, and in those cases they also receive some minute vessels. The majority of the veins of the heart end in the coronary sinus, which opens into the lower part of the right atrium; some few very small veins, however, open directly into the right atrium, and others are said to end in the left atrium, and in the cavities of the ventricles.

Lymphatics of the Heart.—Lymphatic vessels are freely distributed throughout the whole substance of the heart. They all communicate with the superficial network which lies beneath the epicardium. The efferent vessels from the subepicardial network accompany the coronary arteries to the coronary sulcus and pass thence to the anterior mediastinal glands.

Nerves of the Heart.—The heart receives its nerves from the superficial and deep cardiac plexuses. The former lies beneath the aortic arch and the latter between the arch and the bifurcation of the trachea. Through the plexuses it is connected with the vagus, the accessory (through the vagus), and the sympathetic nerves. After leaving the cardiac plexuses many of the nerve-fibres enter the walls of the atria and anastomose together in the subepicardial tissue, forming a plexus in which many ganglion cells are embedded, especially near the terminations of the inferior vena cava and the pulmonary veins. From the subepicardial atrial plexus, nerve filaments, on which nerve ganglion cells have been found, pass into the substance of the atrial walls.

Other fibres from the cardiac plexuses accompany the coronary arteries to the ventricles, and upon those also ganglion cells are found in the region immediately below the coronary sulcus.

The nerve-fibres which issue from the gangliated plexuses of the heart are non-medullated. They form fine plexuses round the muscle fibres, and they terminate either in fine fibrils on the surfaces of the muscle fibres, or in nodulated ends which lie in contact with the muscle cells.

Abnormalities of the Heart.—The **heart** may be transposed from the left to the right side of the body, a condition which is usually associated with general transposition of the viscera, and with the presence of a right instead of a left aortic arch.

The external form of the heart does not as a rule vary much, but occasionally the apex is slightly bifid, a character it normally possesses at an early stage of its development, and which is retained in the adult in many cetaceans and sirenians. The internal conformation of the heart deviates from the normal much more frequently; more particularly is this the case with regard to the septa which separate the right from the left chambers. The interatrial septum may be entirely absent, as in fishes; it may be fenestrated and incomplete, as in some amphibians; or the foramen ovale may remain patent, as in amphibians and reptiles.

The interventricular septum may be absent, as in fishes and amphibians, or incomplete, as in reptiles; when incomplete, it is usually the "pars membranacea septi" which is deficient, but perforations are occasionally found in the muscular portion.

The communication between the infundibular part of the right ventricle and the body of the ventricle may be constricted or the infundibular part may be entirely cut off from the remainder of the cavity.

PERICARDIUM.

The **pericardium** is a fibro-serous sac which surrounds the heart. It lies in the middle mediastinum, and is attached below to the diaphragm, and above and posteriorly to the roots of the great vessels. Anteriorly and posteriorly it is in relation with the structures in the corresponding mediastina and laterally it is in close apposition with the pleural sacs.

The **fibrous pericardium** is a strong fibrous sac of conical form; its base is attached to the central tendon and to the adjacent part of the muscular substance of the diaphragm, and it is pierced by the inferior vena cava. At its apex

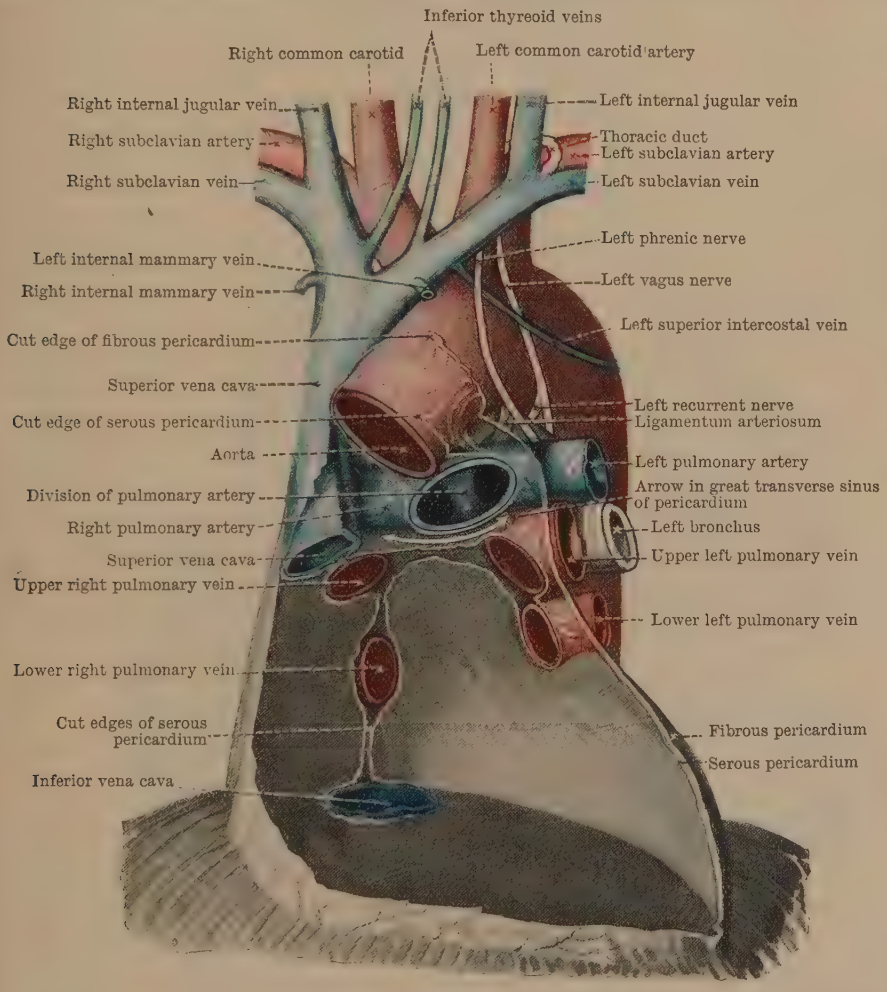

FIG. 727.—POSTERIOR WALL OF THE PERICARDIUM AFTER THE REMOVAL OF THE HEART. Showing the relation of the serous pericardium to the great vessels.

and posteriorly it is gradually lost upon the great vessels which enter and emerge from the heart, giving sheaths to the aorta, the two branches of the pulmonary artery, the superior vena cava, the four pulmonary veins, and the ligamentum arteriosum. Its anterior surface forms the posterior boundary of the anterior mediastinum, and it is attached, above and below, by the superior and inferior sterno-pericardial ligaments, to the sternum. In the greater part of its extent it is separated from the anterior wall of the thorax by the anterior margins of the lungs and pleural sacs, but it is in direct relation with the left half of the lower portion of the body of the sternum and, in many cases, with the medial ends of the cartilages of the fourth, fifth, and sixth ribs of the left side and the left transversus

thoracis muscle. Its posterior surface forms the anterior boundary of the posterior mediastinum; it is in relation with the œsophagus and the descending aorta, both of which it separates from the back of the left atrium. Each lateral aspect is in close contact with the mediastinal portion of the parietal pleura, the phrenic nerve and its accompanying vessels intervening. The inner surface of the fibrous sac is lined by the serous pericardium, which is closely attached to it.

The **serous pericardium** is a closed sac containing a little fluid (liquor pericardii). It is surrounded by the fibrous pericardium and invaginated by the heart. It is, therefore, separable into two portions—the parietal, which lines the inner surface of the fibrous sac, and the visceral, which ensheathes, or partially ensheathes, the heart and the great vessels; but the two portions are, of course, continuous with one another where the serous layer is reflected on to the great vessels as they pierce the fibrous layer. The majority of the great vessels receive only partial coverings from the visceral layer: thus, the superior vena cava is covered anteriorly and on each side; the pulmonary veins anteriorly, above, and below; and the inferior vena cava anteriorly and on each side. The aorta and the pulmonary artery are enclosed together in a complete sheath of the visceral layer. Therefore, when the pericardial sac is opened from the front, it is possible to pass the fingers behind them and in front of the atria, from the right to the left side, through a passage called the **great transverse sinus** of the pericardium (Fig. 727). The spaces or pouches which intervene between the vessels which receive partial coverings from the serous pericardium are also called sinuses; and the largest of them, which is bounded below and on the right by the inferior vena cava, and above and on the left by the left inferior pulmonary vein, is known as the **great oblique sinus**. It passes upwards and to the right behind the left atrium, and lies anterior to the œsophagus and the descending thoracic aorta.

A small fold of the serous pericardium, the **vestigial fold**, passes from the left pulmonary artery to the left superior pulmonary vein, posterior to the left extremity of the transverse sinus. It merits special attention because it encloses a fibrous strand, the *ligamentum venæ cavæ sinistræ*. This is a remnant of the left superior vena cava or duct of Cuvier, which atrophied at an early period of fœtal life.

Structure.—The fibrous pericardium consists of ordinary connective tissue fibres felted together into a dense, unyielding membrane. The serous pericardium is covered on its inner aspect by a layer of flat endothelial cells. The endothelium rests upon a basis of mixed white and elastic fibres in which run numerous blood-vessels, lymphatics, and nerves.

ARTERIÆ.

ARTERIA PULMONALIS.

The **pulmonary artery** springs from the anterior and left angle of the base of the right ventricle, at the termination of the conus arteriosus. It is slightly larger at its commencement than the aorta, and is dilated, immediately above the cusps of the valve, into three pouches, the **sinuses** of the pulmonary artery. It runs upwards and posteriorly, towards the concavity of the aortic arch, curving from the front round the left side of the ascending aorta to reach a plane posterior to the latter; and it terminates, by dividing into right and left branches, opposite the fifth thoracic vertebræ. Its length is a little more than two inches.

Relations.—The pulmonary artery is enclosed within the fibrous pericardium, and is enveloped, along with the ascending aorta, in a common sheath of the visceral layer of the serous pericardium. It lies behind the anterior extremity of the second left intercostal space, from which it is separated by the anterior margins of the left lung and pleural sac.

Its posterior relations are the bulb of the aorta, the anterior wall of the left atrium, and the first part of the left coronary artery. To the right it is in relation with the right coronary artery, the auricle of the right atrium, and the ascending aorta, and to the left with the left coronary artery and the auricle of the left atrium. Immediately above its bifurcation, between it and the aortic arch, is the superficial cardiac plexus.

The **right branch of the pulmonary artery** is longer and larger than the left. It passes to the hilum of the right lung, forming one of the constituents of the root of the lung, and, after entering the lung, it descends, with the main bronchus, to the lower extremity of the organ (Fig. 728).

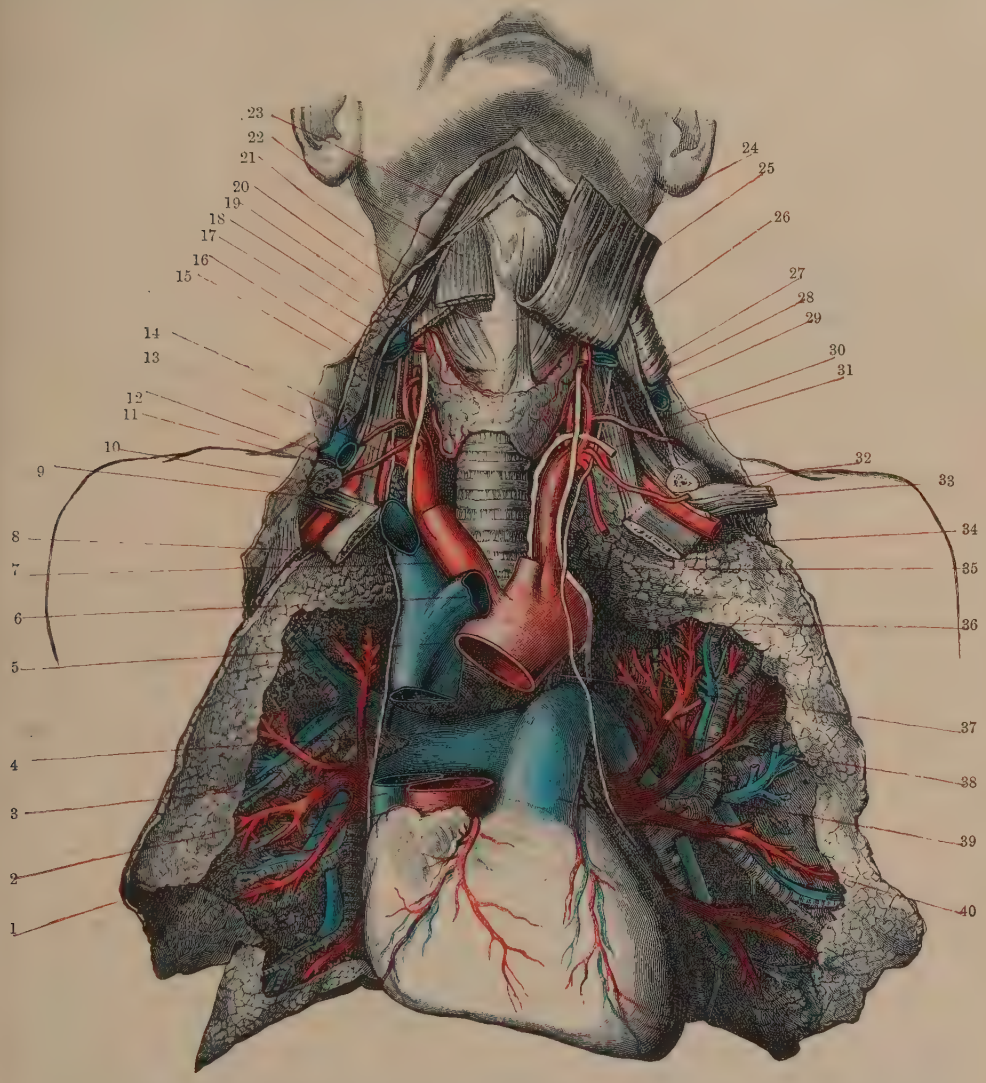

FIG. 728.—THE PULMONARY ARTERIES AND VEINS AND THEIR RELATIONS IN A FORMALIN-HARDENED PREPARATION.

The ascending aorta and part of the superior vena cava have been removed.

35. Left common carotid artery.
36. Aorta.
37. Ligamentum arteriosum.
38. Left pulmonary artery.
39. Upper left pulmonary vein.
40. Pulmonary artery.

Relations.—Before it enters the lung the right pulmonary artery passes posterior to the ascending aorta, the superior vena cava, and the upper right pulmonary vein. At first, it lies below the arch of the aorta and the right bronchus, anterior to the œsophagus, and above the left atrium and the lower right pulmonary vein ; then it crosses anterior to the right bronchus, immediately below the eparterial branch of that bronchus, and reaches the

hilum of the lung. After it has passed through the hilum the artery descends, in the lung, posterior and lateral to the main bronchus and between its ventral and dorsal branches.

Branches.—Before entering the hilum it gives off a large branch to the upper lobe of the right lung which accompanies the eparterial bronchus, and in the substance of the lung it gives off numerous branches which correspond with and accompany the dorsal, ventral, and accessory branches of the right bronchus. (See Respiratory System.)

The **left branch of the pulmonary artery**, shorter, smaller, and somewhat higher in position than the right, passes laterally and posteriorly from the bifurcation of the pulmonary stem, and runs, in the root, to the hilum of the left lung; it then descends, in company with the main bronchus, to the lower end of the lung.

Relations.—Before it enters the lung it is crossed, *anteriorly*, by the upper left pulmonary vein; *posterior to* it, are the left bronchus and the descending aorta; *above*, are the aortic arch, to which it is connected by the ligamentum arteriosum, and the left recurrent nerve; *below*, it is in relation with the lower left pulmonary vein. After entering the lung it descends, like the right pulmonary artery, posterior and lateral to the stem bronchus, and between its ventral and dorsal branches.

Branches.—Just before it passes through the hilum it gives off a branch to the upper lobe of the left lung, and in the substance of the lung its branches correspond with the ventral, dorsal, and accessory branches of the bronchial tube.

THE SYSTEMIC ARTERIES.

AORTA.

The **aorta** is the main trunk of the general arterial system. It commences at the base of the left ventricle and ascends, with an inclination to the right, to the level of the second right costal cartilage; then it curves backwards and to the left, until it reaches the left side of the lower border of the fourth thoracic vertebra; there it turns downwards and descends, through the thorax into the abdomen, where it terminates, on the left of the median plane, at the level of the fourth lumbar vertebra, by bifurcating into the two common iliac arteries. The portion of the aorta which is situated in the thorax is, for convenience, termed the *thoracic aorta*, and the rest of the vessel is known as the *abdominal aorta*.

AORTA THORACALIS.

The thoracic aorta is subdivided into aorta ascendens, arcus aortæ, and aorta descendens.

Aorta Ascendens.—The **ascending aorta** lies in the middle mediastinum. It springs from the base of the left ventricle, posterior to the left margin of the sternum, opposite the lower border of the third left costal cartilage and at the level of the body of the sixth thoracic vertebra. From its origin it passes upwards, anteriorly, and to the right, and it terminates in the arch of the aorta, posterior to the right margin of the sternum, at the level of the second costal cartilage. Its *length* is from 50 to 56 mm. (2 to $2\frac{1}{4}$ inches), and its diameter is 28 mm. ($1\frac{1}{8}$ inches). In the adult it is a little narrower at its commencement than the pulmonary artery is, but in old age it enlarges and exceeds the latter vessel in size. The diameter, however, is not uniform throughout the whole length of the ascending aorta. Its dilated commencement, the **bulbus aortæ**, has three secondary dilatations, the **sinus aortæ** (Valsalva) in its wall, immediately opposite the semilunar cusps of the aortic valve; one is anterior in position, and two are situated posteriorly. At a higher level there is a diffuse bulging of the right wall, which is known as the *great sinus* of the aorta.

Relations.—The ascending aorta is completely enclosed within the fibrous pericardium which blends above with the sheath of the vessel, and it is enveloped, together with the stem of the pulmonary artery, in a tubular prolongation of the serous pericardium. At its origin it has the pulmonary artery in front, the transverse sinus of the pericardium and the anterior wall of the left atrium behind, and the right atrium on its

right side. In the upper part of its course the ascending aorta is overlapped by the anterior margins of the right lung and right pleural sac, whilst posterior to it are the right atrium, the right branch of the pulmonary artery, the right bronchus, and the left margin of the superior vena cava. The superior vena cava lies on the right side, and partly posterior to the upper part of the ascending aorta, whilst the pulmonary artery is at first anterior to it and then, at a higher level, on its left side.

Branches.—Two branches arise from the ascending aorta, viz., the right and the left coronary arteries. The right coronary artery springs from the anterior, and the left from the left posterior sinus of the aorta (Fig. 725).

Arcus Aortæ.—The **arch of the aorta** lies in the superior mediastinum, posterior to the lower part of the manubrium sterni, and connects the ascending with the descending aorta. It commences posterior to the right margin of the sternum, on a level with the second costal cartilage, and extends to the level of the left side of the lower border of the fourth thoracic vertebra. As its name implies, it forms an arch; and the arch makes two curves, one with the convexity upwards (Fig. 727), and the other with the convexity forwards and to the left. From its origin it runs for a short distance upwards, posteriorly, and to the left, anterior to the trachea; then it passes posteriorly, round the left side of the trachea to the left side of the body of the fourth thoracic vertebra (Fig. 729). Finally it turns downwards to become continuous with the descending aorta.

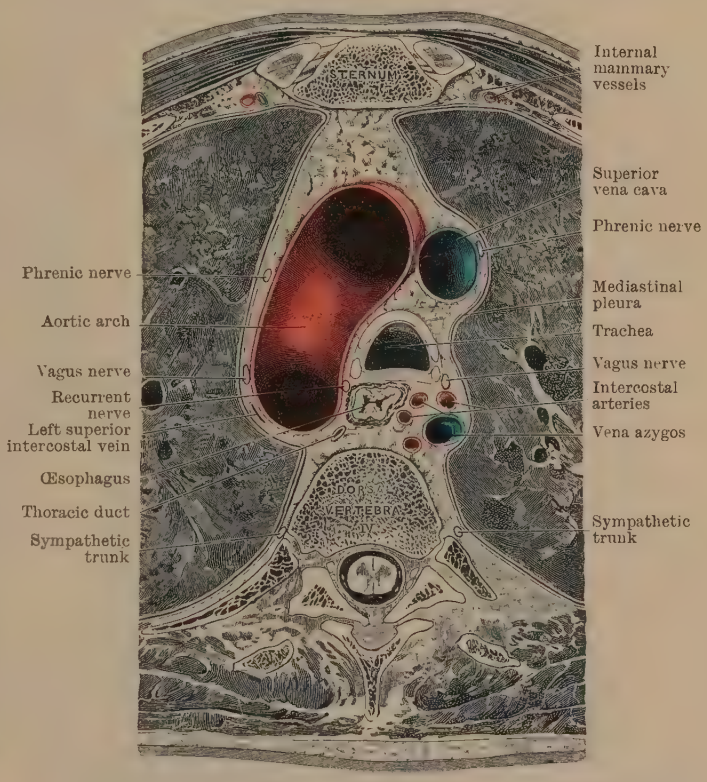

FIG. 729.—TRANSVERSE SECTION THROUGH THE SUPERIOR MEDIASTINUM AT THE LEVEL OF THE FOURTH THORACIC VERTEBRA.

At its commencement it has the same diameter as the ascending aorta, 28 mm. ($1\frac{1}{8}$ inches), but after giving off three large branches, the diameter is reduced to 23 mm. (a little less than one inch).

Relations.—It is overlapped anteriorly and on the left side by the right and left lungs and pleural sacs, but much more by the left than the right, and in the interval between and posterior to the anterior borders of the pleural sacs it is covered by the remains of the thymus. As it turns backwards it is crossed vertically, on the left side, by four nerves in the following order from before backwards:—the left phrenic, the inferior cervical cardiac branch of the left vagus, the superior cardiac branch of the left sympathetic, and the trunk of the left vagus. The left superior intercostal vein passes obliquely upwards and to the right, across it, between the left vagus and left phrenic nerves.

Posterior to, and *to the right side* of the arch, are the trachea, the deep cardiac plexus, the left recurrent nerve, the left border of the œsophagus, and the thoracic duct. *Above* are its three large branches—the innominate, the left common carotid, and the left

subclavian arteries; and crossing anterior to their roots is the left innominate vein. *Below* is the bifurcation of the pulmonary artery and the root of the left lung; the ligamentum arteriosum, which is also below, attaches it to the commencement of the left pulmonary artery, whilst to the right of the ligament lies the superficial cardiac plexus, and to its left the left recurrent nerve.

Branches.—The three great vessels which supply the head and neck, part of the thoracic wall, and the upper extremities—viz. the innominate, the left common carotid, and the left subclavian arteries—arise from the aortic arch.

Aorta descendens.—The thoracic portion of the **descending aorta** lies in the posterior mediastinum; it extends from the termination of the arch, at the lower border of the left side of the fourth thoracic vertebra, to the aortic opening in the diaphragm, where, opposite the twelfth thoracic vertebra, it becomes continuous with the abdominal portion. Its length is from 17·5 to 20 cm. (seven to eight inches), and its diameter diminishes from 23 mm. at its commencement to 21 mm. at its termination.

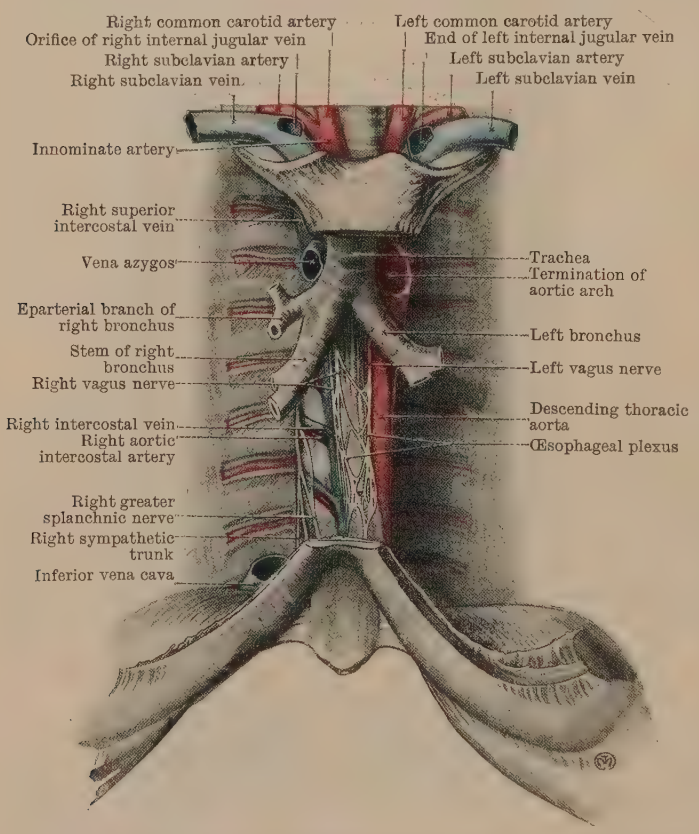

FIG. 730.—DISSECTION OF THE POSTERIOR MEDIASTINUM AND THE POSTERIOR PART OF THE SUPERIOR MEDIASTINUM, FROM THE ANTERIOR ASPECT.

Relations.—Immediately *posterior to* it are the vertebral column and the anterior longitudinal ligament. It rests also on the accessory hemiazygos and the hemiazygos veins, whilst from its posterior aspect the aortic intercostal branches are given off.

Anteriorly it is in relation, from above downwards, with the root of the left lung, the pericardium, which separates it from the back of the left atrium, the œsophagus with the œsophageal plexus of nerves, and the crura of the diaphragm which separate it from the caudate lobe of the liver. On the *left side* are the left lung and pleura. On the *right side* the thoracic duct and the vena azygos form immediate relations along its whole length. The œsophagus also lies to the right of the upper part of the descending aorta, whilst the right lung and pleura are in relation below.

Branches.—Nine pairs of aortic intercostal arteries, two left bronchial arteries, four or five œsophageal, some small pericardial, and a few posterior mediastinal and superior phrenic branches, usually arise from the thoracic part of the descending aorta.

AORTA ABDOMINALIS.

The abdominal portion of the descending aorta lies in the epigastric and umbilical regions of the abdomen. It extends from the middle of the lower border of the last thoracic vertebra to the body of the fourth lumbar vertebra, where, to the left of the median plane, it bifurcates into the right and left common iliac arteries.

The point of division is a little below and to the left of the umbilicus, opposite a line drawn transversely across the abdomen on a level with the highest points of the iliac crests.

At its commencement it is 21 mm. in diameter, but after the origin of two large branches, the cœliac and the superior mesenteric arteries, it diminishes considerably, and then retains a fairly uniform diameter to its termination.

Relations.—*Posteriorly*, it is in contact with the upper four lumbar vertebræ and intervening fibro-cartilages, the anterior longitudinal ligament, and the left lumbar veins;

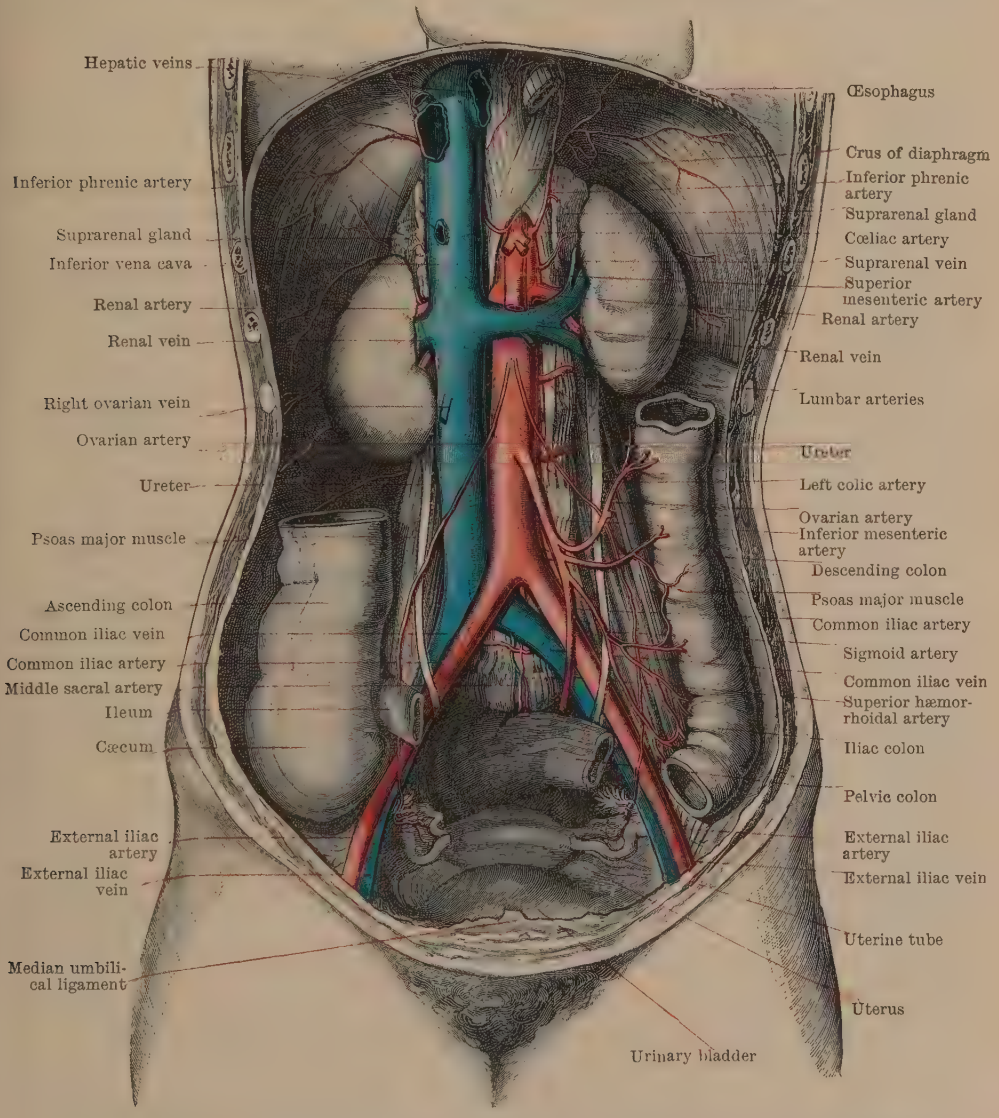

Fig. 731.—The Abdominal Aorta and its Branches in a Formalin-hardened Preparation.

the lumbar and the middle sacral arteries spring from the posterior surface of the vessel. *Anteriorly*, and in close relation with it, there are from above downwards the following structures: the cœliac axis and cœliac plexus, the pancreas and splenic vein, the superior mesenteric artery, the left renal vein, the third part of the duodenum, the root of the mesentery, the aortic plexus, the inferior mesenteric artery, the peritoneum and coils of small intestine. More superficially the stomach, the transverse colon, and the greater and lesser omenta are in front. On the *right side*, in the upper part of its extent, are the thoracic duct and cisterna chyli, the vena azygos, and the right crus of the diaphragm, the latter separating it from the right cœliac ganglion and from the upper part of the

inferior vena cava. Its lower part is in direct relation, on the right side, with the inferior vena cava. On the *left side*, the left crus of the diaphragm with the left cœliac ganglion, and the terminal portion of the duodenum, are in close relation with its upper part, whilst in the lower portion of its extent the peritoneum and some coils of the small intestine are in contact with it. Lumbar lymph glands lie around it, on all sides.

Branches.—The branches form two groups, visceral and parietal, and each group consists of paired and unpaired vessels, as follows :—

Visceral.		Parietal.	
Unpaired.	**Paired.**	**Unpaired.**	**Paired.**
Cœliac	Suprarenal	Middle sacral (which is the original continuation)	Inferior phrenic
Superior mesenteric	Renal		
Inferior mesenteric	Testicular or ovarian		Lumbar (four pairs)
			Common iliac

Abnormalities of the Pulmonary Artery and Aorta.—The **pulmonary artery** and the **aorta** may arise by a common stem, as in fishes and some amphibians, and the common stem may spring either from the right or the left ventricle, or from both. In these cases the truncus arteriosus has remained undivided, and the normal position of the interventricular septum in relation to the lower orifice of the aortic bulb has been altered.

Again, owing to malposition of the aortic septum, the pulmonary artery may spring from the left ventricle and the aorta from the right ventricle. In some cases the root of the pulmonary artery is obliterated, and the blood passes to the lungs along the patent ductus arteriosus.

Occasionally the arch of the aorta is on the right side instead of the left, a condition which is normal in birds. More rarely there are two permanent aortic arches, right and left, as in reptiles; the œsophagus and trachea in these cases are enclosed in a vascular collar, the two arches unite dorsally, and the beginning of the descending aorta is double. Quite independent of this condition, however, the two primitive dorsal aortæ sometimes fail, either altogether or partially, to unite together, and the descending aorta is accordingly represented, to a corresponding extent, by two tubes. A more common, though still rare, form of double aorta is that due to the persistence, in whole or in part, of the septum formed by the fused walls of the primitive dorsal aortæ from which the descending aorta is developed.

The length of the descending aorta is determined largely by the extent to which fusion of the two primitive aortæ takes place. Accordingly, when this deviates from the normal, the termination of the descending aorta is at a correspondingly higher or lower level than usual, and resulting from this the lengths of the common iliac arteries are almost invariably proportionately modified. The bifurcation of the aorta may be as low as the fifth lumbar vertebra; less frequently it is higher than usual; it is rare, however, to find it as high as the third, and still more rare to find it at the level of the second, lumbar vertebra.

The aorta, instead of bifurcating into two common iliac arteries, may terminate in a common iliac artery on one side and a hypogastric artery on the opposite side, the external iliac artery on the irregular side arising, at a higher level, as a branch of the aortic stem. This arrangement approaches the condition met with in carnivores and many other mammals, in which the aorta bifurcates into two hypogastric arteries, the external iliacs arising from the aorta at a higher level as lateral branches; it is probably due either to a fusion of the secondary roots of the umbilical arteries of opposite sides or to a caudal continuation of the fusion of the primitive dorsal aortæ.

BRANCHES OF THE ASCENDING AORTA.

Arteriæ Coronariæ.

The coronary arteries are two in number, a right and a left; they are distributed almost entirely to the heart, but give also some small branches to the roots of the great vessels, and to the pericardium (Figs. 721, 722, and 725).

The **right coroanry artery** springs from the anterior aortic sinus. It runs forwards, between the root of the pulmonary artery and the auricle of the right atrium, to the coronary sulcus, in which it passes downwards and to the right to the junction of the right and inferior margins of the heart. There it turns to the left, in the inferior part of the coronary sulcus, as far as the posterior end of the inferior interventricular sulcus, where it gives off its interventricular branch and then ends by anastomosing with the circumflex branch of the left coronary

artery. It is accompanied by branches from the cardiac plexus and the right coronary vein.

Branches.—The **interventricular** branch runs forwards in the inferior interventricular sulcus; it supplies both ventricles, and anastomoses, at the apex of the heart, with the interventricular branch of the left coronary artery.

Aortic and **pulmonary twigs** are distributed to the roots of the aorta and pulmonary artery respectively. A **right atrial branch** passes upwards on the anterior surface of the right atrium, between it and the ascending aorta; one or more **anterior ventricular** branches, of small size, descend on the anterior surface of the right ventricle; a branch of larger size, the **right marginal artery**, runs along the inferior margin of the heart and gives branches to both surfaces of the right ventricle.

The **left coronary artery** arises from the left posterior aortic sinus. Its short trunk runs forwards, between the root of the pulmonary artery and the auricle of the left atrium, to the coronary sulcus at the upper end of the anterior interventricular groove, where it divides into a circumflex and an interventricular branch.

Branches.—The **circumflex branch** runs to the left margin of the heart, and there turns to the inferior surface where it comes into relation with the coronary sinus; it ends by anastomosing with the right coronary artery. It supplies branches to the left atrium, the left margin of the heart, and the posterior part of the inferior surface of the left ventricle. The **interventricular terminal branch** passes down the anterior interventricular sulcus to the apex of the heart, where it anastomoses with the interventricular branch from the right coronary; it supplies both ventricles, and is accompanied by cardiac nerves and by the great cardiac vein.

A **left atrial branch** or branches of small size pass to the wall of the left atrium, and small **aortic** and **pulmonary branches** are also given to the roots of the aorta and pulmonary artery.

Abnormalities.—The **coronary or cardiac arteries** may arise by a single stem. When arising separately both may spring from the same aortic sinus; or again, their interventricular and circumflex branches may arise as distinct vessels from a single aortic sinus. This variability is not very remarkable, seeing that the arteries in question are merely enlarged "vasa vasorum" raised to a position of special importance by the development of the heart.

BRANCHES OF THE ARCH OF THE AORTA.

The branches which arise from the arch of the aorta supply the head and neck, the upper extremities, and part of the body wall.

They are three in number, viz., the **innominate**, the **left common carotid**, and the **left subclavian arteries**. The innominate is a short trunk, from the termination of which the right common carotid and the right subclavian arteries spring (Figs. 727 and 728); thus there is, at first, a difference between the stem vessels of opposite sides, but the subsequent course and the ultimate distribution of those vessels closely correspond.

Variations.—The **branches of the arch of the aorta** are sometimes increased and sometimes decreased in number.

The highest number recorded is six, viz., right subclavian, right vertebral, right common carotid, left common carotid, left vertebral, and left subclavian. Apparently this condition is the result of the absorption into the arch of the innominate artery and of the roots of the subclavian arteries, to points beyond the origins of the vertebrals. By variations of this process of absorption other combinations may be produced; thus, instead of the roots of the subclavian arteries being absorbed, the right common carotid and innominate arteries may alone be absorbed, in which case the five following branches spring separately from the arch of the aorta: right subclavian, right external carotid, right internal carotid, left common carotid, and left subclavian. The trunk most commonly absorbed is the initial part of the left subclavian; the number of branches then arising from the arch of the aorta is four, the additional vessel being the left vertebral, which arises between the left common carotid and the left subclavian. Occasionally the usual three branches from the arch are increased to four by the formation of a new vessel, the "thyreoidea ima." This may be placed between the innominate and left carotid trunks, in which case it represents a persistent ventral visceral branch from the ventral root of the fourth left aortic arch; in other cases the thyreoidea ima springs from the innominate artery and represents a ventral visceral branch of the ventral root of the fourth *right arch*. Very rarely the right vertebral artery arises separately, and forms a fourth branch of the arch of the aorta, the rest of the branches being normal. This condition cannot be accounted for by any modification of the ordinary developmental processes. It may possibly be due to the persistence of an irregular or unimportant anastomosis between the ventral root of an aortic arch and the seventh somatic segmental artery.

Decrease in the number of branches from the arch of the aorta is most frequently due to fusion of the ventral roots of the fourth aortic arches, the result being that a stem is formed

common to the right subclavian and the right and left common carotid arteries; whilst the left subclavian, arising separately, is the only other branch which springs from the arch of the aorta.

If the fusion of the ventral roots proceeds further and includes those of the third arches, the result, as regards the branches given off from the arch of the aorta, is the same, viz., there is a common stem for the right subclavian and both carotids, and a separate left subclavian trunk; but the common stem now gives off the right subclavian artery, and then continues as a single vessel for some distance before it divides into the two common carotids, of which the left crosses in front of the trachea. This arrangement is common in many quadrumana and in some other mammals.

It is only in rare cases when the number of branches from the arch of the aorta is reduced to two, that these consist of a right subclavian artery and of a single stem common to the two carotids and the left subclavian artery. In such cases, however, the right common carotid crosses in front of the trachea, and the variation is one of practical importance, but it does not appear to exist as a normal condition in any mammal. Probably it is due to fusion of the ventral roots of the fourth aortic arches, with absorption of the left fourth arch and the left subclavian into the stem so formed, whilst the right subclavian is relatively displaced. The two common carotids may arise by a common stem, and the left subclavian arise separately from the arch of the aorta, whilst the right subclavian springs from the descending aorta. This arrangement probably results from the disappearance of the fourth right arch, the fusion of the ventral roots of the fourth arches of opposite sides and the persistence of the dorsal roots of the right fourth and sixth arches. (See Development of Vascular System.)

Sometimes two innominate arteries, right and left, replace the usual three branches of the arch of the aorta. This is the normal arrangement in bats, moles, and hedgehogs. It is obviously the result of the disappearance of that portion of the arch which intervenes between the left carotid and left subclavian arteries, and the consequent fusion of these two vessels.

In a similar way may be explained the rarer condition in which the three ordinary branches of the arch arise by one single stem, which divides into right and left innominate arteries. In most ruminants, in the horse and in the tapir, this arrangement is constant.

It will be evident that other combinations and modifications may be met with in the branches of the arch of the aorta as the result of fusions and absorption.

The **right subclavian** or the right vertebral may spring from the commencement of the descending aorta.

ARTERIA ANONYMA.

The **innominate artery** (Fig. 727) arises, posterior to the middle of the manubrium sterni, from the convexity of the arch of the aorta near its right or anterior extremity, and it ends opposite the right sterno-clavicular articulation, where it divides into the right subclavian and right common carotid arteries.

Course.—The trunk measures from 37 to 50 mm. in length; it runs upwards, posteriorly, and laterally, in the superior mediastinum, to the root of the neck.

Relations.—*Posterior.*—It is in contact behind, with the trachea below and with the right pleural sac above.

Anterior.—The left innominate vein crosses in front of the lower part of the artery and above that the sterno-thyreoid muscle separates it from the sterno-hyoid and the right sterno-clavicular joint. The remains of the thymus, which separate it from the manubrium sterni, are also in front.

Right Lateral.—The right innominate vein and the upper part of the superior vena cava are on the right side of the artery.

Left Lateral.—On its left side is the origin of the left common carotid artery, whilst at a higher level the trachea is in contact with it.

Branches.—As a rule the innominate artery does not give off any branches except its two terminals, but occasionally it furnishes an additional branch, the thyreoidea ima.

Abnormalities.—From what has already been said, with reference to the branches of the arch of the aorta, it will be noted that the innominate artery may be absent. On the other hand there may be two innominate arteries, a right and a left, each ending in corresponding common carotid and subclavian trunks, and the two vessels may themselves arise by a common stem.

The branches given off by the innominate artery may be increased in number, or the innominate may vary from the normal only as regards length. As a consequence of such modifications in length, the origins of the right common carotid and right subclavian arteries may be situated at a higher or lower level than usual, whilst, in the absence of the innominate artery, both these branches may arise directly from the aorta.

The **thyreoidea ima** is an inconstant and slender vessel. When present it may arise from the arch of the aorta, but it springs usually from the lower part of the innominate. It passes upwards, anterior to the trachea, through the anterior

part of the superior mediastinum and the lower part of the neck, and gives off branches to the lateral lobes and isthmus of the thyreoid body and to the trachea.

THE ARTERIES OF THE HEAD AND NECK.

The vessels distributed to the head and neck are chiefly derived from the carotid trunks; there are, however, in addition, other vessels which arise from the main arterial stems of the upper extremities, and it will be advantageous to describe the most important of those, viz., the vertebral arteries, with the carotid system. The smaller additional branches will be considered along with the remaining branches of the subclavian arteries.

The **carotid system of arteries** consists, on each side, of a **common carotid trunk**, which divides into **internal** and **external carotid arteries**, from which numerous branches are given off (Figs. 726, 727, 730, 732).

The internal carotid arteries are distributed, almost entirely, to the contents of the cranial cavity, internal to the dura mater, and to the structures in the cavity of the orbit. The external carotid arteries, on the other hand, supply structures of the head and neck more externally situated.

It is to be noted, however, that the vascular supply of the brain is not wholly derived from the internal carotid vessels, but that it is contributed to, largely, by the vertebral arteries also.

ARTERIÆ CAROTIDES COMMUNES.

The right and the left **common carotid arteries** are of unequal length. The right common carotid commences at the bifurcation of the innominate artery posterior to the right sterno-clavicular articulation; the left arises in the superior mediastinum, from the arch of the aorta; but each terminates at the level of the upper border of the thyreoid cartilage; the left artery has thus a short intra-thoracic course, and, so far, its relations call for separate consideration; whilst in the rest of its course it passes upwards in the neck, like the right common carotid, and has almost similar relations.

Thoracic Portion of the Left Common Carotid.—The thoracic or mediastinal portion of the left common carotid artery extends from the upper aspect of the aortic arch, immediately posterior and to the left of the origin of the innominate artery, to the left sterno-clavicular articulation, where the cervical portion commences. It is from 25 to 37 mm. (1 or 1½ inches) in length, and it runs upwards and slightly laterally through the upper part of the superior mediastinum. It lies on a more posterior plane than the innominate artery.

Relations.—*Posterior.*—The vessel is in contact posteriorly, and from below upwards, with the trachea, the left recurrent nerve, the œsophagus, and the thoracic duct; and the thoracic part of the left subclavian artery is a postero-lateral relation.

Anterior.—The left innominate vein runs obliquely across the anterior aspect of the artery, upon which cardiac branches from the left vagus and sympathetic descend vertically. These structures, together with the remains of the thymus and the anterior margins of the left lung and pleura, separate the artery from the manubrium sterni, and from the origins of the sterno-hyoid and sterno-thyreoid muscles.

Medial.—The innominate artery below, and the trachea above, are on the right side.

Lateral.—The left pleura, and, on a posterior plane, the left phrenic and vagus nerves and the left subclavian artery are on its left side.

Cervical Portion of the Left Common Carotid Artery.—The cervical part of the left common carotid artery is about 85 mm. (three and a half inches) long; it extends from the left sterno-clavicular articulation to the level of the upper border of the thyreoid cartilage and the lower border of the third cervical vertebra, where it ends by dividing into the external and internal carotid arteries.

Course.—It runs upwards, laterally, and backwards, through the muscular and in the lower portion of the carotid divisions of the anterior triangle of the neck. Below it is separated from its fellow of the opposite side by the trachea and the œsophagus, and above by the relatively wide pharynx.

Relations.—It is enclosed, together with the internal jugular vein and the vagus nerve, in a sheath of deep cervical fascia—the **carotid sheath.**

Posterior.—The longus colli and scalenus anterior, below, and the longus capitis, above, are separated from the posterior surface of the artery and its sheath by the prevertebral fascia and the sympathetic trunk. The vertebral artery and the thoracic duct are posterior to it at the level of the seventh cervical vertebra; the inferior thyreoid artery crosses behind it, either between it and the vertebral or between it and the transverse process of the sixth cervical vertebra, and the vagus nerve lies postero-lateral to it.

Superficial.—The descendens branch of the hypoglossal nerve lies superficial to the artery, usually outside the sheath, but sometimes enclosed in it (Fig. 732). Opposite the

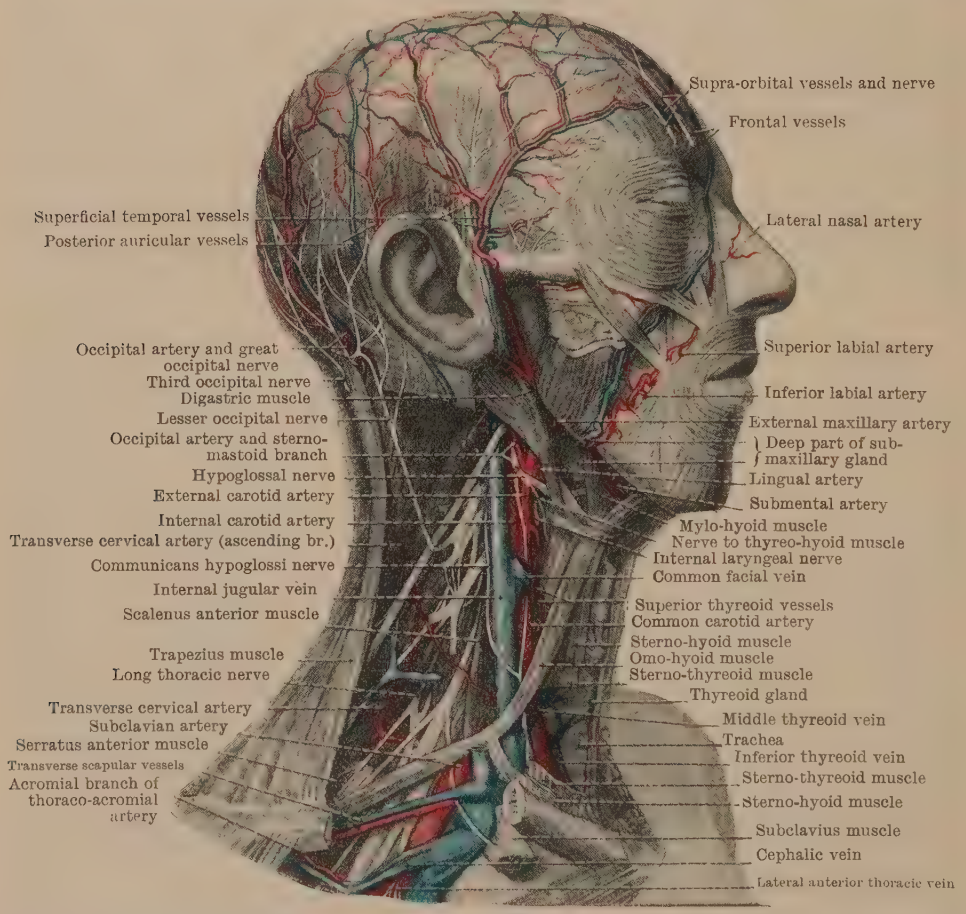

FIG. 732.—DISSECTION OF THE HEAD AND NECK SHOWING THE COURSE OF THE INTERNAL JUGULAR VEIN.

sixth cervical vertebra the omo-hyoid muscle and the sterno-mastoid branch of the superior thyreoid artery cross superficial to the carotid artery, which is overlapped, above the omo-hyoid muscle, by the anterior border of the sterno-mastoid and by cervical lymph glands. It is frequently crossed, in that part of its extent, by the superior thyreoid vein. Below the omo-hyoid the artery is covered by the sterno-thyreoid, the sterno-hyoid, and the sterno-mastoid muscles, and it may be overlapped by the lateral lobe of the thyreoid gland; it is also crossed, deep to the muscles, by the middle thyreoid vein, whilst occasionally a communication between the common facial and anterior jugular veins descends anterior to the artery along the anterior border of the sterno-mastoid. Just above the sternum the anterior jugular vein is in front of the artery, but separated from it by the sterno-hyoid and sterno-thyreoid muscles.

Medial.—The trachea and œsophagus, with the recurrent nerve in the angle between them, are medial to the lower part of the artery; the larynx and pharynx are medial

to its upper part. The carotid gland or glomus caroticum lies on the medial side of the termination of the artery.

Lateral.—The internal jugular vein occupies the lateral part of the carotid sheath. The vein lies not only to the lateral side of the artery, but also slightly in front of it, especially in the lower part of the neck.

Branches.—As a rule no branches are given off from either of the common carotid arteries, except the terminal branches and some minute twigs from each to the corresponding carotid sheath and glomus caroticum.

The **right common carotid artery**, as already stated, differs as regards origin from the left common carotid. In length and general position it corresponds with the cervical portion of the left common carotid, and its relations also are very similar. Such differences as exist may be briefly summarised as follows: The internal jugular vein on both sides lies lateral to the artery; on the left side in the lower part of the neck it is also anterior to the artery, whilst on the right side the vein is separated from the lateral surface of the artery, at its lower end, by a well-marked interval in which the vagus nerve appears. The thoracic duct does not come into relation with the right common carotid, and there is also a difference in the relations of the recurrent nerves to the arteries on the two sides. On the left side the nerve crosses posterior to the mediastinal part of the left artery, and lies medial to its cervical part, whilst the corresponding nerve on the right side passes posterior to the lower part of the carotid artery in the neck to reach its medial side, and the œsophagus has a less intimate relation with the right than with the left common carotid artery.

Abnormalities.—The right common carotid artery may arise separately from the arch of the aorta, then it may be the first, or, much more rarely, the second branch. In the former case the fourth right aortic arch has been obliterated, and the right subclavian artery springs from the descending aorta; in the latter case either the innominate stem has been absorbed into the arch of the aorta, or the ventral root of the fourth right aortic arch has fused with part of an elongated fourth left arch.

Whether arising as the first or second branch, the origin may be to the left of the median plane, and the trunk may pass in front of the trachea, or behind the œsophagus, before it ascends into the neck.

The left common carotid artery varies, as regards its origin, much more frequently than the right vessel; not uncommonly, and apparently because of the fusion of the ventral roots of the fourth aortic arches, it arises from a stem common to it and to the right common carotid and right subclavian arteries.

Both common carotids may vary as regards their termination. They may divide at a higher or lower level than usual, the former more commonly than the latter; whilst in a few exceptional cases the common carotid does not divide, but is continued directly into the internal carotid, and from this the branches usually given off by the external carotid are derived.

This arrangement is probably due to obliteration of the ventral roots of the first and second aortic arches, the arches persisting and being divided into the branches which generally arise from their ventral extremities.

Usually the common carotids give off no branches, but not infrequently one or more of the branches of the external carotids arise from them.

ARTERIA CAROTIS EXTERNA.

The **external carotid artery** (Figs. 732, 733) is the smaller of the two terminal branches of the common carotid; its length is about 62 mm. (2½ inches). It extends from the upper border of the thyreoid cartilage to the back of the neck of the mandible, where it terminates by dividing into the superficial temporal and the internal maxillary arteries.

Course.—It commences in the carotid triangle, passes upwards, medial to the posterior belly of the digastric and the stylo-hyoid muscles and the lower part of the postero-medial surface of the parotid gland, then it enters a groove in the medial border of the gland, through which it passes to the upper part of the antero-medial surface posterior to the neck of the mandible, where it terminates.

At its commencement it lies somewhat anterior and medial to the internal carotid artery, but it inclines posteriorly as it ascends, and thus becomes superficial to the internal carotid. Its course is indicated by a line drawn from the lobule of the ear to the posterior extremity of the greater cornu of the hyoid bone.

Relations.—*Posterior.*—In the lower part of its extent it is in close relation with the internal carotid, and in the upper part of its course with the antero-medial surface of the parotid gland.

Medial.—At its commencement the fibres of the inferior constrictor muscle are in contact with its medial side, but at a higher level the structures which intervene between it and the internal carotid—viz., the stylo-pharyngeus muscle, the tip of the styloid process, the stylo-glossus muscle, the glosso-pharyngeal nerve, and the pharyngeal branch of the vagus—separate it from the wall of the pharynx; whilst medial both to it and to the internal carotid artery are the external and internal laryngeal branches of the superior laryngeal nerve.

Superficial.—In the carotid triangle it is overlapped by the anterior border of the sterno-mastoid, and it is crossed, immediately below the level of its occipital branch, by the hypoglossal nerve. It is also crossed by the lingual and common facial veins, and sometimes by the superior thyreoid vein also. At the level of the angle of the mandible it passes under cover of the posterior belly of the digastric and the stylo-hyoid muscles, which

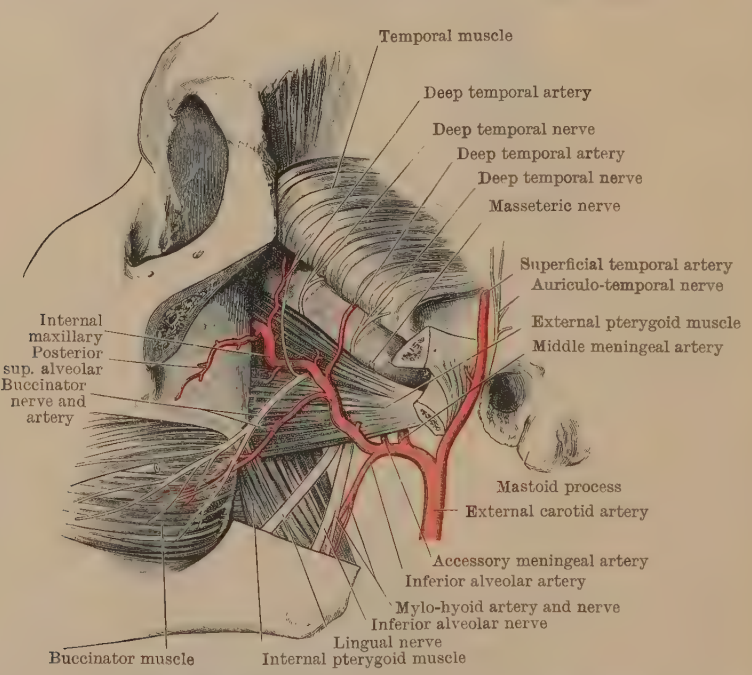

FIG. 733.—DISSECTION SHOWING THE TERMINATION OF THE EXTERNAL CAROTID ARTERY AND THE FIRST AND SECOND PARTS OF THE INTERNAL MAXILLARY ARTERY.

separate it from the medial surface of the internal pterygoid muscle. As it emerges from under cover of the stylo-hyoid it enters a groove in the parotid gland, and as it lies in the gland the posterior facial vein (temporo-maxillary) descends superficial to the artery, and both the artery and the vein are crossed, superficially, by the branches of the facial nerve.

Branches.—Eight branches arise from the external carotid artery; of these, three—the superior thyreoid, the lingual, and the external maxillary—spring from its anterior aspect in the carotid triangle; two arise from its posterior aspect, viz., the occipital and the posterior auricular, the former commencing below the posterior belly of the digastric and the latter above it; one from its medial side, viz., the ascending pharyngeal, which arises in the carotid triangle; and two from its termination, viz., the superficial temporal and the internal maxillary.

Abnormalities.—The external carotid artery may be absent, or it may, in rare cases, arise directly from the arch of the aorta. The number of its branches may be diminished either by fusion of their roots or by transference to the internal or common carotid arteries. On the other hand, the number of its branches may be increased; thus, the sterno-mastoid artery, the hyoid branch usually given off by the superior thyreoid artery, or the ascending palatine branch of the external maxillary, may arise from it. Sometimes the branches may arise in the usual way, but may deviate from the course generally taken; more particularly is this the case with the

internal maxillary artery, which may pass either between the heads, or entirely lateral or medial to both heads of the external pterygoid muscle.

Branches of the External Carotid Artery.

(1) The **superior thyreoid artery** (Figs. 732 and 734) springs from the anterior aspect of the lower part of the external carotid artery, just below the tip of the greater cornu of the hyoid bone, and it terminates at the upper extremity of the corresponding lobe of the thyreoid gland by dividing into terminal branches.

Course.—From its commencement, in the carotid triangle, the artery runs downwards and forwards to its termination.

Relations.—*Medially* it is in relation with the inferior constrictor muscle and the external laryngeal branch of the superior laryngeal nerve.

Superficially it is covered, at its origin, by the anterior border of the sterno-mastoid; afterwards, for a short distance, by fascia, platysma, and skin, and in the lower part of its extent by the omo-hyoid, the sterno-hyoid, and the sterno-thyreoid muscles, and it is overlapped by an accompanying vein.

Branches.—(1) *In the carotid triangle*—(*a*) A **hyoid branch** runs along the lower border of the greater cornu of the hyoid bone, under cover of the thyreo-hyoid muscle, to anastomose with its fellow of the opposite side and with the hyoid branch of the lingual artery. It supplies the thyreo-hyoid muscle and membrane.

(*b*) The **superior laryngeal branch** runs forwards, deep to the thyreo-hyoid muscle. It pierces the hyo-thyreoid membrane, in company with the internal laryngeal nerve, supplies the muscles, ligaments, and mucous membrane of the larynx, and anastomoses with its fellow of the opposite side, with branches of the crico-thyreoid artery, and with the terminal branches of the inferior thyreoid artery.

(*c*) The **sterno-cleido-mastoid branch** passes downwards and posteriorly, along the upper border of the anterior belly of the omo-hyoid muscle and across the common carotid artery, to the deep surface of the sterno-mastoid muscle. It anastomoses, in the sterno-mastoid, with branches of the occipital and transverse scapular arteries.

(2) *In the muscular triangle*—(*d*) A **crico-thyreoid branch** passes anteriorly, either superficial or deep to the sterno-thyreoid. It crosses the crico-thyreoid muscle to anastomose, in front of the crico-thyreoid ligament, with its fellow of the opposite side, and, by branches which perforate the crico-thyreoid ligament, with laryngeal branches of the superior and inferior thyreoid arteries. It supplies the adjacent muscles and membrane.

(*e*) The **terminal branches** are **anterior, medial,** and **lateral.**

The **anterior terminal branch** descends along the anterior border of the corresponding lobe of the thyreoid gland, and the upper border of the thyreoid isthmus, to anastomose with its fellow of the opposite side. The **medial branch** is the largest; it is distributed to the medial surface of the lobe. The **lateral branch,** which ramifies in the lateral surface of the corresponding lobe, is the smallest. All three terminal branches supply glandular branches to the thyreoid gland. They anastomose with each other and with branches from the inferior thyreoid artery.

(2) The **lingual artery** (Figs. 732 and 734) springs from the anterior aspect of the external carotid, opposite the tip of the greater cornu of the hyoid bone, and terminates, as the arteria profunda linguæ, which ends beneath the tip of the tongue, where it anastomoses with its fellow of the opposite side.

Course.—Whilst in the carotid triangle, the *first part of the artery* forms a loop with the convexity upwards. The *second part* passes forwards, medial to the hyo-glossus muscle, immediately above the greater cornu of the hyoid bone, to the anterior border of the hyo-glossus, where it gives off a sublingual branch and becomes the arteria profunda linguæ. The profunda linguæ artery passes obliquely forwards and upwards, under cover of the anterior border of the hyo-glossus, and then turns directly forwards on the under surface of the tongue to the tip, lying between the inferior lingualis laterally and the genio-glossus medially.

Relations.—The first part of the lingual artery is crossed superficially by the hypoglossal nerve, and is covered by skin, fascia, and the platysma; it rests medially against the middle constrictor of the pharynx. The second part is deeper. It lies between the middle constrictor medially and the hyo-glossus laterally, and is separated by the latter

from the hypoglossal nerve, the vena comitans hypoglossi, and the lower part of the submaxillary gland. The profunda artery of the tongue ascends almost vertically, parallel with and medial to the anterior fibres of the hyo-glossus, which are covered by the mylo-hyoid, and between the hyo-glossus and the genio-glossus; then it runs forwards between the inferior lingualis and the genio-glossus muscles, and is covered, on its lower surface, by the mucous membrane of the tongue. Thus, at its termination, near the frenulum linguæ, it is comparatively superficial.

Branches.—(*a*) The **ramus hyoideus,** a small branch which arises in the carotid triangle and runs along the upper border of the greater cornu of the hyoid bone. It anastomoses with its fellow of the opposite side and with the hyoid branch of the superior thyreoid artery.

(*b*) The **dorsalis linguæ** is a branch of moderate size which arises from the second part of the artery and is not uncommonly double. It ascends, between the hyo-glossus and the genio-glossus, to the dorsum of the tongue, where it branches and anastomoses with its fellow of the opposite side around the foramen cæcum. It supplies the posterior part of the tongue as far back as the epiglottis, and sends branches, posteriorly, to the palatine tonsil which anastomose with the tonsillar twigs of the ascending palatine branch of the external maxillary and with the ascending pharyngeal artery.

(*c*) A **sublingual branch** arises at the lower part of the anterior border of the hyo-glossus muscle and runs anteriorly and upwards, between the mylo-hyoid and the genio-glossus, to the sublingual gland, which it supplies; it also supplies the mylo-hyoid, the genio-glossus, and the genio-hyoid muscles. It anastomoses with its fellow of the opposite side, with the arteria profunda by a branch which it sends along the frenulum linguæ, and, through the mylo-hyoid muscle, with the submental branch of the external maxillary.

(3) The **external maxillary artery** (O.T. **Facial**) (Fig. 733) arises from the front of the external carotid, immediately above the lingual. It ends at the angle of the mouth, where it becomes the angular artery.

Course.—It commences in the carotid triangle, immediately above the lingual, and passes upwards to the angle of the mandible, on the lateral surface of the middle constrictor muscle. Still ascending, it lies between the posterior belly of the digastric and the stylo-hyoid muscles laterally, and the superior constrictor medially, and it is separated from the palatine tonsil by the superior constrictor. When it reaches the upper border of the stylo-hyoid it enters a groove in the posterior part of the submaxillary gland and runs downwards and anteriorly, between the lateral surface of the gland and the internal pterygoid muscle, to the posterior end of the lower border of the body of the mandible. There it pierces the deep cervical fascia, turns round the inferior border of the mandible, at the anterior border of the masseter, enters the face and continues upwards and forwards to its termination.

Relations.—In the carotid triangle the artery is comparatively superficial, except just at its origin, which is overlapped by the anterior fibres of the sterno-mastoid muscle. As it ascends it is in relation, on the medial side, with the middle and superior constrictor muscles, and, as already stated, the superior constrictor separates it from the palatine tonsil. Its relations between the point where it passes medial to the posterior belly of the digastric and the point where it turns round the lower border of the mandible have been given in the description of its course.

After turning round the lower border of the body of the mandible, which it grooves slightly, the artery becomes more superficial than in any other part of its course, being covered only by platysma, fascia, and skin. At that point the anterior facial vein is immediately posterior to the artery, lying on the surface of the masseter. In the face the artery lies between the platysma, the risorius, the zygomaticus major, and the infra-orbital section of the quadratus labii superioris, which, with skin and fascia, are superficial to it, and the buccinator and the musculus caninus, which are deeper. The termination of the artery is in the substance of the quadratus labii superioris.

The anterior facial vein, though still posterior to the artery in the face, runs a somewhat straighter course, and is situated at some little distance from it.

Branches.—Four named branches are given off in the neck, and several in the face.

In the Neck.—(*a*) The **ascending palatine branch** (Fig. 735) is a small artery which arises from the external maxillary under cover of the posterior belly of the digastric. It ascends, and, after passing between the stylo-glossus and the stylo-pharyngeus muscles, reaches the apex of the petrous portion of the temporal bone, where it turns downwards,

accompanying the levator veli palatini muscle, pierces the pharyngeal aponeurosis, and enters the soft palate.

It supplies the lateral wall of the upper part of the pharynx, the soft palate, the palatine tonsil, and the auditory tube, and it anastomoses with the tonsillar branch of the external maxillary, the dorsalis linguæ, the descending palatine branch of the internal maxillary, and with the ascending pharyngeal artery, which sometimes replaces it.

(*b*) The **tonsillar branch**, a small artery which arises close to the ascending palatine. It passes upwards between the internal pterygoid and the stylo-glossus, pierces the superior constrictor, and terminates in the palatine tonsil. It supplies the middle and superior constrictor muscles, and it anastomoses with the dorsalis linguæ, with the ascending palatine branch, and with the ascending pharyngeal artery.

(*c*) The **submaxillary** or **glandular branch** is frequently represented by two or three small twigs which pass directly into the submaxillary gland.

(*d*) The **submental branch** arises from the external maxillary just as the latter vessel turns round the inferior border of the mandible. It is the largest branch given off in the neck, and it runs forwards, on the lateral surface of the mylo-hyoid muscle, and medial to the upper part of the submaxillary gland, to the symphysis menti; there it turns upwards, round the margin of the mandible, and it terminates by anastomosing with branches of the mental and inferior labial arteries. In the neck the submental artery supplies the mylo-hyoid muscle, and the submaxillary and sublingual glands, the latter by a branch which perforates the mylo-hyoid muscle. It anastomoses with the mylo-hyoid branch of the inferior alveolar and with the sublingual artery. In the face it supplies the structures of the lower lip, and anastomoses with the mental branch of the inferior alveolar, and with the inferior labial branches of the external maxillary artery.

In the Face.—(*e*) The **inferior labial branch** arises from the front of the external maxillary artery below the level of the angle of the mouth. It runs medially, deep to the triangularis, the quadratus labii inferioris, and the orbicularis oris. In the substance of the lower lip it lies close to the mucous membrane and anastomoses, in the median plane, with its fellow of the opposite side. It supplies the structures in its immediate neighbourhood.

(*f*) The **superior labial** springs from the front of the external maxillary about the level of the angle of the mouth. It runs medially, between the orbicularis oris and the mucous membrane of the upper lip, to the median plane, supplying the skin, muscles, and mucous membrane of the upper lip, and, by a *septal branch*, the lower and anterior part of the septum of the nose. It anastomoses with its fellow of the opposite side, with the lateral nasal, and, on the septum nasi, with the septal branch of the spheno-palatine artery.

(*g*) The **masseteric branch**, sometimes represented by several twigs, arises from the posterior aspect of the facial trunk, a short distance above the lower margin of the mandible. It passes upwards and posteriorly, across the masseter, and anastomoses with the transverse facial artery.

(*h*) The **buccal** is an inconstant branch which, when present, arises from the posterior aspect of the external maxillary artery above the masseteric branch. It runs upwards and posteriorly, across the buccinator muscle, to anastomose with the buccinator branch of the internal maxillary artery.

(*i*) The **lateral nasal** springs from the external maxillary at the point where it becomes the angular. It ramifies on the ala of the nose, supplying the skin, muscles, and alar cartilages, and anastomosing with the angular branch, with the dorsal nasal branch of the ophthalmic, and with branches of the spheno-palatine artery.

(*j*) The **angular artery** is the continuation of the external maxillary beyond the origin of the lateral nasal branch. It runs upwards, in the angular head of the quadratus labii superioris, to the medial commissure of the eye, where it anastomoses with the lateral nasal, and with the nasal and palpebral branches of the ophthalmic artery.

In addition to the above-named branches another branch, formerly called the inferior labial, springs from the anterior aspect of the external maxillary below the level of the alveolar border of the mandible. This vessel runs medially, under cover of the muscles of the lower lip, and it anastomoses with the mental branch of the inferior alveolar artery, with the inferior labial, and with its fellow of the opposite side.

(4) The **occipital artery** (Figs. 732, 734, 735) arises from the posterior aspect of the external carotid artery, below the posterior belly of the digastric muscle, and terminates, near the medial end of the superior nuchal line of the occipital bone, by dividing into medial and lateral terminal branches.

Course.—It commences in the carotid triangle and runs upwards and posteriorly, parallel with and under cover of the posterior belly of the digastric, to the interval between the transverse process of the atlas and the base of the skull; there it turns posteriorly, in a groove on the lower surface of the mastoid portion of the temporal bone; as it leaves the groove it alters its direction and runs upwards and medially, on the superior oblique muscle, to the junction of the medial and intermediate thirds of the superior nuchal line of the occipital bone, where it pierces the deep fascia of the neck and enters the superficial fascia of the scalp.

Relations.—In the first or ascending part of its course the occipital artery crosses successively the internal carotid artery, the hypoglossal nerve, the vagus nerve, the internal jugular vein, and the accessory nerve; it is covered by the lower fibres of the posterior belly of the digastric, and the anterior part of the sterno-mastoid muscle, and, close to its origin, it is crossed by the hypoglossal nerve. In the second and more horizontal part of its course, it is still under cover of the sterno-mastoid and digastric, and lies, medially, against the rectus capitis lateralis, which separates it from the vertebral artery. In the third part of its course it rests upon the superior oblique and semispinalis capitis, under cover of the sterno-mastoid, the splenius capitis, and the longissimus capitis muscles. Near its termination it is crossed by the great occipital nerve, and it passes either through the trapezius or between the trapezius and the sterno-mastoid, and pierces the deep fascia of the neck before it enters the superficial fascia of the scalp.

Branches.—(*a*) **Muscular branches** go to the surrounding muscles. The **sterno-mastoid branch** is the most important of this group; it springs from the commencement of the occipital, is looped downwards across the hypoglossal nerve, and is continued downwards and posteriorly, below and anterior to the accessory nerve, into the sterno-mastoid muscle, where it anastomoses with the sterno-mastoid branch of the superior thyreoid artery. It is sometimes represented by two or more small branches.

(*b*) The **meningeal** are irregular branches given off from the occipital, anterior to the mastoid process. They enter the posterior fossa of the skull through the hypoglossal canal, or through the jugular foramen; they supply the upper part of the internal jugular vein, the sigmoid part of the transverse sinus, and the dura mater in the posterior fossa of the skull, and they anastomose with the middle meningeal and with meningeal branches of the ascending pharyngeal artery.

(*c*) The **mastoid**, a small and inconstant branch which arises posterior to the mastoid process. It enters the posterior fossa of the skull through the mastoid foramen, supplies the dura mater, and anastomoses with branches of the middle meningeal artery.

(*d*) The **descending branch** is given off from the occipital upon the surface of the superior oblique. It passes medially, and at the lateral border of the semispinalis capitis it divides into superficial and deep branches. The superficial branch runs over the semispinalis capitis, between it and the trapezius, and anastomoses with the superficial cervical artery. The deep branch passes between the semispinalis capitis and the underlying semispinalis cervicis, and anastomoses with branches of the vertebral and profunda cervicis arteries.

(*e*) The **auricular** is an inconstant branch which, as a rule, is only given off from the occipital when the posterior auricular artery is absent. It ramifies over the mastoid part of the temporal bone, and supplies the medial surface of the auricle.

(*f*) The **terminal branches** (rami occipitales) are medial and lateral. They ramify in the superficial fascia of the posterior part of the scalp, where they anastomose with the posterior auricular and superficial temporal arteries. Both branches are accompanied by branches of the great occipital nerve. The medial branch gives off a meningeal twig, which passes into the skull through the parietal foramen, to supply the walls of the superior sagittal sinus and to anastomose with the middle meningeal artery.

(5) The **posterior auricular artery** (Figs. 732, 734, 735) springs from the posterior aspect of the external carotid immediately above the posterior belly of the digastric muscle, and it terminates between the mastoid process and the back of the auricle by dividing into mastoid and auricular branches.

Course and Relations.—Commencing at the upper border of the posterior belly of the digastric, it runs upwards and posteriorly, under cover of the postero-medial surface of the parotid gland, to the interval between the mastoid process and the external acoustic meatus. It is accompanied in the terminal part of its course by the posterior auricular branch of the facial nerve.

Branches.—(*a*) **Muscular branches** are given to the sterno-mastoid, the digastric, and the styloid group of muscles.

(*b*) **Parotid branches** pass to the lower and posterior part of the parotid gland.

(*c*) A **stylo-mastoid branch** is given off at the lower border of the external acoustic meatus. It runs upwards, by the side of the facial nerve, enters the stylo-mastoid foramen, and ascends, in the canalis facialis (Fallopius), to the upper part of the medial wall of the tympanum, where it terminates by anastomosing with the petrosal branch of the middle meningeal artery. It supplies branches to the external acoustic meatus, the mastoid cells, the vestibule, and semicircular canals, the stapedius muscle, and a *posterior tympanic branch* which anastomoses with the anterior tympanic branch of the internal maxillary, forming, in young subjects, a vascular circle around the membrana tympani; other branches anastomose with tympanic branches from the internal carotid and the ascending pharyngeal arteries, and with the internal auditory branch of the basilar.

(*d*) The **auricular branch** ascends medial to the posterior auricular muscle. It gives branches to the auricle and to the scalp in the posterior part of the temporal region, which anastomose with the superficial temporal and occipital arteries. The auricular branches supply both surfaces of the auricle, piercing or turning round the margins of the cartilage to gain the lateral surface, and they anastomose with the anterior auricular branches of the superficial temporal artery.

(*e*) The **occipital branch** runs upwards and posteriorly along the insertion of the sterno-mastoid muscle. It supplies the sterno-mastoid and occipitalis muscles, and the skin, and it anastomoses with the occipital artery.

(6) **The Ascending Pharyngeal Artery** (Fig. 735).—This artery arises from the medial surface of the lower part of the external carotid, and its terminal branches are distributed to the wall of the pharynx and in the soft palate.

Course.—It commences in the carotid triangle, usually as the first or second branch of the external carotid, and it ascends on the wall of the pharynx to the apex of the petrous portion of the temporal bone.

Relations.—Medially it is in relation with the constrictor muscles of the pharynx. Posterior to it are the transverse processes of the cervical vertebræ, the sympathetic trunk, and the longus capitis. Laterally it is in relation with the internal carotid artery, and it is crossed by the stylo-pharyngeus muscle, the glossopharyngeal nerve, and the pharyngeal branch of the vagus.

Branches.—The branches of this artery are very irregular and inconstant, but the following have received names:—

(*a*) **Pharyngeal Branches.**—Small twigs which ramify on the walls of the pharynx and supply the middle and superior constrictor muscles, the palatine tonsil, and the lower part of the auditory tube (O.T. Eustachian). They anastomose with branches of the superior thyreoid, lingual, and external maxillary arteries.

(*b*) **Prevertebral.**—Small branches distributed to the prevertebral muscles and fascia, the deep cervical glands, and the large nerve trunks. They anastomose with the ascending cervical and vertebral arteries.

(*c*) **Posterior Meningeal.**—One or more small branches which enter the cranium by the hypoglossal canal, the jugular, or the lacerate foramen, and supply the dura mater. They anastomose with branches of the middle meningeal and vertebral arteries.

(*d*) **Inferior Tympanic.**—A small artery which accompanies the tympanic branch of the glossopharyngeal nerve to the tympanic cavity, where it anastomoses with the other tympanic arteries.

(*e*) **Palatine.**—A very variable artery which sometimes replaces the ascending palatine branch of the external maxillary artery. When present it springs from the upper part of the ascending pharyngeal artery, pierces the pharyngeal aponeurosis above the upper border of the superior constrictor muscle, and descends into the soft palate with the levator veli palatini muscle. It supplies the mucous membrane of the supero-lateral part of the pharyngeal wall and the tissues of the soft palate, and it anastomoses with the palatine branches of the internal maxillary, the external maxillary and the lingual arteries.

(7) **The superficial temporal artery** (Fig. 732), one of the terminal branches of the external carotid, commences between the upper part of the antero-medial surface of the parotid gland, and the neck of the mandible, and terminates in the scalp, from 25 to 50 mm. (1 or 2 inches) above the zygomatic arch, by dividing into a parietal and a frontal branch.

Course.—The artery ascends over the posterior root of the zygoma, and passes into the superficial fascia of the temporal region. It is accompanied by the auriculo-temporal nerve and by the superficial temporal vein, which usually lies posterior to it. As it crosses the zygoma it is covered by the skin alone, and it may be easily compressed against the subjacent bone.

Branches.—(*a*) **Parotid.**—Small branches to the upper part of the parotid gland.

(*b*) **Articular**—to the mandibular articulation.

(*c*) **Anterior Auricular.**—Small branches to the lateral surface of the auricle and to the external acoustic meatus. They anastomose on the surface of the auricle with branches of the posterior auricular artery, and in the external acoustic meatus with branches of the internal maxillary artery.

(*d*) **Transverse Facial.**—A branch of moderate size which emerges from under cover

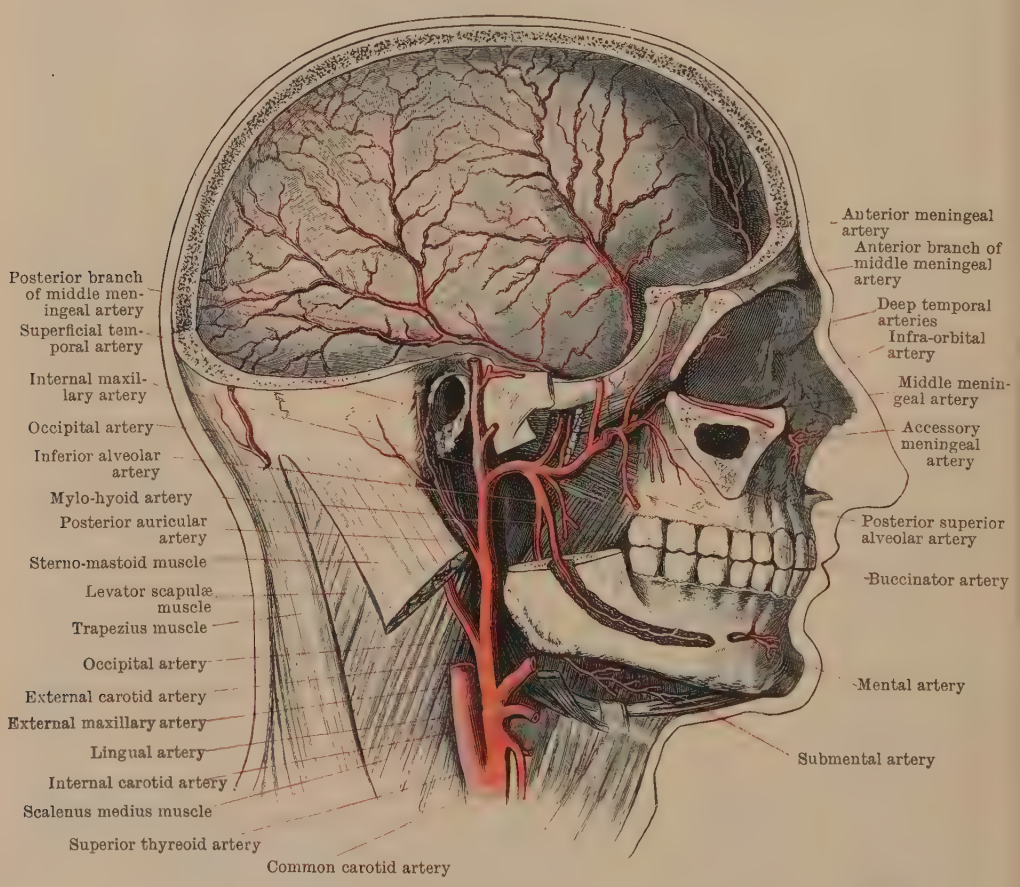

FIG. 734.—THE EXTERNAL CAROTID, INTERNAL MAXILLARY, AND MENINGEAL ARTERIES.

of the upper part of the anterior border of the parotid gland. It runs forwards across the masseter, below the zygoma and above the parotid duct, accompanied by zygomatic branches of the facial nerve, which may lie either above or below it. It supplies the parotid gland, the masseter, parotid duct, and the skin, and it terminates in branches which anastomose with the infra-orbital and buccinator branches of the internal maxillary artery and with the buccal and masseteric branches of the external maxillary artery.

(*e*) **Middle Temporal.**—A branch which usually springs from the commencement of the superficial temporal. It crosses the zygoma, pierces the temporal fascia and the temporal muscle, and terminates in the temporal fossa by anastomosing with the deep temporal branches of the internal maxillary artery.

(*f*) **Zygomatico-orbital.**—This branch may spring directly from the superficial temporal, but it is frequently a branch of the middle temporal. It runs anteriorly, above the zygoma, between the two layers of the temporal fascia. It supplies branches to the

orbicularis oculi, and anastomoses, through the zygomatic bone and round the outer margin of the orbit, with the lacrimal and palpebral branches of the ophthalmic artery.

(*g*) The **frontal branch** runs forwards and upwards, in a tortuous course, through the superficial fascia of the scalp towards the frontal tuberosity, lying at first upon the temporal fascia, and then upon the galea aponeurotica. It supplies the frontalis and the orbicularis oculi, and anastomoses with the lacrimal and supra-orbital branches of the ophthalmic artery, with the parietal terminal branch of the superficial temporal, and with its fellow of the opposite side.

(*h*) The **parietal branch**, less tortuous than the frontal, runs upwards and posteriorly in the superficial fascia of the scalp. It anastomoses, anteriorly, with the frontal terminal branch, posteriorly with the posterior auricular and occipital arteries, and, across the median line, with its fellow of the opposite side. It supplies the skin and fascia, and the anterior and superior muscles of the auricle.

(8) The **internal maxillary artery** commences between the antero-medial surface of the parotid gland and the neck of the mandible, and terminates in the pterygo-palatine fossa (Fig. 733).

Course and Relations.—Although the internal maxillary artery is only a short trunk it has many important relations, in the consideration of which it is convenient to divide the vessel into three parts. The **first part** extends from the back of the neck of the mandible into the infratemporal fossa, as far as the lower border of the external pterygoid muscle. It lies between the spheno-mandibular ligament and the neck of the mandible, along with the auriculo-temporal nerve and the internal maxillary vein. The **second part** is in the infratemporal fossa, and runs upwards and anteriorly. It may lie on the lateral or the medial side of the lower head of the external pterygoid muscle. In the former case it is situated between the temporal and external pterygoid muscles, and in the latter between the external pterygoid muscle and the branches of the mandibular division of the trigeminal nerve. The **third part** passes between the upper and the lower heads of the external pterygoid, and through the pterygo-maxillary fissure into the pterygo-palatine fossa.

Branches.—*From the first part.*—(*a*) **Deep auricular.** A small branch which arises from the commencement of the artery and passes upwards to the external acoustic meatus. It supplies the mandibular joint, the parotid gland, the external acoustic meatus, and the superficial surface of the tympanic membrane. It anastomoses with branches of the superficial temporal and posterior auricular arteries.

(*b*) The **anterior tympanic**, a variable and small branch. It runs upwards and posteriorly, traverses the petro-tympanic fissure (Glaserian), and enters the tympanum through its lateral wall. In the tympanic cavity it anastomoses with tympanic branches from the internal carotid and ascending pharyngeal arteries, and with the stylo-mastoid branch of the posterior auricular, forming with the latter, in young subjects, a circular anastomosis around the tympanic membrane.

(*c*) **Middle Meningeal.**—The largest branch of the internal maxillary. It ascends between the external pterygoid muscle laterally and the spheno-mandibular ligament and the tensor veli palatini medially; passes between the two roots of the auriculo-temporal nerve and through the foramen spinosum, and enters the middle fossa of the cranial cavity. Before it enters the skull it lies posterior to the third division of the trigeminal nerve, and is accompanied by a vein which also passes through the foramen spinosum. In the middle cranial fossa it passes for a short distance anteriorly, in a groove on the great wing of the sphenoid, between the dura mater and the bone, and divides into anterior and posterior terminal branches.

Branches.—(i.) **Superficial Petrosal.**—A small branch which arises from the middle meningeal soon after it enters the cranium. It passes through the hiatus canalis facialis and anastomoses with the stylo-mastoid branch of the posterior auricular artery; it also sends some small branches into the tympanic cavity.

(ii.) **Ganglionic.**—Minute branches which supply the semilunar ganglion and the roots of the fifth cerebral nerve.

(iii.) **Superior Tympanic.**—A small twig which reachse the tympanic cavity through the canal for the tensor tympani muscle, or through the petro-squamous suture.

(iv.) **Orbital.**—An anastomosing branch which arises, occasionally, from the anterior terminal branch. It passes through the superior orbital fissure into the orbit, and anastomoses with the lacrimal artery.

(v.) **Anterior terminal**, the larger of the two terminal branches, passes upwards along the great wing of the sphenoid to the sphenoidal angle of the parietal bone, where it is sometimes enclosed in a distinct bony canal; it is continued upwards, a short distance behind the anterior border of the parietal bone, almost to the vertex of the skull, sending branches forwards into the anterior, and backwards towards the posterior cranial fossa.

(vi.) The **posterior terminal branch** passes posteriorly from the great wing of the sphenoid to the squamous part of the temporal bone, beyond which it ascends to the middle of the inner surface of the parietal bone. It sends branches upwards to the vertex, and backwards towards the posterior cranial fossa.

By means of its various branches the middle meningeal artery anastomoses with its fellow of the opposite side, with meningeal branches from the occipital, ascending pharyngeal, ophthalmic, and lacrimal arteries; also with the stylo-mastoid branch of the posterior auricular, through the substance of the temporal bone, with the accessory meningeal artery, and the deep temporal arteries. The anterior and posterior branches of the middle meningeal arteries and their ramifications are separated from the bone by corresponding veins.

(*d*) An **accessory meningeal branch** may arise either directly from the first part of the internal maxillary or from its middle meningeal branch. It passes upwards, on the medial side of the external pterygoid muscle, enters the middle fossa of the skull through the foramen ovale, supplies the semilunar ganglion and the dura mater, and terminates by anastomosing with branches of the middle meningeal and internal carotid arteries.

(*e*) The **inferior alveolar** is a branch of moderate size which passes downwards, between the spheno-mandibular ligament and the mandible, to the mandibular foramen. It is accompanied by the inferior alveolar nerve, which lies in front of it. After entering the foramen it descends in the mandibular canal, and terminates at the mental foramen by dividing into mental and incisive branches.

Branches.—Before it enters the mandibular foramen it gives off two branches.

(i.) The **lingual**, a small twig, to the buccal mucous membrane, which accompanies the lingual nerve. (ii.) The **mylo-hyoid**, a small branch which is given off immediately above the mandibular foramen. It pierces the spheno-mandibular ligament, and descends in the mylo-hyoid groove, in company with the mylo-hyoid nerve, to the floor of the mouth, where it anastomoses, on the superficial surface of the mylo-hyoid muscle, with the submental branch of the external maxillary artery.

In the mandibular canal the following branches are given off:—

(i.) **Molar branches** to the molar teeth. (ii.) **Premolar branches** to the premolar teeth. (iii.) The **incisive terminal branch**, which supplies the incisor and canine teeth and anastomoses with its fellow of the opposite side. (iv.) The **mental terminal branch**, which passes through the mental foramen, emerges beneath the quadratus labii inferioris, and anastomoses with its fellow of the opposite side, with the inferior labial, and with the submental arteries.

From the second part.—(*a*) The **masseteric**, a small branch which passes laterally, through the mandibular notch, to the deep surface of the masseter muscle. It anastomoses in the substance of the muscle with branches of the transverse facial and with the masseteric branches of the external maxillary artery.

(*b*) **Deep Temporal.**—Two in number, anterior and posterior. They ascend, in the temporal fossa, between the temporal muscle and the squamous portion of the temporal bone, supplying the muscle and anastomosing with the temporal and lacrimal arteries, and, through the substance of the temporal bone, with the middle meningeal artery.

(*c*) Small **pterygoid branches** supply the internal and external pterygoid muscles.

(*d*) The **buccinator branch**, a long, slender branch which passes obliquely forwards and downwards with the buccinator nerve. It supplies the buccinator muscle, the skin and mucous membrane of the cheek, and anastomoses with the buccal branches of the external maxillary artery.

From the third part.—(*a*) A **posterior superior alveolar branch** descends in the infratemporal fossa, on the posterior surface of the maxilla, and ends in branches which supply the molar and premolar teeth and the mucous membrane of the maxillary sinus; they also give twigs to the gums and to the buccinator muscle.

(*b*) An **infra-orbital branch** commences in the pterygo-palatine fossa. It enters the orbit through the inferior orbital fissure, and runs forwards in the infra-orbital groove and canal to the infra-orbital foramen, through which it emerges on the face, deep to the quadratus labii superioris. Whilst in the infra-orbital groove it gives branches to the inferior rectus and the inferior oblique muscles and the lacrimal gland. In the infra-orbital canal it gives small twigs to the incisor and canine teeth (aa. alveolares superiores anteriores) and to the maxillary sinus. In the face it sends branches upwards to the lower eyelid, to the lacrimal sac, and to the frontal process of the maxilla; these anastomose with branches of the ophthalmic and external maxillary arteries; other branches run downwards to the upper lip, where they anastomose with the superior labial artery;

lastly, some branches run laterally into the cheek to unite with the transverse facial and the buccinator arteries.

(*c*) The **descending palatine** runs downwards, through the pterygo-palatine fossa, enters the pterygo-palatine canal, and becomes the great palatine artery, which supplies the mucous membrane of the roof of the mouth. As it descends it gives off the artery of the pterygoid canal, and several small twigs which pass through the accessory palatine canals to supply the soft palate, and to anastomose with the ascending palatine and tonsillar branches of the external maxillary and with the ascending pharyngeal artery. The great palatine artery, which is the continuation of the descending palatine, runs forwards in the roof of the mouth, medial to the alveolar process, to terminate in a small branch, which ascends through the incisive foramen and anastomoses with the posterior artery of the septum nasi, which is a branch of the spheno-palatine artery. In its course forwards in the roof of the mouth the great palatine artery supplies the gums and the mucous membrane of the hard palate, and also the palatine and maxillary bones.

(*d*) The **artery of the pterygoid canal** is a long, slender branch, usually given off from the descending palatine; it runs backwards through the pterygoid canal with the corresponding nerve (Vidian), and supplies branches to the upper part of the pharynx, to the levator and tensor veli palatini muscles, and to the auditory tube. One of the latter branches passes along the wall of the auditory tube to the tympanic cavity, where it anastomoses with the other tympanic arteries.

(*e*) The **pharyngeal branch** is a small artery which runs backwards, with the pharyngeal branch of the spheno-palatine ganglion, through the pharyngeal canal to the roof of the pharynx. It supplies the upper and posterior part of the roof of the nose, the roof of the pharynx, the sphenoidal sinus, and the lower part of the auditory (Eustachian) tube, and anastomoses with the pterygoid branch of the internal carotid.

(*f*) The **spheno-palatine branch** springs from the termination of the internal maxillary artery. It passes medially, through the spheno-palatine foramen, into the nasal cavity, where it gives off (*a*) a branch to the sphenoidal sinus, and (*b*) a branch which may replace the pharyngeal artery and which has a similar course and distribution. Then it divides into lateral and septal posterior nasal branches. The **lateral posterior nasal branches** supply the lateral wall of the nasal cavity and the sinuses which open through it, and they anastomose with the posterior and anterior ethmoidal arteries and the lateral nasal branch of the external maxillary. The **septal posterior nasal branch** accompanies the posterior septal nerve across the roof of the nasal cavity and then anteriorly and downwards in the groove on the vomer. It anastomoses with the great palatine artery and the septal branch of the superior labial.

Abnormalities.—The external carotid artery may be absent, or it may, in rare cases, arise directly from the arch of the aorta. The number of its branches may be diminished either by fusion of their roots or by transference to the internal or common carotid arteries. On the other hand, the number of its branches may be increased; thus, the sterno-mastoid artery, the hyoid branch usually given off by the superior thyreoid artery, or the ascending palatine branch of the external maxillary, may arise from it. Sometimes the branches may arise in the usual way, but may deviate from the course generally taken; more particularly is this the case with the internal maxillary artery, which may pass either between the heads, or entirely lateral or medial to both heads of the external pterygoid muscle.

ARTERIA CAROTIS INTERNA.

The **internal carotid artery** (Figs. 732, 735, 736, and 739) commences at the termination of the common carotid, opposite the upper border of the thyreoid cartilage, and terminates in the middle fossa of the skull, close to the commencement of the stem of the lateral fissure (Sylvius), where it divides into the middle and anterior cerebral arteries.

Course.—From its origin in the carotid triangle it ascends to the base of the skull, lying first in the carotid triangle, medial to the anterior border of the sterno-mastoid, and then between the areolar tissue behind the lateral border of the pharynx, medially, and the posterior belly of the digastric and the styloid process and its muscles laterally. At its commencement it lies postero-lateral to the external carotid, but as it ascends it gradually passes to the medial side of the external carotid, from which it is separated by the styloid process, the stylo-pharyngeus muscle, the glossopharyngeal nerve, and the pharyngeal branch of the vagus.

At the base of the skull it enters the carotid canal, in which it ascends, anterior to the tympanum and the cochlea; then it turns antero-medially to the apex of the bone where it enters the foramen lacerum, through which it ascends, along the side of the body of the sphenoid, to the middle fossa of the cranium.

In the middle fossa it runs forwards, in the lateral wall of the cavernous sinus, to the small wing of the sphenoid; there it turns backwards along the medial border of the anterior clinoid process, which it grooves. At the posterior extremity of the process it turns upwards to its termination at the medial end of the stem of the lateral fissure (Sylvius), below the medial part of the anterior perforated substance.

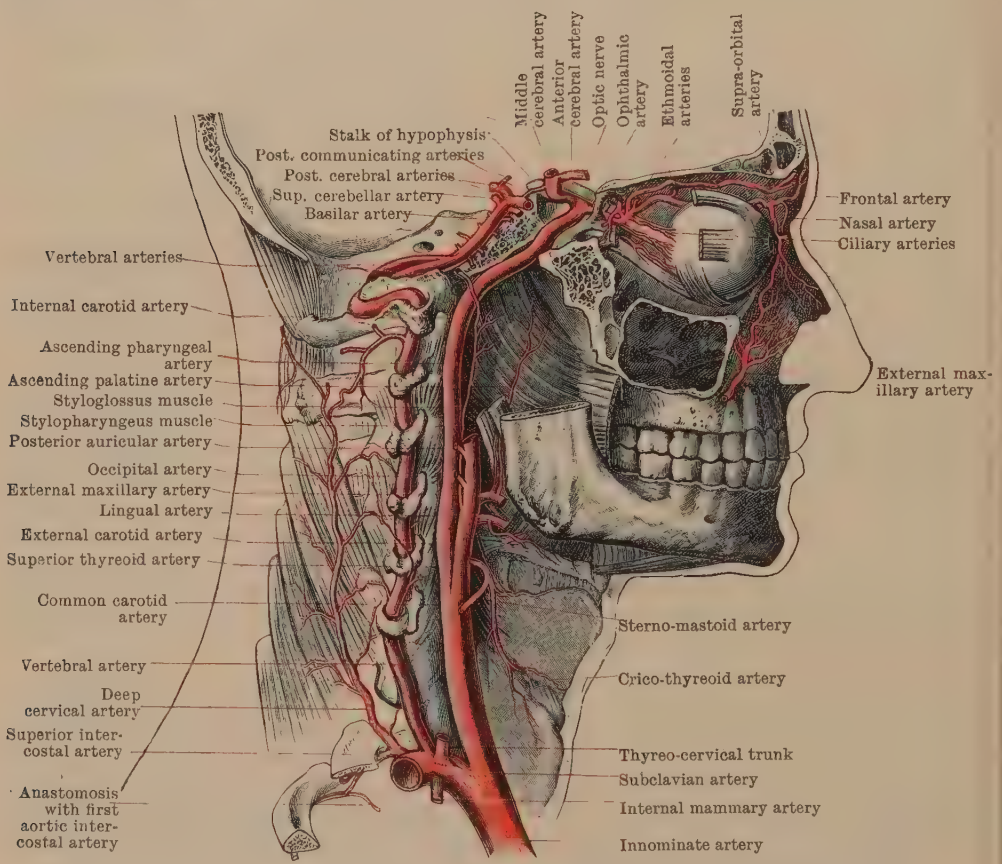

FIG. 735.—THE CAROTID, SUBCLAVIAN, AND VERTEBRAL ARTERIES AND THEIR MAIN BRANCHES.

Relations.—The relations of the various parts of the artery require separate consideration.

In the Neck.—Posterior.—The longus capitis, the prevertebral fascia, and the sympathetic trunk separate it from the transverse processes of the cervical vertebræ, and postero-lateral to it are the internal jugular vein and the vagus nerve. The accessory and the glosso-pharyngeal nerves are also postero-lateral to the artery for a short distance, in the upper part of the neck, where they intervene between it and the internal jugular vein. *Medial* or deep to the internal carotid is the external carotid artery for a short distance below, and afterwards the wall of the pharynx, the areolar tissue posterior to the wall of the pharynx, the ascending pharyngeal artery, the pharyngeal plexus of veins, and the external and internal laryngeal nerves. Just before it enters the temporal bone the levator palati muscle is to its medial side. *Lateral* or superficial to it are the sterno-mastoid, skin, and fasciæ, and it is crossed under cover of the sterno-mastoid, from below upwards, by the hypoglossal nerve, the occipital artery, and the posterior auricular artery. It is also crossed superficially, between the last-mentioned arteries, by the digastric and stylo-hyoid muscles, which separate it from the parotid gland, and below the digastric it is covered by the lower part of the postero-medial surface of the gland.

Passing obliquely across its anterior lateral surface, and separating it from the external carotid artery, are the following structures, viz., the stylo-pharyngeus, the styloid process, or the styloglossus muscle, and the glossopharyngeal nerve, the pharyngeal branch of the vagus, and some sympathetic twigs.

In the Carotid Canal.—The artery, as it passes upwards, is antero-inferior to the cochlea and the tympanum; postero-medial to the auditory (Eustachian) tube and the canal for the tensor tympani; and below the semilunar ganglion. The thin lamina of bone which separates it from the tympanum is frequently perforated, and that between it and the

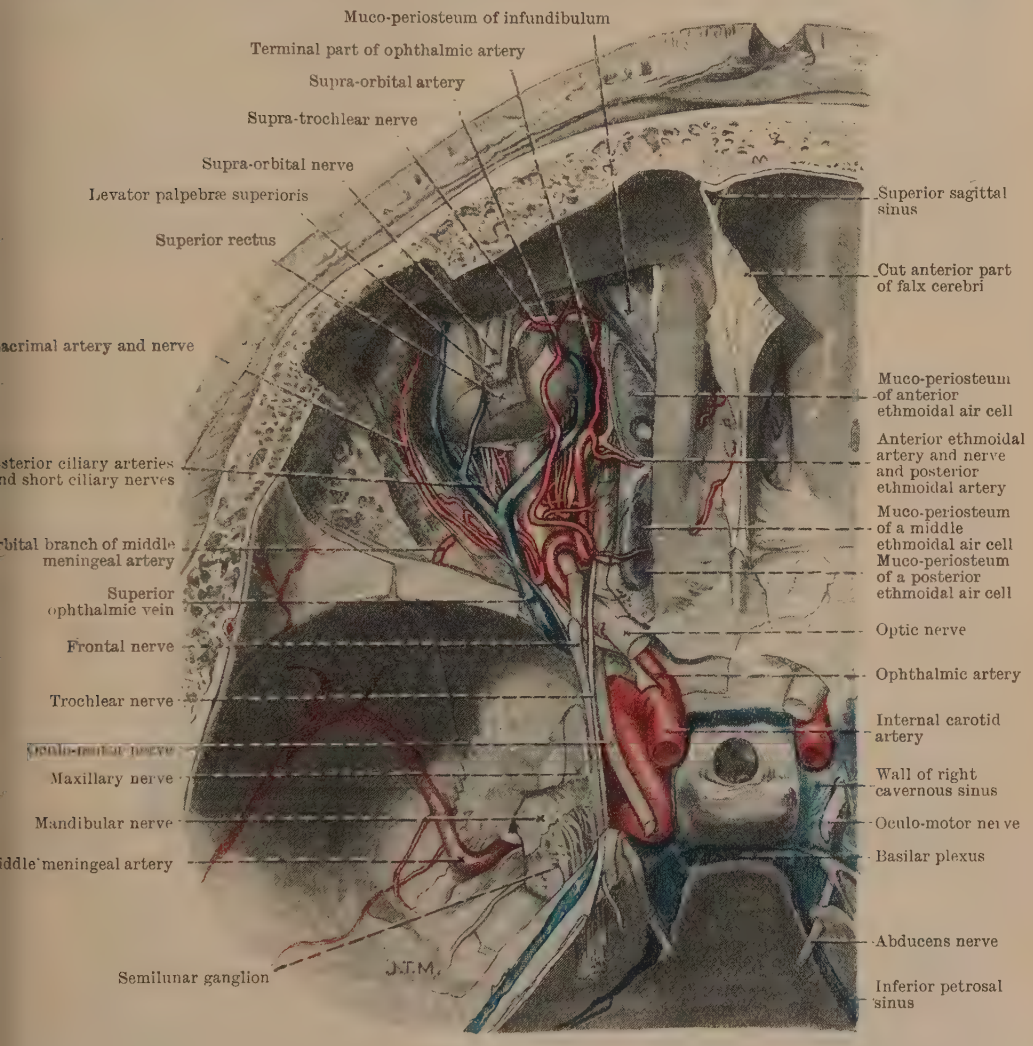

FIG. 736.—DISSECTION OF THE ORBIT AND MIDDLE FOSSA OF THE CRANIUM. On the right side the trochlear nerve has been removed, and in the left orbit portions of the structures above the ophthalmic artery have been taken away. (Dr. E. B. Jamieson.)

semilunar ganglion is frequently absent. In its course through the canal it is accompanied by small veins and sympathetic nerves. The veins receive tributaries from the tympanum, and communicate above with the cavernous sinus and below with the internal jugular vein. The nerves are branches of the nervus caroticus internus, which is the upward continuation of the sympathetic trunk; they form a plexus around the artery, called the internal carotid plexus.

As it enters the cavity of the cranium the internal carotid artery pierces the external layer of the dura mater and passes between the lingula and the sixth cerebral nerve laterally, and the posterior petrosal process of the body of the sphenoid medially.

In the Cranial Cavity.—The artery runs forwards, in the lateral wall of the cavernous

sinus, in relation with the oculo-motor, trochlear, the ophthalmic division of the trigeminal, and the abducens nerves laterally, and with the endothelial wall of the sinus medially. When it reaches the lower root of the small wing of the sphenoid it turns upwards to the medial side of the anterior clinoid process, pierces the inner layer of the dura mater, and comes into close relation with the inferior surface of the optic nerve immediately posterior to the optic foramen. It then turns abruptly backwards below the optic nerve, and on the medial side of the anterior clinoid process which it frequently grooves; inclining laterally, it runs between the optic and oculo-motor nerves, and below the anterior perforated substance, to the medial end of the stem of the lateral fissure (Sylvius), where it turns upwards, at some distance from the corresponding lateral border of the optic chiasma, and, after piercing the arachnoid, divides into its two terminal branches, the anterior and middle cerebral arteries.

Abnormalities.—The internal carotid artery is rarely absent, but its absence has been noted upon one side, more commonly the left; and upon both sides. Occasionally it springs from the arch of the aorta, and in its course through the neck it may vary somewhat in length and in tortuosity. One or more of the branches usually derived from the external carotid artery may arise from it, and it sometimes gives off a large meningeal branch to the posterior fossa of the skull. Its posterior communicating branch may replace the posterior cerebral artery; on the other hand, the upper part of the internal carotid may be absent, and the posterior communicating artery may become the middle cerebral artery.

Branches of the Internal Carotid Artery.

Branches are given off from the internal carotid in the temporal bone and in the cranium, but, as a rule, no regular branches are given off in the neck.

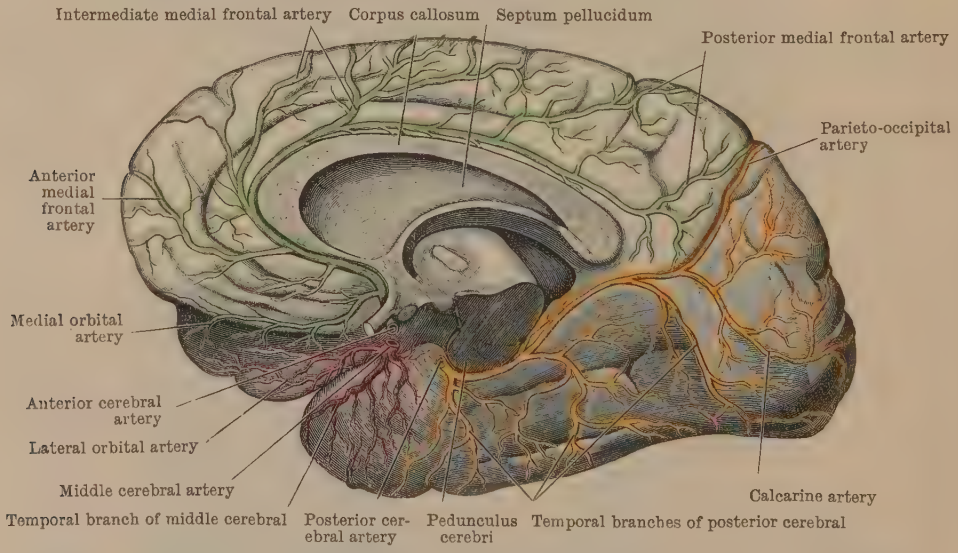

Fig. 737.—Distribution of the Cerebral Arteries on the Medial and Inferior Surfaces of the Cerebral Hemispheres.

The anterior cerebral artery is coloured green, the middle cerebral artery red, and the posterior cerebral artery orange.

In the Temporal Bone.—(1) A **carotico-tympanic branch**, very small, perforates the posterior wall of the carotid canal, and anastomoses in the tympanum with the stylo-mastoid artery and with the tympanic branches of the internal maxillary and ascending pharyngeal arteries.

(2) A small and inconstant branch which accompanies the nerve of the pterygoid canal (Vidian); it anastomoses with a branch of the descending palatine artery.

In the Cranium.—(1) **Cavernous**, small branches to the walls of the cavernous sinus and to the oculo-motor, trochlear, trigeminal, and abducens nerves.

(2) Minute twigs which supply the semilunar ganglion.

(3) **Hypophyseal branches** pass to the hypophysis (O.T. pituitary body).

(4) **Meningeal branches** ramify in the dura mater of the middle cranial fossa, anastomosing with the branches of the middle and accessory meningeal arteries.

(5) The **ophthalmic artery** (Figs. 735, 736) springs from the antero-medial side of the internal carotid as it turns upwards on the medial side of the anterior clinoid process. It passes forwards and laterally, below the optic nerve and through the optic foramen into the orbital cavity. In the orbit it runs forwards, for a short distance, on the lateral side of the optic nerve, and it is in relation laterally with the ciliary ganglion and the lateral rectus muscle; turning upwards and medially, it crosses, between the optic nerve and the superior rectus, to the medial wall of the orbit, where it turns forwards to terminate at the anterior boundary of the cavity by dividing into frontal and dorsal nasal branches. It is accompanied, at first, by the naso-ciliary nerve, and, in the terminal part of its course, by the infra-trochlear nerve.

Branches.—The branches of the ophthalmic artery are numerous. (*a*) The **posterior ciliary**, usually six to eight in number, run forwards at the sides of the optic nerve; they soon divide into numerous branches which pierce the posterior part of the sclera; the majority terminate in the chorioid coat of the eye as the *short posterior ciliary arteries*, but two of larger size, the *long posterior ciliary arteries*, run forwards, one on each side of the eyeball, almost in the horizontal plane, between the sclera and the chorioid coat, to the periphery of the iris,

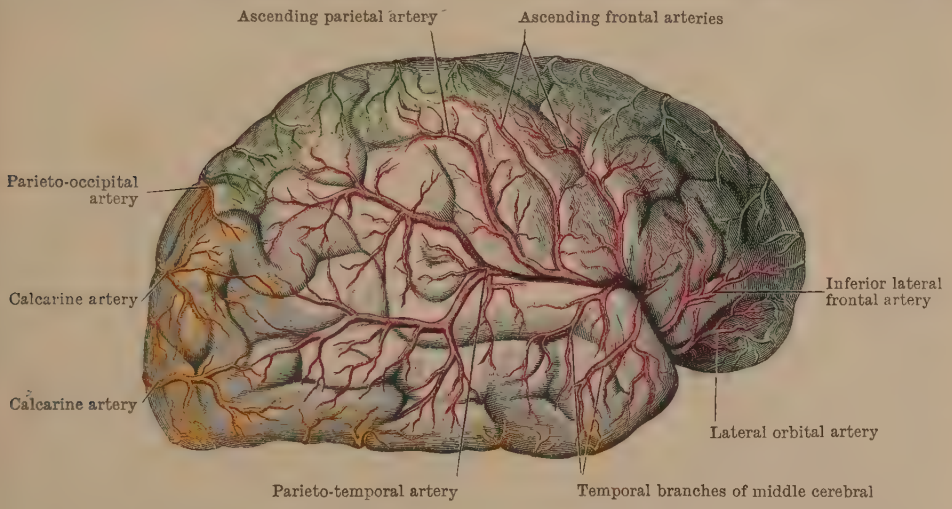

FIG. 738.—DISTRIBUTION OF CEREBRAL ARTERIES ON THE CONVEX SURFACE OF THE CEREBRUM.
Anterior cerebral artery is coloured green, the middle cerebral red, and the posterior cerebral orange.

where they divide. The resulting branches anastomose together and form a circle at the periphery of the iris, from which secondary branches run inwards and anastomose together in a second circle near the papillary margin of the iris.

(*b*) The **central artery of the retina** arises near to, or in common with, the preceding vessels. It pierces the infero-medial aspect of the optic nerve, about 12 mm. (half an inch) posterior to the sclera, and runs in its centre to the retina, where it breaks up into terminal branches.

(*c*) **Anterior Meningeal.**—A small branch which passes backwards through the superior orbital fissure into the middle fossa of the cranium, where it anastomoses with the middle and accessory meningeal arteries, and with the meningeal branches of the internal carotid and lacrimal arteries.

(*d*) The **lacrimal artery** arises from the ophthalmic on the lateral side of the optic nerve. It runs forwards, along the upper border of the lateral rectus, to the upper lateral angle of the orbit, and in its course gives off *glandular branches* to the lacrimal gland, *muscular branches* to the lateral and superior recti, *palpebral branches* to the upper eyelid and the upper and lateral part of the forehead, *temporal* and *zygomatic branches*, which accompany the zygomatico-temporal and zygomatico-facial branches of the zygomatic (temporo-malar) nerve, to the face and the infra-temporal fossa respectively; *anterior ciliary branches*, which perforate the sclera behind the corneo-scleral junction and anastomose with the posterior ciliary arteries; and a *recurrent meningeal branch*, which passes backwards, through the lateral part of the superior orbital fissure, to anastomose, in the middle fossa of the skull, with the middle meningeal artery.

(*e*) **Muscular.**—These branches are usually arranged in two sets, lateral and medial. The former supply the upper and lateral, and the latter the lower and medial orbital muscles. They anastomose with muscular branches from the lacrimal and the supra-orbital vessels, and they give off *anterior ciliary branches.*

(*f*) The **supra-orbital branch** is given off as the ophthalmic artery crosses above the optic nerve. It passes round the medial borders of the superior rectus and levator palpebræ muscles, and runs forwards, between the levator and the periosteum, to the supra-orbital notch, accompanying

the frontal nerve and its supra-orbital branch. Passing through the notch it reaches the scalp, and, after it has perforated the frontalis muscle, it anastomoses with the frontal branches of the superficial temporal and ophthalmic arteries.

(*g*) **Anterior** and **posterior ethmoidal branches** arise from the ophthalmic as it runs forwards along the medial boundary of the orbit. They pass medially, between the superior oblique and the medial rectus. The posterior, which is much the smaller of the two, traverses the posterior ethmoidal canal, and supplies the posterior ethmoidal cells and the posterior and upper part of the lateral wall of the nasal cavity. The anterior ethmoidal artery passes through the anterior ethmoidal canal with the anterior ethmoidal nerve, enters the anterior fossa of the skull, and crosses the lamina cribrosa of the ethmoid to the nasal slit, through which it reaches the nasal cavity, where it descends, with the external branch of the nasal nerve, in a groove on the posterior surface of the nasal bone, and, finally, passes between the lateral cartilage and the lower border of the nasal bone to the tip of the nose. It supplies branches to the membranes of the brain in the anterior cranial fossa as well as to the anterior ethmoidal cells, the frontal sinus, the anterior and upper part of the nasal muco-periosteum, and the skin on the dorsum of the nose.

(*h*) **Palpebral branches**, upper and lower, are given off near the termination of the ophthalmic. They are distributed to the upper and lower eyelids, and they anastomose with the lacrimal, supra-orbital, and infra-orbital arteries.

(*i*) The **dorsal nasal terminal branch** passes out of the orbit above the medial tarsal ligament. It pierces the palpebral fascia, and terminates on the side of the nose by anastomosing with the angular branch of the external maxillary artery.

(*j*) The **frontal terminal branch** pierces the palpebral fascia at the upper and medial part of the orbit, and ascends, with the supra-trochlear nerve, in the superficial fascia of the anterior and medial part of the scalp, anastomosing with its fellow of the opposite side and with the supra-orbital artery.

Abnormalities.—The ophthalmic artery, as it traverses the orbit, may pass either above or below the optic nerve. It is occasionally replaced by a branch of the middle meningeal artery.

(6) The **posterior communicating artery** arises from the internal carotid near its termination. It runs backwards, below the optic tract and anterior to the pedunculus cerebri, and, passing above the oculo-motor nerve, joins the posterior cerebral artery forming part of the circulus arteriosus (Willis). It gives branches to the optic chiasma, the optic tract, the pedunculus cerebri, the interpeduncular region, the internal capsule, and the optic thalamus. The posterior communicating artery varies much in size; it may be small on one or both sides, sometimes it is very large on one side; occasionally it replaces the posterior cerebral artery, and it sometimes arises from the middle cerebral artery.

(7) The **chorioidal** is a small branch, which also arises near the termination of the internal carotid; it passes backwards and laterally, between the pedunculus cerebri and the uncus, to the lower and anterior part of the chorioidal fissure which it enters, and it terminates in the chorioidal plexus in the inferior cornu of the lateral ventricle. It supplies the optic tract, the pedunculus cerebri, the uncus, the posterior part of the internal capsule, the tail of the caudate nucleus, part of the lentiform nucleus, and the amygdaloid nucleus.

(8) The **anterior cerebral artery** is the smaller of the two terminal branches of the internal carotid. It passes forwards and medially, above the optic chiasma and in front of the lamina terminalis, to the commencement of the longitudinal fissure; there it turns round the genu of the corpus callosum, and runs backwards to the parietal lobe of the brain. At the commencement of the longitudinal fissure it is closely connected with its fellow of the opposite side by a wide but short **anterior communicating artery**, and in the remainder of its course it is closely accompanied by its fellow artery of the opposite side.

Branches.—Branches of all the cerebral arteries are distributed both to the basal ganglionic masses of the brain and to the cerebral cortex; they therefore form two distinct groups which do not communicate with one another—(*a*) **central** or **basal**; (*b*) **cortical.**

The branches of the anterior cerebral include:

(*a*) *Central or basal Branches.*—The **antero-medial basal arteries**, a small group of vessels, constitute the basal branches of the anterior cerebral artery; they pass upwards into the base of the brain, in front of the optic chiasma, and supply the rostrum of the corpus callosum, the lamina terminalis, the head of the caudate nucleus, the anterior part of the lentiform nucleus and internal capsule, the columns of the fornix, the septum pellucidum, and the anterior commissure.

(*b*) *Cortical Branches.*—(b^1) **Medial orbital**, one or more small branches which supply the medial orbital convolution, the gyrus rectus, and the olfactory lobe.

(b^2) **Anterior medial frontal**, one or more branches which are distributed to the anterior

and lower part of the medial surface of the superior frontal gyrus, and to the anterior portions of the superior and middle frontal gyri on the lateral surface of the hemisphere.

(b^3) An **intermediate medial frontal** is distributed to the posterior part of the medial lateral surfaces of the superior frontal gyrus and to the upper parts of the anterior and posterior central gyri.

(b^4) The **posterior medial frontal** runs backwards to the præcuneus. It supplies the corpus callosum, the præcuneus, and the upper part of the superior parietal lobule.

(9) **Arteria Cerebri Media.**—The **middle cerebral artery** is the larger of the two terminal branches, and the more direct continuation of the internal carotid artery. It passes laterally, in the stem of the lateral fissure (Sylvius), to the surface of the insula, and it divides, in the posterior part of the circular sulcus (Reil), into parieto-temporal and temporal terminal branches.

Branches.—(a) The **central** or **basal**, which constitute the **antero-lateral basal arteries**, are numerous and very variable in size. They arise at the base of the brain, in the region of the anterior perforated substance. Two sets, known as the medial and the lateral striate arteries, are distinguishable.

(a^1) The **medial striate arteries** pass upwards through the two medial segments of the lentiform nucleus (globus pallidus) and the internal capsule to terminate in the caudate nucleus. They supply the anterior portions of the lentiform and caudate nuclei and of the internal capsule.

(a^2) The **lateral striate arteries** pass upwards through the lateral segment (putamen) of the lentiform nucleus, or between it and the external capsule, and they form two sets: an anterior, the lenticulo-striate, and a posterior, the lenticulo-optic; both sets traverse the lentiform nucleus and the internal capsule, but the *lenticulo-striate arteries* terminate in the caudate nucleus, and the *lenticulo-optic* in the thalamus. One of the lenticulo-striate arteries, which passes in the first instance round the lateral side of the lentiform nucleus, and afterwards through its substance, is larger than its companions; it frequently ruptures, and is known as the "artery of cerebral hæmorrhage."

(b) *Cortical branches* are given off as the middle cerebral artery passes over the surface of the insula at the bottom of the lateral fissure, as follows:—

(b^1) The **lateral orbital** runs forwards and laterally, and is distributed to the lateral part of the orbital surface of the frontal lobe and to the inferior frontal gyrus.

(b^2) The **inferior lateral frontal**, which supplies the inferior and middle frontal gyri.

(b^3) The **ascending frontal**, which turns round the upper margin of the lateral fissure, and is distributed to the anterior central gyrus and to the posterior part of the middle frontal gyrus.

(b^4) The **ascending parietal branch** emerges from the lateral fissure (Sylvius) and passes upwards along the posterior border of the posterior central gyrus, supplying that gyrus and the superior parietal lobule.

(b^5) The **temporal branch** passes out of the lateral fissure, and turns downwards to supply the superior and middle temporal gyri.

(b^6) The **parieto-temporal branch** continues backwards, in the direction of the main stem of the middle cerebral artery, and emerges from the posterior end of the lateral fissure; it supplies the inferior parietal lobule, part of the lateral surface of the occipital lobe, and the posterior part of the temporal lobe.

Abnormalities.—The anterior cerebral branch of the internal carotid may be absent, or rather it may arise from the corresponding artery of the opposite side; or there may be three anterior cerebral arteries, the third arising from the anterior communicating artery which connects the two anterior cerebrals together.

Arteria Vertebralis.

The **vertebral artery** (Figs. 735 and 739) is the first branch given off from the subclavian trunk; it arises from the upper and posterior part of the parent stem, opposite the interval between the anterior scalene and the longus colli muscles, and terminates at the lower border of the pons (Varolii) by uniting with its fellow of the opposite side to form the basilar artery.

Course and Relations.—The vertebral artery is divisible into four parts.

The **first part** runs upwards and backwards, between the scalenus anterior and the lateral border of the longus colli, to the foramen in the transverse process of the

sixth cervical vertebra. It is surrounded by a plexus of sympathetic nerve fibres, is covered anteriorly by the vertebral and internal jugular veins, and it may be crossed anteriorly by the inferior thyreoid artery. On the left side the terminal part of the thoracic duct also passes anterior to it. The **second part** runs upwards through the foramina in the transverse processes of the upper six cervical vertebræ. As far as the second cervical vertebra its course is almost vertical; as it passes through the transverse process of the epistropheus, however, it is directed obliquely upwards and laterally to the atlas. It is surrounded by a plexus of sympathetic nerve fibres, and also by a plexus of veins. The artery lies anterior to the trunks the cervical nerves, and medial to the intertransverse muscles. The **third part**

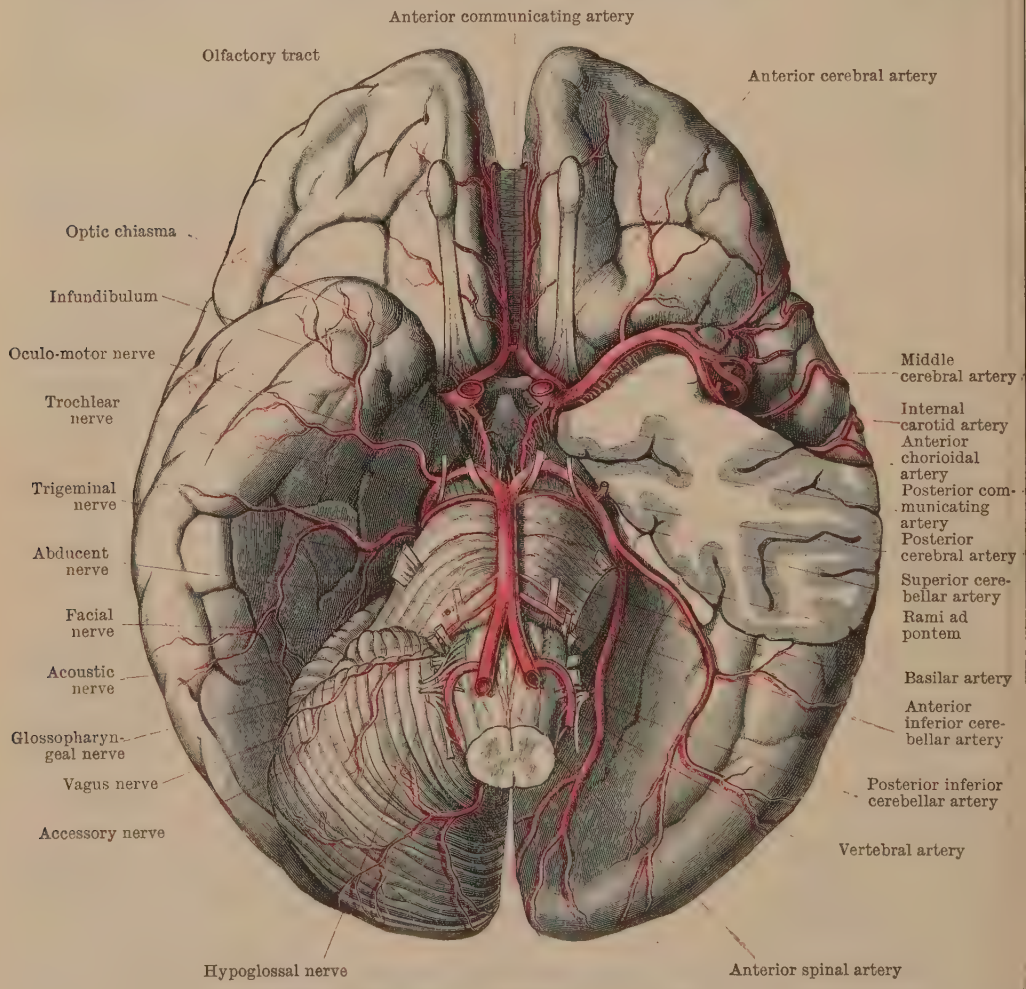

FIG. 739.—THE ARTERIES OF THE BASE OF THE BRAIN. THE CIRCULUS ARTERIOSUS (WILLIS).

emerges from the foramen in the transverse process of the atlas, between the anterior division of the sub-occipital nerve medially and the rectus capitis lateralis laterally, and runs almost horizontally backwards and medially, round the lateral and posterior aspects of the corresponding superior articular process of the atlas. In this part of its course it enters the sub-occipital triangle, where it lies in the groove on the upper surface of the posterior arch of the atlas (sulcus arteriæ vertebralis). It is separated from the bone by the sub-occipital nerve, and is overlapped superficially by the adjacent borders of the superior and inferior oblique muscles. Finally, this part of the artery passes anterior to the oblique ligament of the atlas and enters the vertebral canal.

The **fourth part** pierces the spinal dura mater and runs upwards into the cranial cavity. It passes between the roots of the hypoglossal nerve, posteriorly, and the

first dentation of the ligamentum denticulatum, anteriorly, pierces the arachnoid, and, gradually inclining to the front of the medulla oblongata, reaches the lower border of the pons, where it unites with its fellow of the opposite side to form the basilar artery.

Abnormalities.—The vertebral artery may have a double origin—one from the subclavian, and one from the inferior thyreoid artery or from the aorta.

The right vertebral may arise from the common carotid or from the arch of the aorta. Occasionally it springs from the descending aorta, an arrangement associated with the persistence of the dorsal roots of the fourth and fifth right arches.

The left vertebral artery not infrequently springs from the arch of the aorta, arising between the left common carotid and left subclavian arteries; this is evidently due to the absorption of the stem of the seventh segmental artery into the aortic arch. Very exceptionally the left vertebral is a branch of an intercostal artery.

In its course upwards either vertebral artery may enter the vertebrarterial foramen of any of the lower six cervical vertebra.

The cases in which it does not enter one of the lowest of these are apparently associated with its formation, in part, from the precostal instead of from the postcostal anastomosing channels.

The artery may enter the vertebral canal with the second instead of with the first cervical nerve, or, after leaving the foramen in the transverse process of the third vertebra, it may divide into two branches, one of which accompanies the second and the other the first cervical nerve; the two branches unite together again in the vertebral canal to form a single trunk.

Sometimes, though rarely, it gives off superior intercostal and inferior thyreoid branches. The upper end of one of the vertebrals is sometimes very small, or it may be entirely wanting; in the latter case the basilar artery is formed by the direct continuation of the opposite vertebral.

Branches.—*From the first part.*—As a rule there are only a few small **muscular twigs** from this portion of the artery.

From the second part.—(1) **Muscular branches** which vary in number and size. They supply the deep muscles of the neck, and anastomose with the profunda cervicis, the ascending cervical, and the occipital arteries.

(2) **Spinal branches** pass from the medial side of the second part of the vertebral artery, through the intervertebral foramina, into the vertebral canal, where they give off twigs which pass along the roots of the spinal nerves to reinforce the anterior and posterior spinal arteries; they supply the bodies of the vertebrae and the intervertebral fibro-cartilages, and they anastomose with corresponding arteries above and below.

From the third part.—(1) **Muscular branches** to the sub-occipital muscles.

(2) **Anastomotic branches** which unite with the descending branch (O.T. princeps cervicis) of the occipital and with the profunda cervicis artery.

From the fourth part.—(1) **Meningeal.**—One or two small branches given off before the vertebral artery pierces the dura mater. They ascend into the posterior fossa of the skull, where they anastomose with meningeal branches of the occipital and ascending pharyngeal arteries, and occasionally with branches of the middle meningeal artery.

(2) **Posterior Spinal.**—The posterior spinal branch springs most commonly from the posterior inferior cerebellar branch of the vertebral (Stopford, 1916), but occasionally it arises from the vertebral directly. It runs downwards upon the side of the medulla oblongata and the spinal medulla, either in front of or behind the posterior nerve-roots. It is a slender artery, which is continued to the lower part of the spinal medulla by means of reinforcements from the spinal branches of the vertebral and intercostal arteries. It gives off branches to the pia mater, which form more or less regular anastomoses on the medial and lateral sides of the posterior nerve-roots, and it ends by joining the anterior spinal artery.

(3) The **anterior spinal branch** arises near the termination of the vertebral. It runs obliquely downwards and medially, in front of the medulla oblongata, and unites with its fellow of the opposite side to form a single anterior spinal artery, which descends along the anterior median fissure of the spinal medulla, and is continued as a fine vessel along the filum terminale. The anterior spinal artery is reinforced as it descends by anastomosing twigs from the spinal branches of the vertebral, intercostal, and lumbar arteries. It gives off branches which pierce the pia mater and supply the spinal medulla, and it unites below with the posterior spinal arteries.

(4) The **posterior inferior cerebellar** is the largest branch of the vertebral artery. It arises a short distance below the pons and passes obliquely backwards round the medulla oblongata, at first between the fila of the hypoglossal nerve, and then between the fila of the accessory and vagus nerves, into the vallecula of the cerebellum, where it divides into lateral and medial terminal branches.

The trunk of the artery gives branches to the medulla oblongata and to the chorioid plexus of the fourth ventricle. Some of these branches supply the nuclei of the glosso-

pharyngeal, the vagus, and the accessory nerves, the spino-thalamic, spino-cerebellar, rubro-spinal, olivo-cerebellar tracts, and possibly also the vestibular root of the acoustic and the spinal root of the fifth nerve (Bury and Stopford). The medial terminal runs backwards between the inferior vermis and the hemisphere of the cerebellum; it supplies the former structure, and anastomoses with its fellow of the opposite side. The lateral branch passes to the lower surface of the hemisphere and anastomoses with the superior cerebellar artery.

Arteria Basilaris.—The **basilar artery** is formed by the junction of the two vertebral arteries; it commences at the lower border and terminates at the upper border of the pons (Varolii), bifurcating at its termination into the two posterior cerebral arteries.

Course and Relations.—It runs upwards, in the median part of the cisterna pontis, in a shallow groove on the front of the pons, behind the sphenoidal section of the basi-cranial axis and between the two abducent nerves.

Abnormalities.—The basilar artery may be double in part or the whole of its extent, or its cavity may be divided by a more or less complete septum. It may terminate in one instead of two posterior cerebral arteries, the missing vessel being supplied by the enlargement of the posterior communicating branch of the internal carotid.

Branches.—(1) **Pontine**, a series of small arteries which pass across the front and round the sides of the pons, supplying the pons, the brachia pontis (O.T. middle peduncles of the cerebellum), and the roots of the trigeminal nerve.

(2) The **internal auditory**, a pair of long slender branches. Each internal auditory branch may spring either from the basilar or from the anterior inferior cerebellar artery of the same side (Stopford, 1916). It enters the corresponding internal acoustic meatus with the facial and acoustic nerves, and, after it has passed through the lamina cribrosa, it is distributed to the internal ear.

(3) The **anterior inferior cerebellar**, two branches which arise, one on each side, from the middle of the basilar artery. They pass backwards, on the anterior parts of the lower surfaces of the lateral lobes of the cerebellum, and anastomose with the posterior inferior cerebellar branches of the vertebral arteries.

(4) The **superior cerebellar** branches, two in number, arise near the termination of the basilar. Each passes laterally, at the upper border of the pons, directly below the oculo-motor nerve of the same side, and, after turning round the lateral side of the pedunculus cerebri, below the trochlear nerve, it reaches the upper surface of the cerebellum, where it divides into a medial and a lateral branch. The medial branch supplies the upper part of the vermis, and the anterior medullary velum. The lateral branch is distributed over the upper surface of the lateral lobe; it anastomoses with the inferior cerebellar arteries.

(5) The **posterior cerebral arteries** (Figs. 737 and 739) are the two terminal branches of the basilar. They run backwards and upwards, between the peduncles of the cerebrum and the uncinate gyri and parallel to the superior cerebellar arteries, from which they are separated by the oculo-motor and trochlear nerves. Each posterior cerebral artery is connected with the internal carotid by the posterior communicating artery; it gives branches to the inferior surface of the cerebrum, and is continued backwards, beneath the splenium of the corpus callosum, to the calcarine fissure, where it divides into calcarine and parieto-occipital branches, which pass to the lateral surface of the occipital lobe. It supplies the medial and tentorial surfaces of the occipital lobe and the posterior part of its lateral surface.

Branches.—(A) *Central or basal.*—This group includes (a^1) A **postero-medial** set of small vessels which pass, on the medial side of the corresponding cerebral peduncle, to the posterior perforated substance. They supply the peduncle, the posterior part of the thalamus, the corpora mamillaria, and the walls of the third ventricle.

(a^2) A **postero-lateral** set of small vessels, which pass round the lateral side of the peduncle. They supply the corpora quadrigemina, the brachia, the pineal body, the peduncle, the posterior part of the thalamus, and the corpora geniculata.

(a^3) A **posterior chorioidal** set of small branches which pass through the upper part of the chorioidal fissure; they enter the posterior part of the tela chorioidea of the third ventricle, and end in the chorioid plexus, in the body of the lateral ventricle, and the upper part of its inferior cornu. They also supply the adjacent parts of the fornix.

(B) *Cortical.*—(b^1) The **anterior temporal**, frequently a single branch of variable size,

but not uncommonly replaced by several small branches. It supplies the anterior parts of the uncus, the hippocampal gyrus, and the fusiform gyrus.

(b^2) The **posterior temporal** is a larger branch than the anterior. It supplies the posterior part of the hippocampal gyrus, part of the fusiform gyrus, and the lingual gyrus.

(b^3) The **calcarine branch** is the continuation of the posterior cerebral artery along the calcarine fissure, it is especially associated with the supply of the visual area of the cortex of the brain. It supplies the cuneus, the lingual gyrus, and the posterior part of the lateral surface of the occipital lobe.

(b^4) The **parieto-occipital branch**, smaller than the calcarine, passes along the corresponding fissure to the cuneus and præcuneus.

Circulus Arteriosus (Willis) (Fig. 739).—The cerebral arteries of opposite sides are intimately connected together at the base of the brain by anastomosing channels. Thus, the two anterior cerebral arteries are connected with one another by the anterior communicating artery, whilst the two posterior cerebrals are in continuity through the basilar artery from which they arise. There is also a free anastomosis on each side between the carotid system of cerebral arteries and the vertebral system by means of the posterior communicating arteries, which connect the internal carotid trunks and posterior cerebral arteries.

The vessels referred to form the so-called **circulus arteriosus** which is situated at the base of the brain, in the interpeduncular and chiasmatic subarachnoid cisterns. It encloses the following structures: the posterior perforated substance, the corpora mamillaria, the tuber cinereum, the infundibulum, and the optic chiasma. The "circle" is irregularly polygonal in outline, and is formed posteriorly by the termination of the basilar and by the two posterior cerebral arteries, postero-laterally by the posterior communicating arteries and the internal carotids, antero-laterally by the anterior cerebral arteries, and in front by the anterior communicating artery.

It is stated that this free anastomosis equalises the flow of blood to the various parts of the cerebrum, and provides for the continuation of a regular blood-supply if one or more of the main trunks should be obstructed.

ARTERIES OF THE UPPER EXTREMITY.

The main arterial stem of each upper extremity passes through the root of the neck, traverses the axillary space, and is continued through the arm to the forearm. In the forearm its extent is short, for it terminates, opposite the neck of the radius, by bifurcating into the radial and ulnar arteries, which run through the forearm to the hand. That portion of the common trunk which lies in the root of the neck is known as the **subclavian artery**, the part in the axillary space is termed the **axillary artery**, whilst the remaining part is called the **brachial artery**.

ARTERIÆ SUBCLAVIÆ.

On the right side the subclavian artery (Figs. 727, 728, 730, and 732) commences at the termination of the innominate artery, posterior to the sterno-clavicular articulation, whilst that on the left side arises from the arch of the aorta, behind the upper half of the manubrium sterni.

The right artery is about 75 mm. (3 inches) long; it lies in the root of the neck. The left artery is about 100 mm. (4 inches) long, and is situated not only in the root of the neck, but also in the superior mediastinal part of the thorax. In the root of the neck each artery arches laterally, across the apex of the lung and behind the anterior scalene muscle, and is divided into three parts, which lie respectively to the medial side, behind, and to the lateral side of the muscle. The extent to which the arch rises above the level of the clavicle varies; not uncommonly it reaches the level of the lower part of the thyreoid gland. The first parts of the subclavian arteries differ materially from each other both in extent and relations. The relations of the second and third parts are similar on the two sides.

The **first part of the left subclavian artery** springs from the arch of the aorta, posterior to the commencement of the left common carotid and on the left

side of the trachea. It ascends almost vertically, in the superior mediastinum, to the root of the neck, where it arches upwards and laterally to the medial border of the scalenus anterior muscle.

Relations.—*Posterior.*—In the superior mediastinum it is in relation with the lung and pleura.

Anterior. — In front are the left vagus, the left superior cardiac branch of the sympathetic, the left inferior cardiac branch of the vagus, the left phrenic nerve, and the left common carotid artery. It is also crossed obliquely by the left vagus nerve, and it is overlapped on the left side by the left lung and pleura.

Medial.—Medially it is in relation, from below upwards, with the trachea, the left recurrent nerve, the œsophagus, and the thoracic duct, the latter lying in a plane posterior to the œsophagus and the artery.

Laterally it is closely invested by the left pleura, and it ascends in a groove on the medial aspect of the left lung.

At the root of the neck, as it turns laterally, it lies behind the commencement of the left innominate vein, and the termination of the left vertebral vein, the phrenic nerve, the sterno-thyreoid and sterno-hyoid muscles, the anterior jugular vein, and, more superficially, the sterno-mastoid muscle and the deep cervical fascia; the thoracic duct arches obliquely over it; and it lies in front of the apex of the pleural sac and lung.

The **first part of the right subclavian artery** (Fig. 728) extends from the back of the right sterno-clavicular articulation to the medial border of the scalenus anterior. It is thus limited to the root of the neck.

Relations.—*Posterior.*—Behind this part of the artery, and intervening between it and the upper two thoracic vertebræ, are the recurrent nerve, the posterior part of the ansa subclavia, and the apex of the right pleural sac. *Anterior.*—In front it is in relation with the right vagus, the cardiac branches of the vagus and the sympathetic, the anterior portion of the ansa subclavia, the internal jugular and vertebral veins, and more superficially the sterno-hyoid and sterno-thyreoid muscles, the anterior jugular vein, the sternal end of the clavicle, the sterno-clavicular ligaments, and the sterno-mastoid muscle. The recurrent nerve passes *below* it and intervenes between it and the apex of the pleural sac.

The **second part of the subclavian artery**, on *each side*, extends from the medial to the lateral border of the scalenus anterior, behind which it lies.

Relations.—Posteriorly and *below* it is in relation with the pleural sac. Anteriorly it is covered by the anterior scalene and the sterno-mastoid muscles. The anterior scalene separates it from the subclavian vein, which lies at a slightly lower level, from the transverse cervical and transverse scapular arteries, from the anterior jugular vein, and, on the right side, from the phrenic nerve.

The **third part of the subclavian artery** is the most superficial portion. It extends from the lateral border of the anterior scalene to the outer border of the first rib, lying partly in the clavicular portion of the posterior triangle of the neck and partly behind the clavicle and the subclavius muscle.

Relations.—It rests upon the upper surface of the first rib. Immediately *posterior* to it is the lowest trunk of the brachial plexus, which separates it from the middle scalene muscle. *Anterior* to it, and at a slightly lower level, lies the subclavian vein. The external jugular vein crosses the medial part of this portion of the artery, and just before its termination it receives the transverse cervical and transverse scapular veins; those vessels also pass superficial to the artery, which is thus covered superficially by venous trunks; it is also crossed vertically, behind the veins, by the nerve to the subclavius muscle. The lateral section of this part of the artery lies posterior to the clavicle and the subclavius muscle. It is crossed anteriorly by the transverse scapular artery, but the layer of deep cervical fascia which binds the posterior belly of the omo-hyoid to the posterior border of the subclavian groove intervenes between the two vessels. More superficially the third part of the artery is covered by the superficial layer of the deep fascia, the supra-clavicular branches of the cervical nerves, the platysma, and the skin.

Abnormalities.—The variations, so far as regards the origins of the subclavian arteries, have already been mentioned (p. 885). Other interesting modifications are met with in respect of its position and branches.

The subclavian artery may reach as high as 25 or 37 mm. (1-1½ in.) above the clavicle, though as a rule it does not reach higher than 19 mm. above that bone. On the other hand, it may

not rise even to the level of the upper border of the clavicle. These differences appear to be associated with the descent of the clavicle and sternum, which occurs as age increases.

The artery may pass in front of or through the scalenus anterior instead of behind it, or the vein may accompany it behind the muscle.

The branches of the subclavian artery may be modified with reference to their points of origin; thus, those of the first part may be further medial or lateral than usual, the transverse scapular or some other branch of the thyreo-cervical trunk may arise separately from the third part of the subclavian, and not uncommonly the descending branch of the transverse cervical artery is a branch of that part. The abnormalities of the vertebral branch have already been described; those of the thyreo-cervical trunk and its branches are numerous but not important.

Branches of the Subclavian Artery.

(1) The **vertebral artery** is distributed almost entirely to the head and neck, and its chief function is to supply the posterior part of the brain. Its description has therefore been given with that of the other cerebral arteries (see p. 905).

(2) The **thyreo-cervical trunk** (Figs. 728 and 735) arises close to the medial border of the scalenus anterior, from the upper and front part of the subclavian artery, directly above the origin of the internal mammary artery. After a short upward course of about 4 mm. (two lines), it ends, under cover of the internal jugular vein, by dividing into three branches—viz., the inferior thyreoid, the transverse cervical, and the transverse scapular.

(A) The **inferior thyreoid artery** (Figs. 728, 732) ascends along the anterior border of the scalenus anterior, and turns medially, opposite the cricoid cartilage, to the middle of the posterior border of the corresponding lobe of the thyreoid gland; it then curves medially and downwards, and descends to the lower end of the lobe of the thyreoid gland, where it divides into ascending and inferior terminal branches.

Relations.—*Posterior* are the vertebral artery, and the longus colli muscle; the recurrent nerve passes either anterior or posterior to the vessel, opposite the lower border of the thyreoid gland. It is covered *anteriorly* by the carotid sheath, which contains the common carotid artery, the internal jugular vein, and the vagus nerve; the middle cervical ganglion of the sympathetic lies in front of the artery as it bends medially; and on the left side the thoracic duct also passes in front of it.

Branches.—It gives off the following branches:—

(*a*) **Muscular.**—Numerous small branches pass to the scalenus anterior, the longus colli, the infra-hyoid muscles, and the inferior constrictor of the pharynx.

(*b*) The **ascending cervical** usually springs from the inferior thyreoid near its origin, but it may arise separately from the thyreo-cervical trunk. It ascends, parallel with and medial to the phrenic nerve, in the angle between the longus capitis and the scalenus anterior, to both of which it gives branches. It also gives off spinal branches which pass through the intervertebral foramina to the vertebral canal. It anastomoses with branches of the vertebral, occipital, ascending pharyngeal, and deep cervical arteries.

(*c*) **Œsophageal.**—Small branches given to the walls of the œsophagus, which anastomose with the œsophageal branches of the thoracic aorta.

(*d*) **Tracheal branches** are distributed to the trachea; they anastomose with branches of the superior thyreoid and with the bronchial arteries.

(*e*) An **inferior laryngeal branch** accompanies the recurrent nerve to the lower part of the larynx. It enters the larynx, at the lower border of the inferior constrictor, gives branches to its muscles and mucous membrane, and anastomoses with the laryngeal branch of the superior thyreoid artery.

(*f*) The **ascending terminal branch** supplies the posterior and lower part of the thyreoid gland, and anastomoses with branches of the superior thyreoid artery.

(*g*) The **inferior terminal branch** is distributed to the lower and medial part of the corresponding lobe of the thyreoid gland. It anastomoses with its fellow of the opposite side and with branches of the superior thyreoid artery.

(B) The **transverse cervical artery** (Figs. 728 and 732) arises from the thyreo-cervical trunk and runs upwards and posteriorly across the posterior triangle of the neck to the anterior border of the trapezius; there it divides into a ramus ascendens (O.T. superficial cervical) and a ramus descendens (O.T. posterior scapular). It is very variable in size, and not infrequently the ramus descendens arises separately from the third part of the subclavian.

Immediately after its origin, under cover of the internal jugular vein, it crosses the scalenus anterior, lying superficial to the phrenic nerve and under cover of the sterno-mastoid muscle; on the left side it is also crossed, superficially, by the terminal part of the thoracic duct. Passing from beneath the sterno-mastoid, it enters the lower part of the posterior triangle of the neck, where it lies upon the trunks of the brachial plexus, and as it runs upwards and backwards to its termination it passes medial to the posterior belly of the omo-hyoid.

The ascending branch may be a separate vessel which springs from the thyreo-cervical trunk and takes the course described, whilst the descending branch arises from the third part of the subclavian artery and lies at a lower level. In such cases the upper of the two vessels is called the **superficial cervical artery** and the lower the **transverse cervical artery**. If the superficial cervical artery is absent it is replaced by the ascending branch of the transverse cervical.

Branches.—(*a*) Small **muscular branches** to the surrounding muscles.

(*b*) The **ascending branch**, usually a slender branch, passes beneath the trapezius; it sends branches upwards and downwards, superficial to the levator scapulæ and upon the splenius; the ascending branches anastomose with the descending branch of the occipital artery, and the descending branches accompany the accessory nerve and anastomose with the descending branch and transverse scapular artery.

(*c*) The **descending branch** runs downwards, deep to the levator scapulæ and the rhomboid muscles, close to the vertebral border of the scapula. It runs parallel with, and a short distance away from, the dorsal scapular nerve (O.T. nerve to the rhomboid muscles), and it sends branches into the supraspinous, the infraspinous, and the subscapular fossæ, which anastomose with branches of the transverse scapular and subscapular arteries. It also sends branches backwards, through and between the rhomboid muscles, which anastomose with the branches of the ascending division of the transverse cervical and with the posterior branches of the intercostal arteries.

(C) The **transverse scapular artery** (O.T. **supra-scapular**) springs from the thyreo-cervical trunk and terminates in the infraspinous fossa of the scapula. As a rule it is smaller than the transverse cervical artery.

Commencing behind the internal jugular vein, it crosses the scalenus anterior and phrenic nerve, and is covered superficially by the sterno-mastoid and the anterior jugular vein; on the left side it lies behind the termination of the thoracic duct also. Continuing, laterally, behind the clavicle, and crossing superficial to the third part of the subclavian artery and the cords of the brachial plexus, it reaches the scapular notch and passes over the superior transverse ligament. Then it descends, with the suprascapular nerve, through the supraspinous fossa and deep to the supraspinatus muscle, and after passing through the great scapular notch, deep to the inferior transverse ligament, it enters the infraspinous fossa, where it anastomoses with the circumflex scapular branch of the subscapular artery and with twigs of the descending branch of the transverse cervical artery.

Branches.—(*a*) **Muscular**, to the sterno-mastoid, the subclavius, and the muscles on the dorsum of the scapula.

(*b*) The **medullary**, a small branch to the clavicle.

(*c*) The **suprasternal**, to the sternal end of the clavicle and the sterno-clavicular joint.

(*d*) **Acromial branches**, which ramify over the acromion, anastomosing with the acromial branches of the thoraco-acromial and the posterior circumflex arteries.

(*e*) **Articular**, to the acromio-clavicular and shoulder-joints.

(*f*) The **subscapular**, which is given off as the artery passes over the superior transverse ligament. It passes down into the subscapular fossa, gives branches to the subscapularis, and it anastomoses with the branches of the subscapular artery and the descending branch of the transverse cervical artery.

(*g*) **Supraspinous**, which ramify in the supraspinous fossa, supplying the muscle, and anastomosing with the descending branch of the transverse cervical.

(*h*) **Terminal branches** ramify in the infraspinous fossa, and anastomose with the circumflex scapular and with branches of the descending branch of the transverse cervical artery.

(3) The **internal mammary artery** (Figs. 728, 735) arises from the lower and anterior part of the subclavian, at the medial border of the scalenus anterior and

immediately below the origin of the thyreo-cervical trunk. It terminates, behind the medial extremity of the sixth intercostal space, by dividing into the musculophrenic and the superior epigastric arteries.

The artery passes at first downwards, forwards, and medially, lying upon the pleura, and behind the innominate vein, the sternal extremity of the clavicle, and

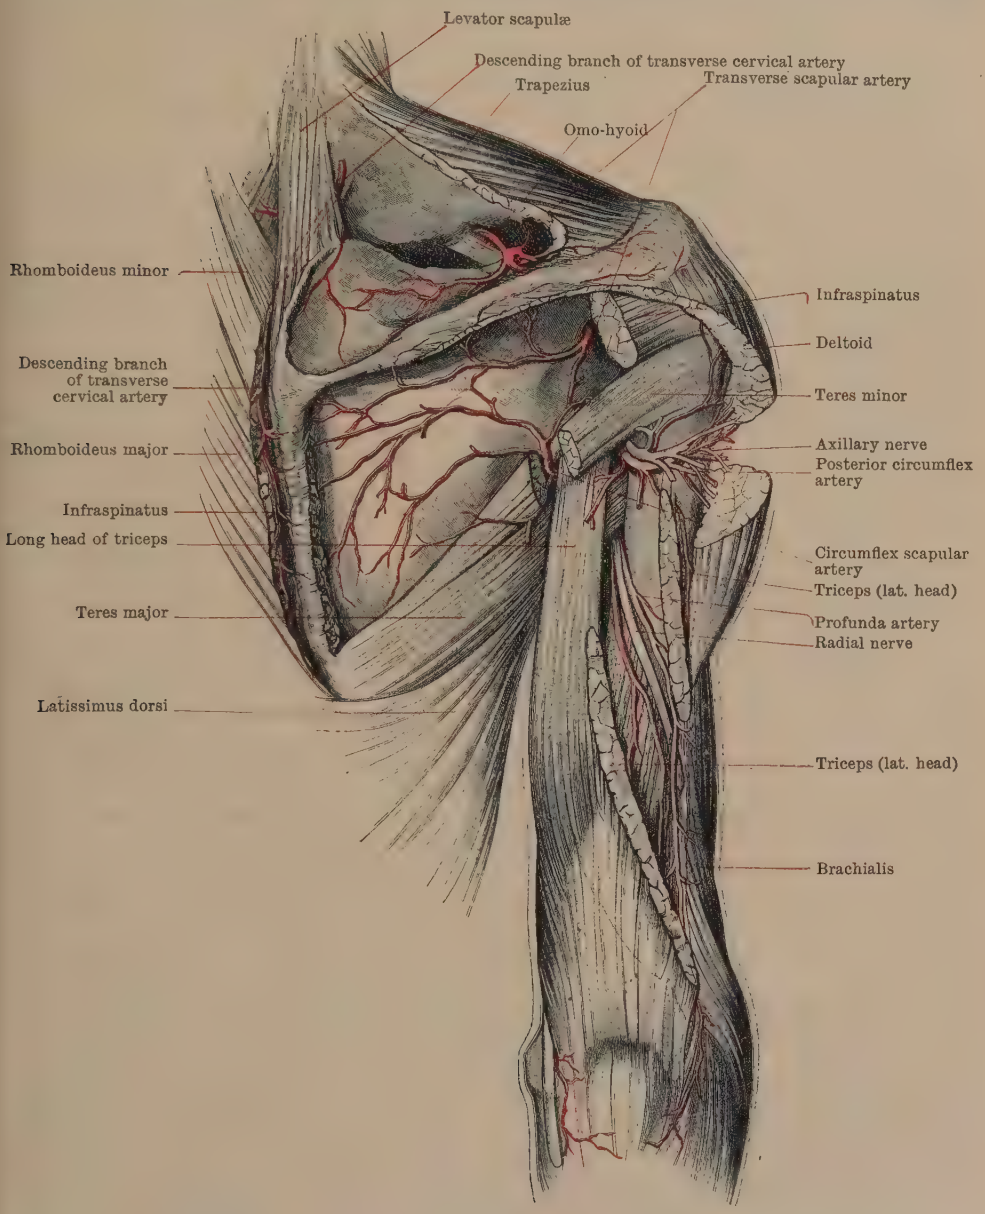

FIG. 740.—DISSECTION OF THE BACK OF THE SHOULDER AND ARM, showing the anastomosing vessels on the dorsum of the scapula, and the posterior humeral circumflex and the profunda arteries.

the cartilage of the first rib; it is crossed obliquely, from the lateral to the medial side, by the phrenic nerve, which usually passes anterior to it. From the cartilage of the first rib it descends vertically, about 12 mm. (half an inch) from the border of the sternum, and lies, in the upper part of its course, in front of the pleura, and, in the lower part, in front of the transversus thoracis muscle. It is covered anteriorly by the cartilages of the upper six ribs, the intervening intercostal muscles, and the terminal portions of the intercostal nerves; and it is accompanied by

two venæ comites, which unite together above, and on its medial side, to form a single trunk which terminates in the innominate vein.

Abnormalities.—The internal mammary artery, though usually a branch of the first part of the subclavian, is very variable as regards its origin. It may arise from the second or third parts, or from the thyreo-cervical, or it may spring from the aorta, or from the innominate or axillary arteries. All these variations are due to obliteration of the normal origin and the opening up of anastomoses. The internal mammary artery sometimes descends in front of the cartilages of one or more of the lower true ribs; and occasionally it gives off a large lateral branch (a. mammaria lateralis) which descends on the inner side of the chest wall, close to the mid-axillary line,—a point of importance in paracentesis.

A few cases have also been noticed in which a bronchial artery has arisen from the internal mammary.

Branches.—(*a*) The **pericardiaco-phrenic** (O.T. **comes nervi phrenici**) is a long slender branch which is given off from the upper part of the internal mammary. It accompanies the phrenic nerve, through the superior and middle mediastina, to the diaphragm, where it anastomoses with the inferior phrenic and musculo-phrenic arteries. In its course downwards this branch gives off numerous small rami to the pleura and pericardium, which anastomose with offsets of the mediastinal and pericardial branches of the aorta and internal mammary arteries, and also with the bronchial arteries, forming the wide-meshed *subpleural plexus* of Turner.

(*b*) **Anterior mediastinal branches**, small and numerous, pass to the areolar tissue of the anterior mediastinum and supply the areolar tissue and the sternum.

(*c*) **Thymic.**—Small twigs which supply the thymus.

(*d*) **Bronchial.**—One or several small branches which pass to the lower end of the trachea and to the bronchi.

(*e*) The **intercostal** are two in number in each of the upper six intercostal spaces. They pass laterally and, for a short distance, they lie either between the pleura and the internal intercostal muscles or between the transversus thoracis and the internal intercostal muscles; they then pierce the internal intercostal muscles, and ramify between them and the external intercostal muscles, anastomosing with the aortic and superior intercostal arteries and their collateral branches.

(*f*) The **perforating branches**, one in each of the upper six intercostal spaces, are small vessels which pass forwards, with the anterior branches of the thoracic nerves, piercing the internal intercostal muscle, the anterior intercostal membrane, and the pectoralis major. They terminate in the skin and subcutaneous tissue. They supply twigs to the sternum, and those in the third and fourth spaces, usually the largest of the series, give off branches to the mammary gland.

(*g*) The **musculo-phrenic**, or lateral terminal branch of the internal mammary artery, runs downwards and laterally, from the sixth intercostal space to the tenth costal cartilage. In the upper part of its course it lies upon the thoracic surface of the diaphragm, but it pierces the diaphragm about the level of the eighth costal cartilage, and terminates on its abdominal surface. Its branches are:—

(i.) **Muscular**, which supply the diaphragm and anastomose with the superior and inferior phrenic arteries.

(ii.) **Intercostal branches**, two in each of the seventh, eighth, and ninth intercostal spaces; they are distributed in the same manner as the corresponding branches of the internal mammary artery, and terminate by anastomosing with the aortic intercostals and their collateral branches.

(*h*) The **superior epigastric**, or medial terminal branch of the internal mammary artery, descends into the anterior wall of the abdomen. It leaves the thorax, between the sternal and costal origins of the diaphragm, and enters the sheath of the rectus abdominis muscle, lying first behind, and then in the substance of the muscle. It terminates by anastomosing with branches of the inferior epigastric artery. Its branches are:—

(i.) **Muscular**, to the rectus, to the flat muscles of the abdominal wall, and to the diaphragm.

(ii.) **Anterior Cutaneous.**—Small branches which pierce the rectus abdominis muscle and the anterior portion of its sheath. They accompany the anterior terminal branches of the lower thoracic nerves, and terminate in the subcutaneous tissues and skin of the middle portion of the anterior abdominal wall.

(iii.) **Xiphoid**, a small branch which crosses the front of the xiphoid process to anastomose with its fellow of the opposite side. It supplies the adjacent muscles and skin.

(iv.) **Hepatic branches** of small size pass backwards in the falciform ligament to the liver, where they anastomose with branches of the hepatic artery.

(4) The **costo-cervical trunk** (Fig. 735) springs from the posterior aspect of the second part of the subclavian artery on the right side and from the first part

on the left side. It runs upwards and backwards, over the apex of the pleural sac, to the neck of the first rib, where it divides into superior intercostal and deep cervical branches.

Branches.—(*a*) The **deep cervical** branch sometimes arises from the subclavian artery directly; but more commonly it springs from the costo-cervical trunk at the upper border of the neck of the first rib. It runs backwards, to the back of the neck, passing between the first thoracic and last cervical nerves, and between the transverse process of the last cervical vertebra and the neck of the first rib. In the back of the neck it ascends between the semispinalis capitis (O.T. complexus) and the semispinalis cervicis muscles and it terminates by anastomosing with the descending branch of the occipital artery. It anastomoses also with branches of the ascending cervical and vertebral arteries, supplies the adjacent muscles, and sends a spinal branch, through the intervertebral foramen between the last cervical and the first thoracic vertebræ, into the vertebral canal; this branch anastomoses with the spinal branches of the vertebral and intercostal arteries.

(*b*) The **superior intercostal branch** descends, anterior to the neck of the first rib, between the first thoracic nerve laterally and the first thoracic ganglion of the sympathetic trunk medially and, at the lower border of the neck of the rib, it gives off the posterior intercostal artery of the first space; then, after crossing anterior to the neck of the second rib, it becomes the posterior intercostal artery of the second intercostal space. The first two posterior intercostal arteries, which are respectively a branch and the continuation of the superior intercostal artery, run laterally, each in its own space, lying first between the pleura and the posterior intercostal membrane, and then between the internal and external intercostal muscles. Their branches terminate by anastomosing with anterior intercostal branches of the internal mammary artery. Each gives off *muscular* branches to the intercostal muscles, a *nutrient branch* to the rib below which it lies, and a *collateral branch* which runs along the lower border of the corresponding space.

Abnormalities.—The **superior intercostal branch** of the costo-cervical trunk may be absent, and the profunda cervicis branch may arise directly from the subclavian trunk. The superior intercostal is sometimes formed from a postcostal instead of a precostal primitive channel. In such cases it passes between the necks of the ribs and the transverse processes of the vertebræ instead of, as usual, in front of the necks of the ribs.

ARTERIA AXILLARIS.

The **axillary artery**, which lies in the axillary space, is the direct continuation of the subclavian artery, and it becomes the brachial artery.

It commences at the external border of the first rib, at the apex of the axillary space. It passes distally, with a lateral inclination, along the lateral wall of the space, *i.e.* to the medial side of the shoulder-joint and the humerus, to the lower border of the teres major, where it becomes the brachial artery. A line drawn from the middle of the clavicle to the medial border of the prominence of the coracobrachialis muscle, when the arm is abducted until it is at right angles with the side, indicates the position and direction of the artery.

The position and direction, however, and to a certain extent the relations of the axillary artery, are modified by changes in the position of the upper extremity. With the arm hanging by the side the axillary artery describes a curve with the concavity directed downwards and medially, and the vein is to its medial side. When the arm is at right angles with the side, the axillary artery is almost straight; it lies closer to the lateral wall of the axilla, and the vein overlaps it antero-medially. When the arm is raised above the level of the shoulder the axillary artery is curved over the head of the humerus, with the convexity of the curve below, and the vein lies still more in front of it.

For descriptive purposes the artery is divided into three parts: the first part lies above, the second behind, and the third part below the pectoralis minor.

Though it is the usual custom to describe three parts of the axillary artery,—a division which is of practical interest in so far as it emphasises the fact that the axillary artery is surgically accessible above the pectoralis minor,—it is to be noted that the upper border of the pectoralis minor is frequently exactly opposite the external border of the first rib, at the point where the axillary artery begins. In the strict sense, therefore, no part of the artery is above the pectoralis minor.

Relations of the First Part—*Posterior.*—The first part of the artery is enclosed, together with the vein and the cords of the brachial plexus, in a prolongation of the cervical fascia known as the axillary sheath. Posterior to the sheath are the upper serration of the serratus anterior, the contents of the first intercostal space, and the long thoracic nerve, the latter descending vertically between the artery and the serratus anterior; whilst, within the sheath, the medial anterior thoracic nerve and the medial cord of the brachial plexus lie behind the artery. *Anterior.*—It is covered in front by the costo-coracoid membrane. The membrane intervenes between the artery and the cephalic vein, the branches of the lateral anterior thoracic nerve, the branches of the thoraco-

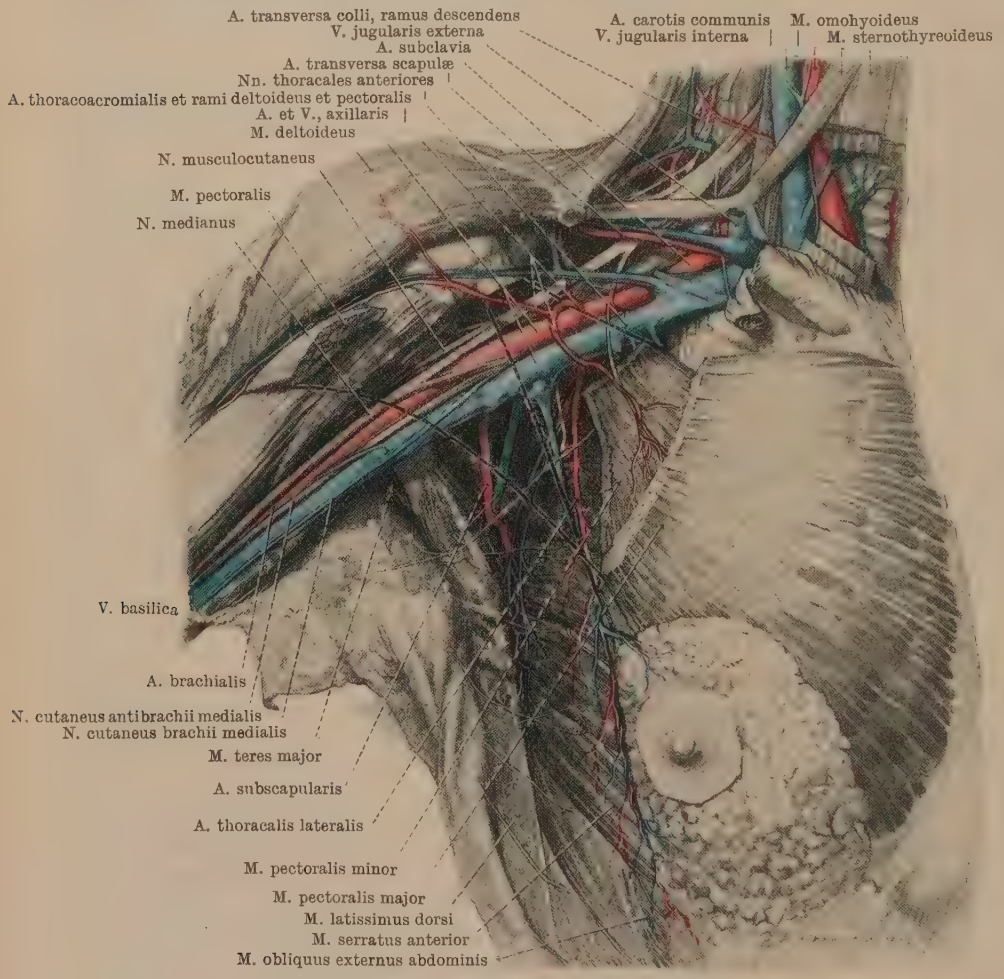

FIG. 741.—THE AXILLARY ARTERY AND ITS BRANCHES.

NOTE.—The middle third of the clavicle has been removed; and the arm has been slightly abducted and rotated laterally. Parts of the pectoralis major and minor have been removed; the positions of the lower border of the pectoralis major and the upper and lower borders of the pectoralis minor are indicated by broken black lines.

acromial artery with their accompanying veins, and the clavicular part of the pectoralis major muscle, superficial to which are the deep fascia, the platysma, the supra-clavicular branches of the cervical plexus, and the superficial fascia and the skin. Posterior to the costo-coracoid membrane the artery is crossed by a loop of communication between the lateral and medial anterior thoracic nerves. *Lateral.*—Above and to the lateral side are the lateral and posterior cords of the brachial plexus and the lateral anterior thoracic nerve. Below and to the medial side is the axillary vein, the medial anterior thoracic nerve intervening.

Relations of the Second Part—*Posterior.*—Behind the second part of the artery are the posterior cord of the brachial plexus and a layer of fascia which separates it from the subscapularis muscle. *Anterior.*—In front is the pectoralis minor, and, more superficially,

the pectoralis major, the fasciæ and skin. *Lateral.*—To the lateral side lies the lateral cord of the brachial plexus. *Medial.*—On the medial side the medial cord of the plexus lies in close relation to the artery, and intervenes between it and the axillary vein.

Relations of the Third Part—*Posterior.*—The third part of the artery rests posteriorly upon the lower border of the subscapularis, the latissimus dorsi, and the teres major. It is separated from the fibres of the subscapularis by the axillary (O.T. circumflex) and radial (O.T. musculo-spiral) nerves, and from the latissimus dorsi and teres major by the radial nerve alone. *Anterior.*—It is crossed in front by the medial head of the median nerve. In its upper half it lies under cover of the lower part of the pectoralis major, the fasciæ and skin, whilst its lower part, which is superficial, is covered by skin and fasciæ only. *Lateral.*—To the lateral side lie the median and musculo-cutaneous nerves and the coraco-brachialis muscle. *Medial.*—To the medial side is the axillary vein. The two vessels are, however, separated by two of the chief branches of the medial cord of the brachial plexus, for in the angle between the vein and the artery, and somewhat in front of the latter, lies the medial cutaneous nerve of the forearm (O.T. internal cutaneous nerve); and in the angle behind is the ulnar nerve. The medial cutaneous nerve of the arm (O.T. lesser internal cutaneous) lies medial to the vein, and the venæ comites of the brachial artery ascend along the medial side, to terminate in the axillary vein at the lower border of the subscapularis muscle.

Abnormalities.—The **axillary artery** does not vary much as regards its origin or course. Its relations may be modified by the existence of a muscular or tendinous "axillary arch," which, passing from the latissimus dorsi to the pectoralis major, crosses the distal part of the artery superficially; and a further interesting modification is associated with an anomalous arrangement of its branches. Occasionally the subscapular, circumflex, and profunda and superior ulnar collateral arteries arise from the axillary by a common stem. In those cases the chief branches of the brachial plexus are grouped round the common stem instead of round the main trunk. The arrangement is due to the persistence of a different part of the original vascular plexus.

Sometimes the axillary artery divides into the radial and ulnar arteries, and more rarely the interosseous artery may spring from it.

Obviously there is no brachial artery when the radial and ulnar arteries are formed by the division of the axillary; its place is taken by the two abnormal vessels which, as a rule, are separated by the median nerve as they run through the arm; the radial is usually more superficial than the ulnar, and crosses laterally in front of it at the bend of the elbow.

Branches of the Axillary Artery.

(1) **Arteria Thoracalis Suprema.**—The **highest thoracic artery** is a small branch which arises from the first part of the axillary at the lower border of the subclavius. It runs downwards and medially, across the first intercostal space, pierces the medial part of the costo-coracoid membrane, and supplies branches to the subclavius, the pectoralis major and minor, and to the serratus anterior (O.T. magnus) and the intercostal muscles; it anastomoses with branches of the transverse scapular, the internal mammary, and the thoraco-acromial arteries.

(2) The **thoraco-acromial artery** (Fig. 741) arises near the upper border of the pectoralis minor, from the second part of the axillary artery. It is a very short trunk, of considerable size, which passes forwards, pierces the costo-coracoid membrane, and terminates, deep to the clavicular portion of the pectoralis major, by dividing into four terminal branches—clavicular, pectoral, deltoid, and acromial.

(*a*) The **clavicular branch** is a long slender artery which runs upwards and medially, to the sterno-clavicular joint, anastomosing with the supreme thoracic, with branches of the transverse scapular, and with the first perforating branch of the internal mammary artery. It supplies the adjacent muscles and the sterno-clavicular articulation.

(*b*) The **pectoral** is a large branch which descends between the two pectoral muscles, to both of which it gives branches, and it anastomoses with the intercostal and lateral thoracic arteries.

(*c*) The **deltoid branch** runs distally, in the groove between the pectoralis major and the deltoid, where it lies by the side of the cephalic vein, as far as the insertion of the deltoid. It anastomoses with the acromial branch and with the anterior circumflex artery, and it gives branches to the pectoralis major and deltoid muscles and to the skin.

(*d*) The **acromial branch** runs upwards and laterally, across the tip of the coracoid process, to the acromion; it anastomoses with the deltoid branch, with the acromial

branches of the transverse scapular, and with the posterior circumflex arteries. It gives branches to the deltoid.

(3) The **lateral thoracic artery** arises from the second part of the axillary, and descends, along the lower border of the pectoralis minor, to anastomose with the intercostal and subscapular arteries and with the pectoral branch of the thoraco-acromial. It supplies the adjacent muscles, and sends mammary branches to the lateral part of the corresponding mammary gland.

(4) The **subscapular artery** is the largest branch of the axillary artery. It arises from the third part of the artery, opposite the lower border of the subscapularis, along which it descends, giving branches to the muscle and to the medial wall of the axillary space. After a short course it divides into two terminal branches, the circumflexa scapulæ and the thoraco-dorsalis.

(1) The **circumflexa scapulæ** is frequently the larger branch. It arises about 37 mm. (one and a half inches) from the commencement of the subscapular trunk, and passes backwards into the triangular space which lies between the subscapularis above, the teres major below, and the long head of the triceps laterally. Turning round, and usually grooving the axillary border of the scapula, under cover of the teres minor, it enters the infraspinous fossa, where it breaks up into branches which anastomose with branches of the descending branch of the transverse cervical artery and the transverse scapular arteries. Whilst it is in the triangular space the artery gives off an *infrascapular branch* which passes into the subscapular fossa and terminates by anastomosing with the branches of the descending branch of the transverse cervical and the transverse scapular arteries. It gives off, in the same situation, a descending branch also, which runs downwards, to the lower angle of the scapula, between the teres major and minor muscles, and small branches are given to the deltoid and long head of triceps.

(2) The thoraco-dorsal continuation of the subscapular trunk accompanies the thoraco-dorsal nerve (O.T. long subscapular) along the axillary border of the scapula to the wall of the thorax, where it anastomoses with the lateral thoracic artery and with branches of the intercostal arteries.

(5) The **posterior humeral circumflex artery** arises from the third part of the axillary artery and passes backwards, accompanied by the axillary nerve, through an intermuscular cleft, the so-called quadrilateral space, which is bounded by the teres minor and subscapularis above, the teres major below, the long head of the triceps medially, and the humerus laterally. It turns round the surgical neck of the humerus, under cover of the deltoid muscle, and terminates in numerous branches which supply the deltoid. As a rule it is an artery of large size, only slightly smaller than the subscapular.

Branches.—(*a*) **Muscular** to the teres major and minor, the long and lateral heads of the triceps, and the deltoid; (*b*) An **acromial branch,** which ascends to the acromion, where it anastomoses with the acromial branches of the transverse scapular and the thoraco-acromial arteries; (*c*) A **descending branch,** which runs distally, along the lateral head of the triceps, to anastomose with the profunda artery; (*d*) **Articular** to the shoulder-joint; (*e*) **Nutrient** to the head of the humerus; (*f*) **Terminal,** which supply a large portion of the deltoid, and anastomose with the anterior circumflex and thoraco-acromial arteries.

(6) The **anterior humeral circumflex artery** is a small branch; it is given off from the third part of the axillary close to, or in common with, the posterior circumflex. It passes laterally, posterior to the coraco-brachialis and the two heads of the biceps, round the front of the surgical neck of the humerus, and it terminates by anastomosing with the posterior circumflex. At the intertubercular groove it gives a well-marked branch which accompanies the tendon of the long head of the biceps, supplying the sheath of the tendon, and giving branches to the shoulder-joint. It also gives muscular branches to the adjacent muscles, one of which runs distally along the tendon of insertion of the pectoralis major.

ARTERIA BRACHIALIS.

The **brachial artery** is the direct continuation of the axillary. It commences at the lower border of the teres major, and ends, in the cubital fossa,

at the level of the neck of the radius, by dividing into the radial and ulnar arteries.

The general course of the brachial artery is distally and laterally, along the *medial* side of the arm, at first on the medial side and then in front of the humerus. Its position and that of the axillary artery may be indicated on the surface, when the arm is abducted, by a line drawn from the middle of the clavicle to the centre of the bend of the elbow.

Relations — *Posterior.* — It lies, successively, anterior to the long head of the triceps, the radial nerve and the profunda vessels intervening; the medial head of the triceps; the insertion of the coraco-brachialis; and the brachialis. *Anterior.*—It is overlapped *anteriorly* by the medial border of the biceps; it is crossed, at the middle of the arm, by the median nerve, and, in addition, it is covered by deep and superficial fascia and skin. In the cubital fossa a thickened portion of the deep fascia, the lacertus fibrosus (O.T. semilunar or bicipital fascia), separates it from the median basilic vein and the volar branch of the medial cutaneous nerve of the forearm, both of which lie in the superficial fascia. *Lateral.*—To the *lateral side* it is in relation, proximally, with the median nerve, and, distally, with the biceps. *Medial.*—To the *medial side* it is in relation, in the proximal part of its extent, with the basilic vein, the medial cutaneous nerve of the forearm, the medial cutaneous nerve of the arm, and the ulnar nerve, and in the distal part with the median nerve. Two venæ comites, a medial and a lateral, accompany the artery, and communications between these pass across the vessel.

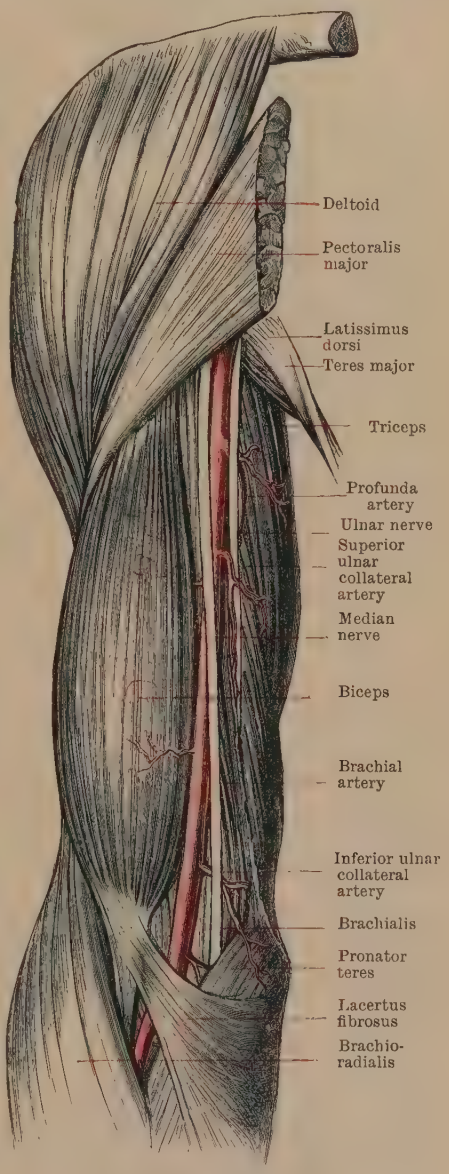

FIG. 742.—THE BRACHIAL ARTERY AND ITS BRANCHES.

Abnormalities.—The **brachial artery** is rarely prolonged beyond its usual point of bifurcation; not uncommonly, however, it bifurcates at a more proximal level. Of the two terminal branches of the brachial, one may divide into radial and interosseous, the other forming the ulnar; or one may divide into radial and ulnar, whilst the other is the interosseous artery. Occasionally the brachial artery terminates by dividing into three branches —viz., the radial, the ulnar, and the interosseous. In any case, the branch which gives origin to or becomes the interosseous was, in all probability, the original trunk.

Division of the brachial artery at a more proximal level than usual occurs most commonly in the proximal third of the arm, and least commonly in the distal third; the resulting trunks are often united near the bend of the elbow by a more or less oblique anastomosis.

In cases of proximal division of the brachial artery the radial branch may pierce the deep fascia of the arm near the bend of the elbow, and passes distally in the forearm immediately deep to the skin; in other cases the radial runs deeper, and passes behind the tendon of the biceps. The ulnar branch sometimes runs, on the medial intermuscular septum, towards the medial epicondyle, and then laterally towards the middle of the bend of the elbow, under a band of fascia from which the proximal fibres of the pronator teres arise, or round the supracondylar process of the humerus if it is present. More commonly the ulnar branch runs distally towards the medial epicondyle, and crosses superficial to the flexor muscles or deep to the palmaris longus; and in a few cases it is subcutaneous. In rare cases the ulnar artery accompanies the ulnar nerve behind the medial epicondyle; in those cases it has obviously been formed by enlargement of the ordinary superior ulnar collateral and dorsal ulnar recurrent arteries.

Instead of following its usual course along the brachialis muscle, the brachial artery may accompany the median nerve behind a supracondylar or epicondylic process, or ligament, as in many carnivora; it may pass in front of the median nerve instead of behind it. It may give off a "vas aberrans" or a median artery, and any of its ordinary branches may be absent.

The vas aberrans given off from the brachial artery usually ends in the radial artery, sometimes in the radial recurrent, and rarely in the ulnar artery.

Branches of the Brachial Artery.

(1) The **profunda artery** of the arm is a large branch which arises from the postero-medial aspect of the brachial, soon after its commencement. It runs distally and laterally, with the radial nerve, in the radial sulcus and divides, at the back of the humerus, into two terminal branches, anterior and posterior. Not infrequently the division takes place at a higher level, and the artery appears double. The anterior terminal branch accompanies the radial nerve through the lateral intermuscular septum, and passes distally, between the brachio-radialis and the brachialis, to the front of the lateral epicondyle, where it anastomoses with the radial recurrent artery. The posterior terminal branch continues distally, behind the lateral intermuscular septum, and anastomoses, posterior to the lateral epicondyle, with the interosseous recurrent artery and with the inferior ulnar collateral artery.

Whilst they are posterior to the humerus one of the terminal branches gives off—(*a*) a slender *medial collateral twig*, which descends in the substance of the medial head of the triceps to the back of the elbow, where it anastomoses with the inferior ulnar collateral artery; (*b*) a *nutrient branch*, which enters a foramen on the posterior surface of the humerus; and (*c*) an *ascending branch*, which anastomoses with the descending branch of the posterior circumflex artery.

(2) **Muscular branches** are given to the biceps, coraco-brachialis, brachialis, triceps, and pronator teres.

(3) **Nutrient.**—A small artery which arises from the middle of the brachial and enters the nutrient foramen on the antero-medial surface of the body of the humerus.

(4) The **superior ulnar collateral artery** is smaller than the profunda, with which it sometimes arises by a common trunk; usually, however, it springs from the postero-medial aspect of the middle of the brachial artery. It runs distally and posteriorly, with the ulnar nerve, through the medial intermuscular septum, and then, passing more vertically, reaches the back of the medial epicondyle of the humerus, where it terminates by anastomosing with the dorsal and volar ulnar recurrent and inferior ulnar collateral arteries.

(5) The **inferior ulnar collateral artery** arises from the medial side of the brachial artery about 50 mm. (2 inches) above its termination. It runs medially, posterior to the median nerve and anterior to the brachialis. Then it pierces the medial intermuscular septum, and turns laterally, between the medial head of the triceps and the posterior surface of the bone, to the lateral epicondyle. It supplies the adjacent muscles and anastomoses, anterior to the medial epicondyle, with the volar ulnar recurrent, behind the medial epicondyle with the dorsal ulnar recurrent and the superior ulnar collateral, at the middle of the back of the humerus with the medial collateral branch of the profunda, and posterior to the lateral epicondyle with the posterior terminal branch of the profunda and with the interosseous recurrent artery.

ARTERIA RADIALIS.

The **radial artery** (Figs. 743 and 744) is the smaller of the two terminal branches of the brachial artery, but it is the more direct continuation of the parent trunk. It commences, in the cubital fossa, opposite the neck of the radius, and terminates in the palm of the hand, by anastomosing with the deep branch of the ulnar artery, and thus completing the deep volar arch (O.T. palmar).

The trunk is divisible into **three parts.**

The *first part* lies in the volar part of the forearm. It runs distally and somewhat laterally to the apex of the styloid process of the radius. The *second part*

curves round the lateral side of the wrist, and across the back of the os multangulum majus, to reach the proximal end of the first interosseous space. The *third part* passes volarwards, through the first interosseous space, to the palm of the hand, where it joins the deep branch of the ulnar artery.

Relations of the First Part—*Dorsal.*—It passes successively across the volar aspects of the following structures: the tendon of insertion of the biceps, the supinator, the pronator teres, the radial portion of the flexor digitorum sublimis, the flexor pollicis longus, the pronator quadratus, and the volar ligament of the wrist-joint.

Volar.—The artery is covered superficially, in the proximal half, by the volar border of the brachio-radialis; in the remainder of its extent it is covered only by skin and fasciæ.

To the *radial side* are the brachio-radialis and the superficial branch of the radial nerve. The nerve lies quite near to the middle third of the artery. To the *ulnar side* are the pronator teres, proximally, and the flexor carpi radialis, distally. Two venæ comites, one on each side, accompany the artery.

Branches of the First Part.—(1) The **radial recurrent** arises in the cubital fossa where it springs from the lateral side of the radial, on the volar surface of the supinator. It runs towards the radial border of the forearm, passes between the superficial and deep divisions of the radial (musculo-spiral) nerve, and then runs proximally to the lateral epicondyle of the humerus, where it anastomoses with the anterior terminal branch of the profunda. The radial recurrent supplies numerous muscular branches to the brachio-radialis, the supinator, the extensor carpi radialis longus, and the extensor carpi radialis brevis.

(2) **Muscular branches** to the muscles on the radial side of the volar aspect of the forearm.

(3) The **superficial volar branch** (Fig. 743) is a slender vessel which arises a short distance proximal to the wrist and runs distally across the ball of the thumb. It usually pierces the superficial muscles of the thenar eminence, and terminates either in their substance or by uniting with the ulnar artery and completing the superficial arch of the palm of the hand.

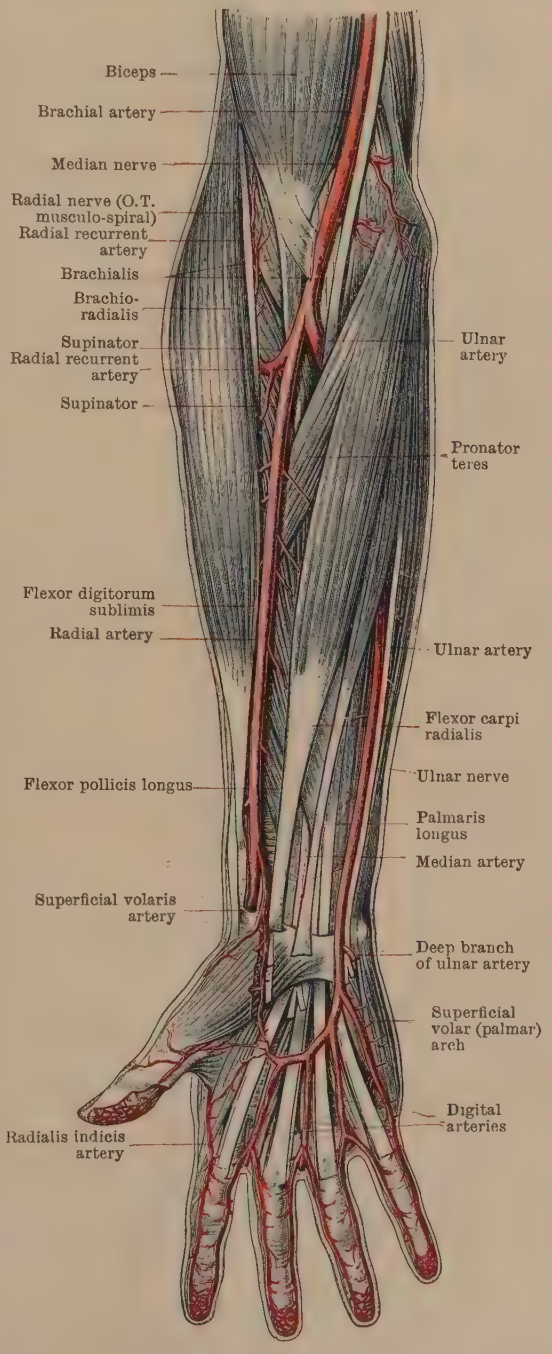

FIG. 743.—SUPERFICIAL DISSECTION OF THE VOLAR ASPECT OF THE FOREARM AND HAND, showing the radial and ulnar arteries and the superficial volar arch with its branches.

(4) A **volar carpal branch** passes ulnarwards, between the flexor tendons and their synovial sheaths, and the radial attachments of the volar carpal ligaments. It anasto-

moses with the volar carpal branch of the ulnar artery to form the volar carpal arch. and it receives communications from the volar interosseous artery and from the deep volar arch.

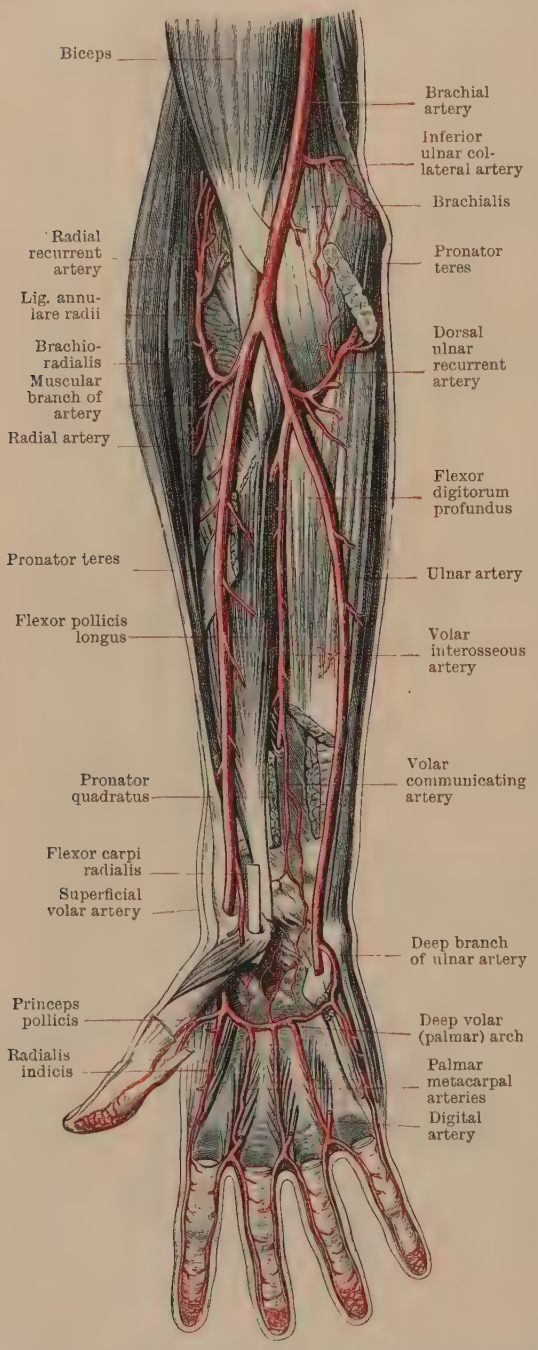

FIG. 744.—DEEP DISSECTION OF THE FRONT OF THE FOREARM AND HAND, showing the radial and ulnar arteries and their branches and the deep volar arch and its branches.

Relations of the Second Part.—As it curves round the radial side and the dorsum of the wrist, the radial artery lies upon the radial collateral ligament of the intercarpal joint and upon the back of the os multangulum majus. It is crossed by the abductor pollicis longus, the extensor pollicis brevis, and the extensor pollicis longus; more superficially it is covered by skin, and by fascia, which contains the cephalic vein and some filaments of the superficial branch of the radial nerve.

Branches of the Second Part—(1) **Dorsales Pollicis.**—Two small arteries which run along the borders of the dorsal aspect of the thumb; they supply the skin, tendons, and joints, and anastomose with the volar digital arteries.

(2) **Dorsalis Indicis Radialis.**—A slender artery which runs distally, on the ulnar head of the first dorsal interosseous muscle and along the dorsal aspect of the radial border of the index-finger.

(3) and (4) The **first dorsal metacarpal** and the **dorsal radial carpal** arise by a common trunk which crosses deep to the extensor pollicis longus.

(*a*) The metacarpal branch passes distally, on the dorsal aspect of the second dorsal interosseous muscle, and divides, opposite the heads of the metacarpal bones, into two dorsal digital branches which supply the adjacent sides of the index and middle fingers. (*b*) The dorsal carpal branch runs ulnarwards, on the dorsal carpal ligaments, deep to the extensor tendons, to anastomose with the dorsal carpal branch of the ulnar artery, and to complete the **dorsal carpal arch** which receives the terminations of the volar and dorsal interosseous arteries. The dorsal carpal arch gives off the **second** and **third dorsal metacarpal arteries**, which run distally, on the dorsal aspects of the third and fourth dorsal interosseous muscles, as far as the heads of the metacarpal bones, where each divides into two dorsal digital branches for the adjacent sides of the third and fourth and the fourth and fifth digits, respectively.

Each dorsal metacarpal artery is connected with the deep volar (palmar) arch by a **proximal perforating branch** which passes through the proximal part of the corresponding interosseous space, and with a digital branch from the superficial volar (palmar) arch by a **distal perforating branch** which passes through the distal part of the space.

Relations of the Third Part.—The third part of the radial artery passes volarwards, between the two heads of the first dorsal interosseous muscle, to reach the palm, where it turns ulnarwards, deep to the proximal oblique part of the adductor muscle of the thumb,

and, after passing through the proximal fibres of the transverse part of the adductor pollicis, or between the adjacent borders of the oblique and transverse parts of that muscle, it unites with the deep branch of the ulnar artery, completing the deep volar (palmar) arch.

Branches of the Third Part.—(1) The **princeps pollicis** branch is given off as soon as the radial artery enters the palm. It runs distally, on the volar aspect of the first metacarpal bone, between the adductor and the opponens pollicis, and under cover of the long flexor tendon, and divides, near the distal end of the bone, into collateral branches which run along the sides of the thumb and anastomose with the dorsales pollicis arteries.

(2) The **arteria volaris indicis radialis** is a branch which runs distally between the ulnar head of the first dorsal interosseous muscle and the adductor of the thumb and along the radial side of the index-finger to its tip. It supplies the adjacent tissues, and not uncommonly it anastomoses with the superficial volar (palmar) arch.

Abnormalities.—The **radial artery** may be absent, its place being taken by branches of the ulnar or interosseous arteries; it may arise, more proximal than usual, from the axillary, or from the brachial. It may terminate in muscular branches in the volar part of the forearm, or as the superficial volar, or in carpal branches; the distal portion of the artery, in those cases, is usually replaced by branches of the ulnar or interosseous arteries. Occasionally the radial divides some distance proximal to the wrist into two terminal branches, one of which gives off the carpal branches, and becomes the superficial volar, whilst the other crosses superficial to the extensor tendons and passes to the dorsum of the wrist.

The radial artery may run a superficial course, or, and especially when it commences at a more distal level than usual, it may pass deep to the pronator teres and the radial origin of the flexor digitorum sublimis. In some cases it passes to the dorsum of the wrist across the brachioradialis, and in others it lies superficial, instead of deep, to the extensor tendons of the thumb.

Its branches may be diminished or increased in number. The radial recurrent may spring from the brachial or ulnar arteries, or may be represented by several branches from the proximal part of the radial. The dorsal artery of the index digit may be large, and may replace the princeps pollicis and the volaris indicis radialis. On the contrary, the dorsal carpal artery and dorsal digital branches of the radial may be small, or the former may be replaced by branches of the metacarpal arteries, and the latter by the proximal perforating branches of the deep volar arch.

The **princeps pollicis** and **volaris indicis radialis** arteries may be absent, their places being taken either by branches of the superficial volar arch or by the dorsalis indicis radialis artery.

The **superficial volar arch** is sometimes absent; its branches are then given off from the deep arch. On the other hand, it may be larger than normal, and it may be completed on the radial side by the volaris indicis radialis, the princeps pollicis, or the comes nervi mediani arteries.

The **deep volar arch** is much more rarely absent than the superficial arch. When absent its branches are supplied by the superficial arch, the proximal perforating arteries, or the volar carpal arch.

ARTERIA ULNARIS.

The **ulnar artery** (Figs. 743 and 744) is the larger terminal branch, but the less direct continuation of the brachial artery. It commences in the cubital fossa, opposite the neck of the radius, and terminates in the palm of the hand, where it anastomoses with the superficial volar artery to form the superficial volar (palmar) arch.

From its origin it runs obliquely, distally and ulnarwards, deep to the muscles arising from the medial epicondyle, to the junction of the proximal and middle thirds of the forearm, where it comes into relation with the ulnar nerve; it then passes directly distally, on the radial side of the ulnar nerve, to the wrist; crosses anterior to the main part of the transverse carpal ligament, on the radial side of the pisiform bone, and enters the palm of the hand to form the main part of the superficial volar (palmar) arch.

Relations—*Dorsal.*—Proximo-distally it lies volar to the distal part of the brachialis, the flexor digitorum profundus, and the transverse carpal ligament. *Volar.*—On its volar aspect it is crossed, in the oblique part of its course, by the pronator teres, the median nerve, which is separated from the artery by the deep head of the pronator teres, the flexor digitorum sublimis, the flexor carpi radialis, and the palmaris longus. In the middle third of the forearm it is overlapped by the volar border of the flexor carpi ulnaris, and in the distal third it is covered by skin and fasciæ only. A short distance proximal to the wrist the palmar cutaneous branch of the ulnar nerve lies volar to it, and as it crosses the transverse carpal ligament, it is bound down by a fascial expansion from the tendon of the flexor carpi ulnaris. Two venæ comites, which frequently communicate with one another, lie one on each side of the artery. On the *radial side* there is also, in

its distal two-thirds, the flexor digitorum sublimis. On its *ulnar side* are the flexor carpi ulnaris and the ulnar nerve.

Branches.—(1) The **volar ulnar recurrent** is a small branch which arises in the cubital fossa, frequently in common with the dorsal ulnar recurrent. It passes proximally, to the anterior aspect of the medial epicondyle, under cover of the pronator teres, and anastomoses with branches of the superior and inferior ulnar collateral arteries.

(2) The **dorsal ulnar recurrent branch**, larger than the volar, arises in the cubital fossa, from the ulnar side of the ulnar artery, and ascends, on the brachialis and under cover of the muscles which arise from the medial epicondyle, to the posterior aspect of that prominence, where it passes between the humeral and olecranoid heads of the flexor carpi ulnaris, and anastomoses with the superior and inferior ulnar collateral arteries. It gives branches to the adjacent muscles and to the elbow-joint.

(3) The **common interosseous artery**, a short trunk which springs from the radial and dorsal aspect of the ulnar artery, in the distal part of the cubital fossa. It passes dorsally, towards the proximal border of the interosseous membrane, and divides into volar and dorsal interosseous branches.

(3*a*) The **volar interosseous artery** runs distally, on the volar surface of the interosseous membrane, between the adjacent borders of the flexor pollicis longus and the flexor digitorum profundus, to the proximal border of the pronator quadratus; there it pierces the interosseous membrane, and continues distally, first on the dorsal surface of the membrane, deep to the extensor pollicis longus and extensor indicis proprius, and then on the dorsal surface of the radius, in the groove for the extensor digitorum communis; and it terminates, on the dorsum of the carpus, by joining the dorsal carpal arch. It is accompanied on the volar aspect of the interosseous membrane by the volar interosseous nerve, and, after it has pierced the membrane, by the dorsal interosseous nerve.

Branches.—(*a*) **Nutrient** to the radius and ulna; (*b*) **Muscular** to the adjacent muscles; (*c*) The **volar communicating**, a slender branch which passes distally, deep to the pronator quadratus and on the volar surface of the interosseous membrane, to anastomose with the volar carpal arch; (*d*) Small **anastomotic branches** are given off, on the dorsum of the forearm, to anastomose with the dorsal interosseous artery; (*e*) The **median artery** (O.T **comes nervi mediani**) is a long slender branch which arises from the proximal part of the volar interosseous artery and runs with the median nerve to the palm, where it anastomoses with recurrent branches of the superficial volar arch.

(3*b*) The **dorsal interosseous artery** is usually smaller than the volar interosseous. It passes dorsally between the proximal border of the interosseous membrane and the oblique cord, and then between the supinator and abductor pollicis longus, after which it runs distally, between the superficial and deep muscles on the dorsum of the forearm, to the wrist. At the wrist it anastomoses with the volar interosseous artery and with the dorsal carpal arch. As it crosses the abductor pollicis longus it is accompanied by the dorsal interosseous nerve, but in the remainder of its course it is separated from the nerve by the deep muscles.

Branches.—(*a*) An **interosseous recurrent** branch is given off at the dorsal margin of the distal border of the supinator. It runs proximally, on the dorsal surface of the supinator, under cover of the anconæus, to the back of the lateral epicondyle of the humerus, where it anastomoses with the posterior terminal branch of the profunda and with branches of the inferior ulnar collateral artery. (*b*) **Muscular branches** to both superficial and deep muscles on the dorsum of the forearm. (*c*) **Cutaneous branches** to the skin on the dorsum of the forearm and the wrist.

(4) The **volar carpal** branch of the ulnar artery is a small branch, given off proximal to the transverse carpal ligament; it passes towards the radial side, deep to the flexor tendons and their sheaths, on the volar surface of the proximal attachments of the volar radio-carpal ligament, and anastomoses with the volar carpal branch of the radial to form the volar carpal arch.

(5) The **dorsal carpal branch** of the ulnar artery arises from the ulnar side of the ulnar artery, immediately proximal to the pisiform bone. It passes dorsally, deep to the ulnar flexor and the ulnar extensor of the carpus, to the dorsum of the carpus, where it unites with the dorsal carpal branch of the radial to form the dorsal carpal arch.

(6) **Profunda.**—This branch passes distally between the abductor and flexor brevis digiti quinti, and, turning towards the radial side, deep to the flexor brevis, the opponens digiti quinti, and the long flexor tendons and their sheaths, it joins the termination of the radial artery to complete the deep volar (palmar) arch.

Abnormalities.—The **ulnar artery** may be absent, being replaced by the median artery or the interosseous artery, and it may terminate in the deep instead of in the superficial volar arch.

It rarely arises more distally than usual, and when it arises at a more proximal point it most commonly passes superficial to the muscles which spring from the medial epicondyle. Moreover, in those cases it frequently has no interosseous branch, the latter vessel springing from the radial artery and in all probability variations of this description are produced by the ulnar artery taking origin from the main trunk, which is represented by the radio-interosseous vessel, at a more proximal level than usual. Even when it commences in the usual way the ulnar artery may pass superficial to the muscles arising from the medial epicondyle, and in those cases its interosseous and recurrent branches spring from the radial artery.

The volar and dorsal interosseous arteries may arise separately from the ulnar instead of by a common interosseous trunk. The recurrent branches of the ulnar may spring from the interosseous, and the interosseous itself may be a branch of the radial.

The small median artery, the companion artery of the median nerve, usually a branch of the volar interosseous, may spring from the axillary, brachial, or ulnar arteries; it may be much larger than usual, and it may terminate either by breaking up into digital branches, or by joining one or more digital branches of the superficial volar arch or the arch itself.

THE ARTERIAL ARCHES OF THE WRIST AND HAND.

The Volar Carpal Arch (Figs. 743 and 744).—The volar carpal arch lies on the volar aspect of the volar carpal ligaments, deep to the long flexor tendons and their synovial sheaths. It is formed by the union of the volar carpal branches of the radial and ulnar arteries, and it receives the communicating branch from the volar interosseous artery and recurrent branches from the deep volar arch. The branches of distribution which pass from it supply the ligaments and synovial membrane of the radio-carpal and intercarpal joints.

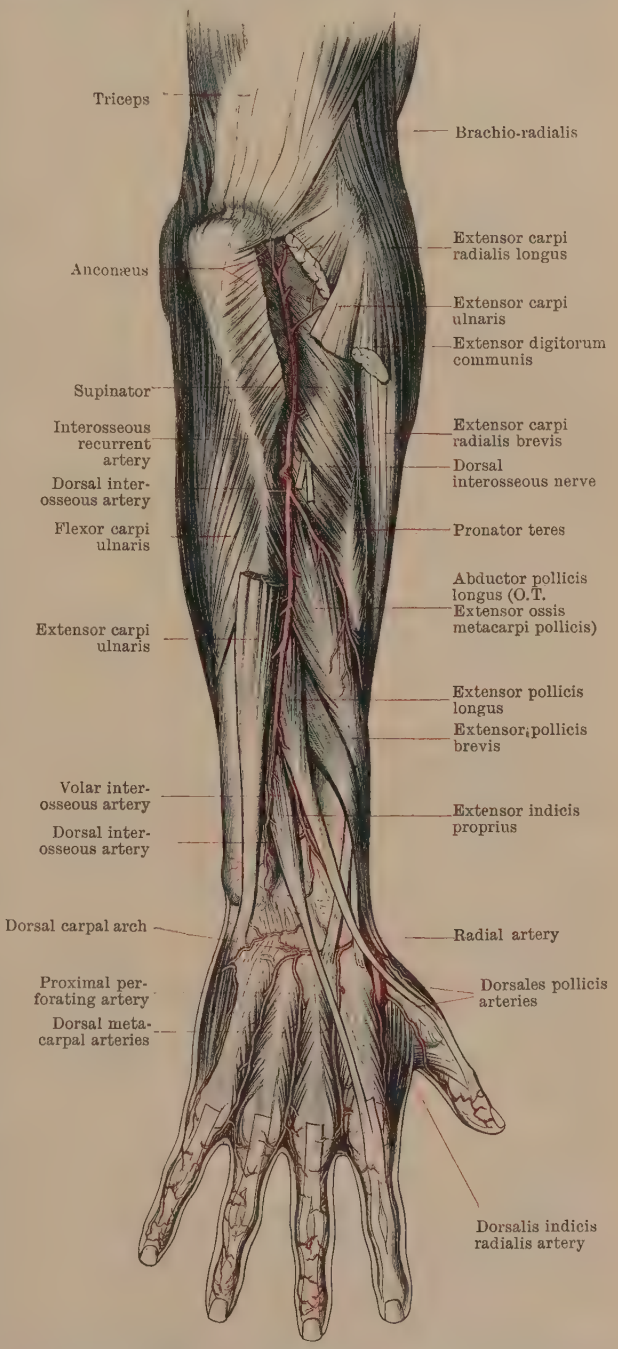

FIG. 745.—THE DORSAL INTEROSSEOUS ARTERY AND THE SECOND PART OF THE RADIAL ARTERY, WITH THEIR BRANCHES.

The Dorsal Carpal Arch (Fig. 745).—This arch lies on the dorsal carpal ligaments deep to the extensor tendons and their sheaths. It is formed by the union of the dorsal carpal branches of the radial and ulnar arteries, and receives the terminations of the volar and dorsal interosseous arteries.

Branches.—(*a*) **Articular** to the adjacent articulations. (*b*) **Dorsal metacarpal**

two slender branches which run distally, along the third and fourth dorsal interosseous muscles, to the clefts of the fingers, where each divides into dorsal digital branches. They communicate near their origins with the deep volar arch by the proximal perforating arteries, and near their terminations with the volar digital vessels through the distal perforating arteries. Their digital terminal branches run distally, on the dorso-lateral aspects of the fingers which bound the third and fourth interosseous spaces, and they anastomose with the special volar digital branches of the volar digital arteries.

The **superficial volar arch** (O.T. **superficial palmar**) (Fig. 743) includes the terminal portion of the ulnar artery, and is usually completed on the radial side by the superficial volar, or by the volaris indicis radialis or the princeps pollicis branches of the radial artery. It extends from the ball of the little finger to the ulnar border of the superficial head of the flexor pollicis brevis, and reaches distally to a line drawn across the palm at the level of the distal border of the fully abducted thumb. It is accompanied by venæ comites and it is covered by the integuments and the central portion of the palmar aponeurosis, and, on the ulnar side of the palm, by the palmaris brevis. It is in contact dorsally with the flexor brevis and opponens digiti quinti, and with the common digital branches of the ulnar and median nerves, as well as with the flexor tendons and the lumbrical muscles.

Branches.—Four **volar common digital arteries** arise from the convexity of the arch. The most ulnar of the four passes along the ulnar border of the little finger, accompanied by the common digital branch of the ulnar nerve; the other three pass distally superficial to the common digital nerves, one along the middle of each of the ulnar three interosseous spaces, towards the interdigital clefts, just proximal to which each common digital artery divides into two **special digital arteries** which supply the contiguous sides of the fingers bounding the cleft. As the special digital branches pass along the sides of the fingers they lie superficial to the corresponding special digital nerves, and supply branches to the joints, to the flexor tendons and their sheaths, and to the skin and subcutaneous tissues on the volar surfaces of the fingers; they give off dorsal branches also which anastomose with the dorsal digital arteries and supply the tissues on the dorsal aspects of the second and terminal phalanges. Some of the dorsally directed branches form a plexus in the matrix of the nail. In the pulp of the finger-tips anastomosing twigs join to form arches from which numerous branches are given off to the skin and subcutaneous fat.

Each of the three most radial special digital arteries is joined, immediately proximal to its division, by a volar metacarpal artery from the deep volar arch and a distal perforating artery from a dorsal metacarpal artery. The most ulnar digital artery is joined by a branch which arises either from the most ulnar volar metacarpal artery or from the deep volar arch.

The **deep volar arch** (O.T. **deep palmar**) (Fig. 744) extends from the base of the metacarpal bone of the little finger to the proximal end of the first interosseous space, and is formed by the terminal part of the radial artery anastomosing with the profunda branch of the ulnar. It is from 12 to 18 mm. (half to three-quarters of an inch) proximal to the level of the superficial volar arch. It lies deeply in the palm, in contact with the proximal ends of the bodies of the metacarpal bones and on the origin of the interossei muscles, and deep to the long flexor tendons and their synovial sheaths.

Branches.—(*a*) The **proximal perforating**: three small arteries which pass dorsally, through the ulnar three interosseous spaces and between the origins of the dorsal interosseous muscles. They anastomose on the dorsum of the hand with the dorsal metacarpal arteries.

(*b*) Small irregular **recurrent branches** pass proximally and unite with the volar carpal arch.

(*c*) The **articular** to the adjacent articulations.

(*d*) The **volar metacarpal arteries** are three vessels which pass distally, on the interosseous muscles of the three ulnar interosseous spaces, deep to the flexor tendons. They terminate by anastomosing with the volar digital arteries just before the latter vessels divide into special volar digital branches.

(*e*) The **communicating**, a small irregular branch which passes ulnarwards between the flexor tendons and the short muscles of the little finger to anastomose with the ulnar volar digital artery.

BRANCHES OF THE DESCENDING THORACIC AORTA.

The branches given off from the thoracic portion of the descending aorta are distributed chiefly to the walls of the thorax and to the thoracic viscera. They contribute also to the supply of the spinal medulla and its membranes, and to that of the vertebral column and of the upper part of the abdominal wall. The branches, which are numerous and for the most part arranged in pairs, are as follows:—

Visceral.
- Bronchial.
- Œsophageal.
- Pericardial.
- Mediastinal.

Parietal.
- Intercostal.
- Subcostal.
- Superior phrenic.
- The vas aberrans.

Visceral Branches of the Descending Thoracic Aorta.

1. The **bronchial branches** of the thoracic aorta are usually two in number—an upper and a lower—and both pass to the left lung. The *upper left bronchial artery* arises from the front of the aorta opposite the fifth thoracic vertebra; the *inferior left bronchial artery* usually takes origin near the lower border of the left bronchus. Both vessels are directed downwards and laterally to the back of the bronchus which they accompany, and, dividing similarly, they follow its ramifications in the lung. They not only supply the walls of the bronchial tubes and the substance of the lungs, but also give branches to the bronchial glands, the pulmonary vessels, the pericardium, and the œsophagus.

As a rule there is only one *right bronchial artery*. It arises either from the first right aortic intercostal artery or from the upper left bronchial artery. More rarely it springs directly from the aorta. In its course and distribution it corresponds to the bronchial arteries of the left side.

Abnormalities.—The **bronchial arteries** obviously correspond to splanchnic arteries and their continuations to diverticula from the walls of the gut; therefore the usual origin of the right bronchial artery from the first right aortic intercostal artery must result from the persistence of an anastomosis between a splanchnic artery and the first part of a somatic intersegmental artery; the origin of the right from the upper left bronchial artery, which sometimes occurs, is due to the fusion of the roots of two splanchnic arteries. The occasional origin of a bronchial vessel from an internal mammary artery can result only from the persistence and enlargement of an anastomosis between a splanchnic artery and the ventral branch of a somatic segmental artery. The origin of a bronchial branch from a subclavian artery may have the same or a different significance on opposite sides of the body. A bronchial artery arising from the left subclavian artery corresponds with the origin of the right bronchial artery from the first aortic intercostal artery; it is due to the persistence of an anastomosis between a splanchnic artery and the root of a somatic intersegmental artery; and the origin of a bronchial artery from a right subclavian artery may be due to a similar cause. It may, on the other hand, be due to the enlargement of an anastomosis between a splanchnic branch of the descending aorta and a splanchnic branch of the fourth right aortic arch. When, as occasionally happens, the bronchial artery arises from the inferior thyreoid, it is due to the persistence and enlargement of an anastomosis between splanchnic arteries.

2. The **œsophageal branches** are variable; usually four or five small branches spring from the front of the aorta and pass forwards to the œsophagus, in the walls of which they ramify, anastomosing above with branches of the left bronchial and inferior thyreoid arteries, and below with œsophageal branches of the left gastric and the phrenic arteries.

3. The **pericardial branches** are three or four small irregular vessels which are distributed on the surface of the pericardium.

4. Small **mediastinal branches** pass to the areolar tissue and glands in the posterior mediastinum, and to the posterior part of the diaphragm.

Parietal Branches of the Descending Thoracic Aorta.

1. **The Intercostal Arteries.**—There are nine pairs of aortic intercostal arteries which usually arise separately from the back of the aorta, but, not uncommonly, a pair may take origin by a common trunk. They are distributed to the lower nine intercostal spaces, to the vertebral column, to the contents

of the vertebral canal, and to the muscles and skin of the back. The first three on each side give branches to the mammary gland also. The arteries of opposite sides closely correspond, but, since the aorta, in the thoracic region, lies on the left of the vertebral column, the right intercostal arteries cross the front of the column, posterior to the œsophagus, the thoracic duct, and the vena azygos, and are longer than the left arteries. In other respects the courses of all the aortic intercostal arteries are almost identical. As each artery runs postero-laterally, across the side of the vertebral column, to an intercostal space, it passes posterior to the pleura, and is crossed, opposite the head of a rib, by the sympathetic trunk. The lower arteries are crossed by the splanchnic nerves also, and those on the left side are crossed by the hemiazygos or accessory hemiazygos veins.

As each artery passes laterally, between the necks of two adjacent ribs, it gives off a posterior branch. Then it ascends to the upper border of the space to which it belongs, and, passing either behind or in front of the corresponding intercostal nerve, is continued along the space, in the costal groove. In the space, as far as the angle of the rib, it lies between the pleura and the posterior intercostal membrane, and, in that part of its course, it is embedded in the endothoracic fascia. Then it is continued forward between the internal and external intercostal muscles. In the costal groove the artery lies between the corresponding vein above and the intercostal nerve below, and it terminates anteriorly by anastomosing with an anterior intercostal branch of the internal mammary or of the musculo-phrenic artery. The lower two intercostal arteries, on each side, extend beyond their spaces into the abdominal wall, and anastomose with branches of the superior epigastric, subcostal, and lumbar arteries. The first right aortic intercostal artery frequently gives off the right bronchial artery.

Branches.—(*a*) The **posterior branch** passes backwards, accompanied by the posterior branch of a spinal nerve, medial to the anterior superior costo-transverse ligament, between the necks of the ribs which bound the space, and between the adjacent transverse processes, to the vertebral groove, where it divides into a medial and a lateral cutaneous terminal branch. The *medial cutaneous branch* passes backwards and medially, either over or through the multifidus, giving branches to the muscles between which it passes and to the vertebral column. The *lateral branch* runs laterally under cover of the longissimus dorsi to the interval between it and the iliocostalis dorsi. It terminates in the skin of the back, after giving branches to the adjacent muscles. Before it divides, each posterior branch gives off muscular branches, and a *spinal branch* which passes through the corresponding intervertebral foramen, and enters the vertebral canal, to the contents and walls of which it is distributed. The spinal branch divides into three branches—neural, post-central, and pre-laminar. The *neural branch* divides into two branches which run medially, on the roots of the spinal nerve; they pierce the dura mater and arachnoid, and divide into branches some of which pass to the membranes of the spinal medulla, whilst others are continued on to reinforce the posterior and anterior spinal arteries. The *post-central branch* divides into ascending and descending branches which, anastomosing with similar branches above and below, form a series of vertical arches on the backs of the bodies of the vertebræ. The arches of opposite sides are connected by short transverse anastomoses. The *pre-laminar branch* is small, and its ascending and descending branches are distributed in a similar though less regular manner on the posterior wall of the vertebral canal.

(*b*) A **collateral branch** arises near the angle of the rib. It descends and runs forward along the lower border of the intercostal space, to anastomose in front with an anterior intercostal branch of the internal mammary or musculo-phrenic artery. The collateral branches of the lower two intercostal arteries, on each side, are inconstant; when present they are small, and terminate in the abdominal wall.

(*c*) **Muscular branches** to the adjacent muscles are given off both by the main trunk and its collateral branch.

(*d*) A **lateral cutaneous** offset accompanies the lateral cutaneous branch of the intercostal nerve.

In addition to the secondary branches above-named, the trunk of the first aortic intercostal, on each side, anastomoses with the superior intercostal, and may supply the whole or the greater part of the second intercostal space. The upper three or four aortic intercostal arteries, on each side, give branches to the mammary gland which anastomose with branches of the lateral thoracic and internal mammary arteries. Longitudinal anastomoses

between adjacent trunks and also between adjacent posterior branches of intercostal arteries sometimes exist near the necks of the ribs, or near the transverse processes. These longitudinal anastomoses are of considerable morphological interest.

2. The **subcostal arteries** are the last pair of parietal branches given off from the thoracic aorta. They are in series with the aortic intercostal arteries, but are situated below the last ribs. Each gives off a posterior branch which behaves in the same manner as the posterior branch of an ordinary aortic intercostal artery. The trunk runs along the lower border of the twelfth rib in company with the last thoracic nerve. It passes below the arcus lumbocostalis lateralis to the abdomen, and there crosses anterior to the quadratus lumborum, and posterior to the kidney and the adjacent part of the colon. It next pierces the aponeurosis of origin of the transversus abdominis, and runs between the transversus and the internal oblique muscles, anastomosing with the lower intercostal arteries, with the lumbar arteries, and with branches of the superior epigastric artery.

Abnormalities.—Variations of the intercostal arteries are not very common, but they are significant and interesting. Corresponding vessels of opposite sides may arise from a common stem which has been formed by the fusion of the roots of two somatic intersegmental arteries after or simultaneously with the fusion of the primitive dorsal aortæ. The number of intercostal arteries may be reduced, one artery supplying two or more intercostal spaces; in these cases the roots of origin of some of the somatic intersegmental arteries in the thoracic region have disappeared, and the precostal anastomoses between their ventral branches have persisted.

Occasionally the number of the aortic intercostal arteries is increased, an additional artery being given to the second intercostal space, which is usually supplied by the superior intercostal artery; this is brought about by the persistence of the root of the tenth somatic intersegmental artery and the disappearance of the precostal anastomosis between the ventral branches of the ninth and tenth somatic intersegmental arteries. Very rarely the first aortic intercostal artery sends a branch upwards between the necks of the ribs and the transverse processes of the upper thoracic region; this branch supplies the upper intercostal spaces, the superior intercostal artery being small or absent, and it terminates by becoming the profunda cervicis artery. It is due to the persistence of the postcostal anastomoses in the upper thoracic region, and is a repetition of a condition regularly present in some carnivores.

There are no very important variations of the œsophageal, pericardial, and mediastinal arteries.

3. **Superior phrenic branches** are given off from the lower part of the thoracic aorta. They are small vessels which ramify on the upper and posterior surfaces of the diaphragm, and anastomose with branches of the pericardiaco-phrenic and musculo-phrenic arteries.

4. The **vas aberrans** is a variable and inconstant branch of the thoracic aorta; it represents the dorsal roots of the fourth and sixth right aortic arches of the embryo. When present it arises from the front and right side of the upper part of the descending aorta near the upper left bronchial artery, and passes upwards and to the right behind the œsophagus; it frequently anastomoses with the right superior intercostal artery, and it may be enlarged and form the first part of the right subclavian artery.

BRANCHES OF THE ABDOMINAL AORTA.

The branches of the abdominal portion of the aorta are distributed almost entirely to the walls and contents of the abdominal cavity, but some supply small branches to the vertebral column, and to the contents of the vertebral canal, and others are prolonged into the pelvis minor. They are divisible into visceral and parietal groups, both of which include paired and single (unpaired) vessels.

- **Visceral.**
  - **Paired.**
    - Suprarenal.
    - Renal.
    - Spermatic or ovarian.
  - **Single.**
    - Cœliac axis.
    - Superior mesenteric.
    - Inferior mesenteric.
- **Parietal.**
  - **Paired.**
    - Inferior phrenic.
    - Lumbar.
    - Common iliac.
  - **Single.** Middle sacral.

The Paired Visceral Branches of the Abdominal Aorta.

1. **Suprarenal Arteries** (Fig. 748).—There are three pairs of **suprarenal arteries**—the superior, middle, and inferior. Of these the middle only arise

directly from the aorta; the superior spring from the inferior phrenic, and the inferior from the renal arteries.

The *middle suprarenal arteries* are two small branches which arise, posterior to the pancreas, from the sides of the aorta, close to the origin of the superior mesenteric artery. They run, one on each side, laterally and upwards, upon the crura of the diaphragm just above the renal arteries, to the suprarenal glands, to which they are distributed. They anastomose with the superior and inferior suprarenal arteries.

2. The **renal arteries** (Fig. 748) arise, one on each side, from the aorta, about 12 mm. (half an inch) below the origin of the superior mesenteric artery and opposite the second lumbar vertebra.

Both arteries are of large size, and the right is frequently slightly lower in position than the left. Each artery runs almost transversely to the hilum of the corresponding kidney. It passes anterior to the crus of the diaphragm and the upper part of the psoas muscle. The left artery lies posterior to the pancreas; the right vessel passes behind the inferior vena cava, the head of the pancreas, and the descending part of the duodenum. The renal vein usually lies below and anterior to the artery, but near the kidney the vein not infrequently occupies a posterior position.

On reaching the hilum of the kidney each artery divides into three branches, two of which pass anterior to the pelvis renalis, and between it and the renal vein, and the third posterior to the pelvis. In the renal sinus these primary branches break up into numerous secondary branches which enter the kidney substance between the pyramids.

Branches.—The following branches are given off by each renal artery, in addition to the terminal branches :—

(*a*) **Inferior suprarenal,** which passes upwards to the lower part of the suprarenal gland.

(*b*) **Ureteral.**—Small branches to the upper part of the ureter, which anastomose with branches of the internal spermatic or ovarian arteries.

(*c*) **Peri-nephric.**—Small branches to the fatty capsule of the kidney, which anastomose with the lumbar arteries.

(*d*) **Glandular offsets,** either from the main trunk or from some of its branches, pass to the lumbar lymph glands.

Abnormalities.—The **renal arteries** frequently deviate from the normal arrangement. The arteries of opposite sides may spring from a common stem, or there may be two or more renal arteries on one or both sides. The accessory arteries are more common on the left than on the right side, and an accessory artery arising below the ordinary vessel is more common than one arising above it.

Accessory renal arteries may be derived not only from the aorta, but also from the common iliac or hypogastric arteries; they have been described as arising also from the inferior phrenic, spermatic, lumbar, or middle sacral arteries, and even from the external iliac artery. As the kidney is developed in the region of the first sacral vertebra, and afterwards ascends to its permanent position, it is not surprising that it occasionally receives arteries from the main stem of more than one of the segments of the body through which it has passed, and it is usually found that the lower the position of the kidney in the abdomen the more likely it is to receive its arteries from the lower part of the aorta or from the common iliac arteries. The accessory renal arteries which spring from the inferior phrenic, the spermatic, and lumbar arteries can only be the result of the persistence and enlargement of anastomosing channels between the renal and either another intermediate visceral, or a somatic artery.

3. The **internal spermatic arteries** are present in both sexes; in the male they are called the **testicular arteries** and in the female **ovarian arteries.** In each sex they are long slender vessels which spring from the front of the aorta a short distance below the origins of the renal arteries.

3*a*. **The Testicular Arteries.**—Each testicular artery runs downwards and forwards, on the anterior surface of the psoas major, to the abdominal inguinal ring, where it comes into relation with the ductus deferens. It accompanies the ductus deferens through the inguinal canal to the testis, to which it is distributed.

Relations—*Posterior.*—The right artery passes in front of the inferior vena cava, and as each artery descends, on the anterior surface of the psoas major, it passes in front of the corresponding genito-femoral nerve and the ureter.

Anterior.—Each artery is in relation anteriorly with the peritoneum to which it is attached; but crossing in front of the right artery and intervening between it and the peritoneum are the third or transverse part of the duodenum, the right colic and the

ileo-colic arteries, the terminal part of the superior mesenteric artery, and the cæcum. Crossing anterior to the left artery are the left colic and sigmoid branches of the inferior mesenteric artery and the iliac colon.

In the lower part of the abdominal portion of its course each testicular artery is accompanied by two veins, which issue from the pampiniform plexus in the inguinal canal and enter the abdomen through the abdominal inguinal ring, but at a higher level the two veins usually fuse into a single stem.

As it enters the inguinal canal each testicular artery passes in front of the inferior epigastric artery, and the lower end of the external iliac artery; and as it runs downwards and medially, in the canal, it is accompanied by the ductus deferens, and is more or less enclosed in the meshes of the pampiniform venous plexus. At the lower end of the canal it passes through the subcutaneous inguinal ring and descends in the scrotum, lying antero-lateral to the ductus deferens and in close association with the anterior group of testicular veins. At the upper end of the testis it breaks up into branches, some of which are distributed to the testis and others to the epididymis.

Branches.—In the abdominal part of its course each testicular artery gives off:—
(*a*) **Ureteral branches,** to the abdominal part of the ureter.
(*b*) **Peri-nephric twigs,** to the peri-nephric fat.
(*c*) **Peritoneal branches,** which are distributed to the peritoneum.
(*d*) **Glandular branches,** which supply blood to the lumbar lymph glands.
Its terminal branches are the **testicular** and **epididymal** twigs already mentioned.

3*b*. **Ovarian Arteries.**—The course and the relations of each ovarian artery, as far as the level of the brim of the pelvis minor, are the same as the relations of the corresponding testicular artery; but at the level of the upper end of the external iliac artery each ovarian artery turns medially, crosses anterior to the upper end of the corresponding external iliac artery and vein, and enters the upper part of the broad ligament of the uterus. In the broad ligament it runs medially, below the uterine tube, to the level of the ovary. There it turns backwards and passes between the layers of the mesovarium, where it breaks up into terminal branches which enter the ovary through the hilum in its anterior border. As it lies in the broad ligament each ovarian artery is accompanied by the pampiniform plexus of ovarian veins. In the lower portion of the abdominal part of its course it is accompanied by two veins, which issue from the pampiniform plexus at the brim of the pelvis minor, and unite at a higher level into a single trunk.

Branches.—(*a*) In the abdominal part of its course the branches of the ovarian artery are the same as those of the testicular artery.
In the pelvic part of its course it gives off:—
(*a*) **Tubal branches,** to the walls of the uterine tube.
(*b*) **Branches** to the round ligament of the uterus.
(*c*) **Uterine branches,** which pass towards the uterus to anastomose with the branches of the uterine artery.

Abnormalities.—The **testicular or ovarian arteries** may be double on one or both sides; the arteries of the two sides may spring from a common trunk, or each may arise from the renal, accessory renal, or suprarenal arteries. The right artery may pass behind instead of in front of the inferior vena cava. The spermatic and ovarian arteries arise from the upper lumbar portion of the aorta, because the testes and ovaries are developed in and obtain their arterial supply in that region, and the vessels are elongated as the testes and ovaries descend to their permanent positions. The occurrence of two spermatic arteries on one side is probably an indication that the testis was developed in two segments of the body. The origin of a spermatic artery from a renal or suprarenal artery is due to the obliteration of the root of the original vessel and the enlargement of an anastomosis between the intermediate visceral arteries of adjacent segments.

The Unpaired or Single Visceral Branches of the Abdominal Aorta.

1. **The cœliac artery** (Figs. 746 and 748) arises from the front of the abdominal aorta, immediately below the aortic orifice of the diaphragm and between its crura. It is a short but wide vessel which runs almost horizontally forwards, for a distance of about 12 mm. (half an inch), and it terminates by dividing into three branches—**the left gastric, the hepatic, and the splenic.**

Abnormalities of the Cœliac Artery.—The **cœliac artery** may be absent, its branches arising separately from the aorta or from some other source. Sometimes it gives off only two branches, usually the left gastric and splenic, and occasionally it gives four branches, the additional branch being either a second left gastric artery or a separate gastro-duodenal artery.

Relations.—As the short trunk lies behind the omental bursa it runs forwards, below the caudate lobe of the liver and above the upper border of the pancreas and the splenic vein. It is surrounded by the cœliac plexus of the sympathetic, and has the right cœliac ganglion to its right side and the left cœliac ganglion to its left side.

Branches.—(*a*) The **left gastric** (O.T. **coronary**) is the smallest branch of the cœliac artery. It runs obliquely upwards and to the left, and reaches the lesser curvature of the stomach close to the œsophagus. It then turns sharply forwards, downwards, and to the right, and runs towards the pyloric end of the stomach to anastomose with the right gastric branch of the hepatic artery. In the first part of its course the artery lies posterior to the omental bursa; it then passes into the left gastro-pancreatic fold, and is continued between the layers of the lesser omentum.

Branches.—(i.) **Œsophageal.**—When the left gastric artery reaches the stomach it gives off an œsophageal branch which passes upwards, on the œsophagus, and breaks up into branches

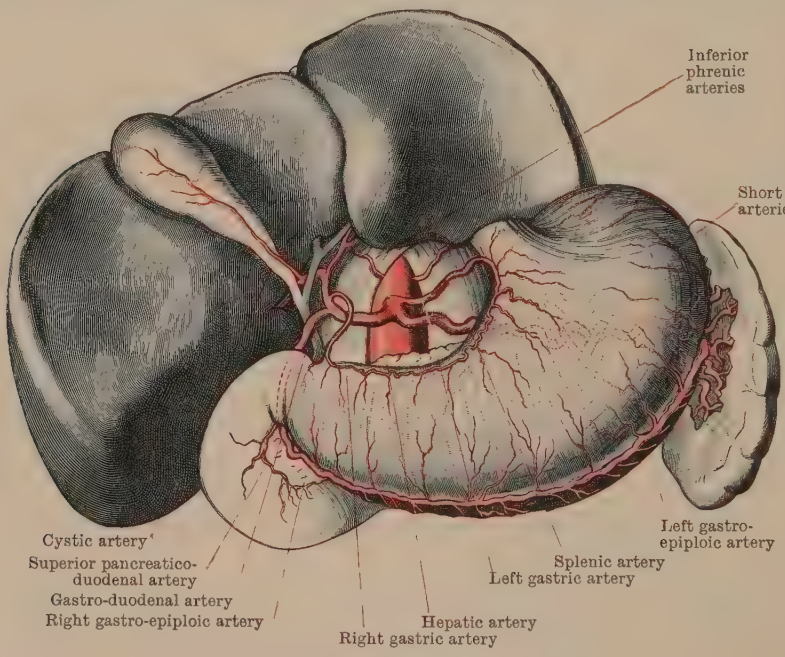

FIG. 746.—THE CŒLIAC ARTERY AND ITS BRANCHES.

which anastomose with œsophageal branches of the thoracic aorta and with branches of the inferior phrenic. (ii.) **Gastric branches** are distributed to both surfaces of the stomach. They anastomose with the short gastric branches of the splenic, and with branches of the gastro-epiploic arterial arch on the greater curvature of the stomach.

Abnormalities.—The **left gastric artery** is occasionally double; it may spring directly from the aorta, and it may give off the left hepatic or an accessory hepatic artery.

(*b*) The **splenic artery** (Fig. 746) is the largest branch of the cœliac artery. It runs a tortuous course behind the stomach and the omental bursa, and along the upper border of the pancreas. It lies anterior to the left suprarenal gland and the upper end of the left kidney, and passes forwards between the two layers of the lieno-renal ligament, in which it divides into from five to eight terminal branches which enter the hilum of the spleen and supply the splenic substance. It is accompanied by the splenic vein, which lies below it.

Abnormalities.—The **splenic artery** may arise from the middle colic, from the left hepatic, or from the superior or inferior mesenteric artery.

Branches.—(i.) **Pancreatic.**—Numerous small branches are given off to the pancreas. A larger branch (pancreatica magna), occasionally present, enters the upper border of the pancreas, about the junction of its middle and left thirds, and runs from left to right in the substance of the pancreas, a little above and posterior to the pancreatic duct. Both

the small and large arteries supply the substance of the pancreas, and anastomose with one another and with branches of the pancreatico-duodenal arteries.

(ii.) The **short gastric branches**, four or five in number, are given off, either from the terminal part of the splenic artery or, more commonly, from some of its terminal branches. They pass between the layers of the gastro-splenic ligament to the left part of the greater curvature of the stomach, and anastomose with the œsophageal, the left gastric, and the left gastro-epiploic arteries.

(iii.) The **left gastro-epiploic branch** arises from the front of the splenic, close to its termination, and passes forwards, between the layers of the gastro-splenic ligament, to the left end of the lower part of the greater curvature of the stomach, along which it is continued, from left to right, between the layers of the greater omentum. It ends by anastomosing with the right gastro-epiploic artery, and it gives off numerous *gastric* branches to both surfaces of the stomach; they anastomose with the short gastric and with branches of the left and right gastric arteries. Long slender *omental* branches pass to the omentum and anastomose with branches of the colic arteries.

(*c*) The **hepatic artery** (Fig. 746) runs along the upper border of the head of the pancreas to the right gastro-pancreatic fold of peritoneum in which it turns forwards to the upper border of the first part of the duodenum. It then passes upwards, between the layers of the hepato-duodenal ligament, anterior to the portal vein and to the left of the bile duct, and reaches the porta hepatis, where it divides into right and left branches.

Abnormalities.—The **hepatic artery** may spring directly from the aorta or from the superior mesenteric artery, and the left hepatic artery arises occasionally from the left gastric artery. Accessory hepatic arteries are not uncommon, and they originate either from the left gastric, superior mesenteric, renal, or inferior mesenteric artery.

Branches.—(i.) The **right gastric artery** is a small branch which arises opposite the upper border of the first part of the duodenum. It runs to the pylorus, between the layers of the lesser omentum, and then turns to the left along the smaller curvature of the stomach. It gives branches to both surfaces of the stomach, and terminates by anastomosing with the left gastric artery.

(ii.) The **gastro-duodenal artery.**—This branch of the hepatic arises just above the upper border of the first part of the duodenum, descends behind it and terminates opposite its lower border. In its course it lies between the neck of the pancreas and the first part of the duodenum, and anterior to the portal vein. The bile duct is on its right side. The vessel ends by dividing into the right gastro-epiploic and the superior pancreatico-duodenal arteries. The **right gastro-epiploic artery** is the larger of the two terminal branches of the gastro-duodenal; it passes from right to left, along the greater curvature of the stomach, between the layers of the greater omentum, and unites with the left gastro-epiploic branch of the splenic artery. From the arterial arch so formed branches pass upwards on both surfaces of the stomach, to anastomose with branches of the right and left gastric arteries. Other branches pass downwards in the greater omentum, and anastomose with branches of the colic arteries. The **superior pancreatico-duodenal artery** runs a short course to the right, between the duodenum and the head of the pancreas, and divides into anterior and posterior terminal branches, which descend, the former in front of and the latter behind the head of the pancreas, to anastomose with similar branches of the inferior pancreatico-duodenal artery. They supply the head of the pancreas, anastomosing in it with the pancreatic branches of the splenic artery; branches are given also to the second part of the duodenum and to the bile duct.

(iii.) **Terminal Branches.**—The **right hepatic artery** passes, either in front of or behind the hepatic duct and behind the cystic duct, to the right end of the porta hepatis; there it divides into two or more branches which enter the substance of the liver and accompany the branches of the portal vein and the hepatic duct. As it crosses above the junction of the hepatic and cystic ducts, the right hepatic artery gives off a cystic branch. The *cystic artery* runs downwards and anteriorly, along the cystic duct, to the gall-bladder, where it divides into anterior and posterior branches; the anterior passes downwards between the gall-bladder and the visceral surface of the liver, to both of which it gives offsets; the posterior branch is distributed on the posterior surface of the gall-bladder, between it and the peritoneum. The **left hepatic artery** is longer and narrower than the right. It runs to the left end of the porta hepatis, gives one or two branches to the caudate lobe, crosses the fossa of the umbilical vein, and breaks up into branches which terminate in the substance of the left lobe of the liver.

2. The **superior mesenteric artery** (Figs. 747 and 748) springs from the front of the aorta, about 12 mm. (half an inch) below the origin of the cœliac artery and opposite the first lumbar vertebra.

It passes obliquely downwards and forwards, crossing anterior to the left renal vein, the uncinate process of the head of the pancreas, and the third or transverse

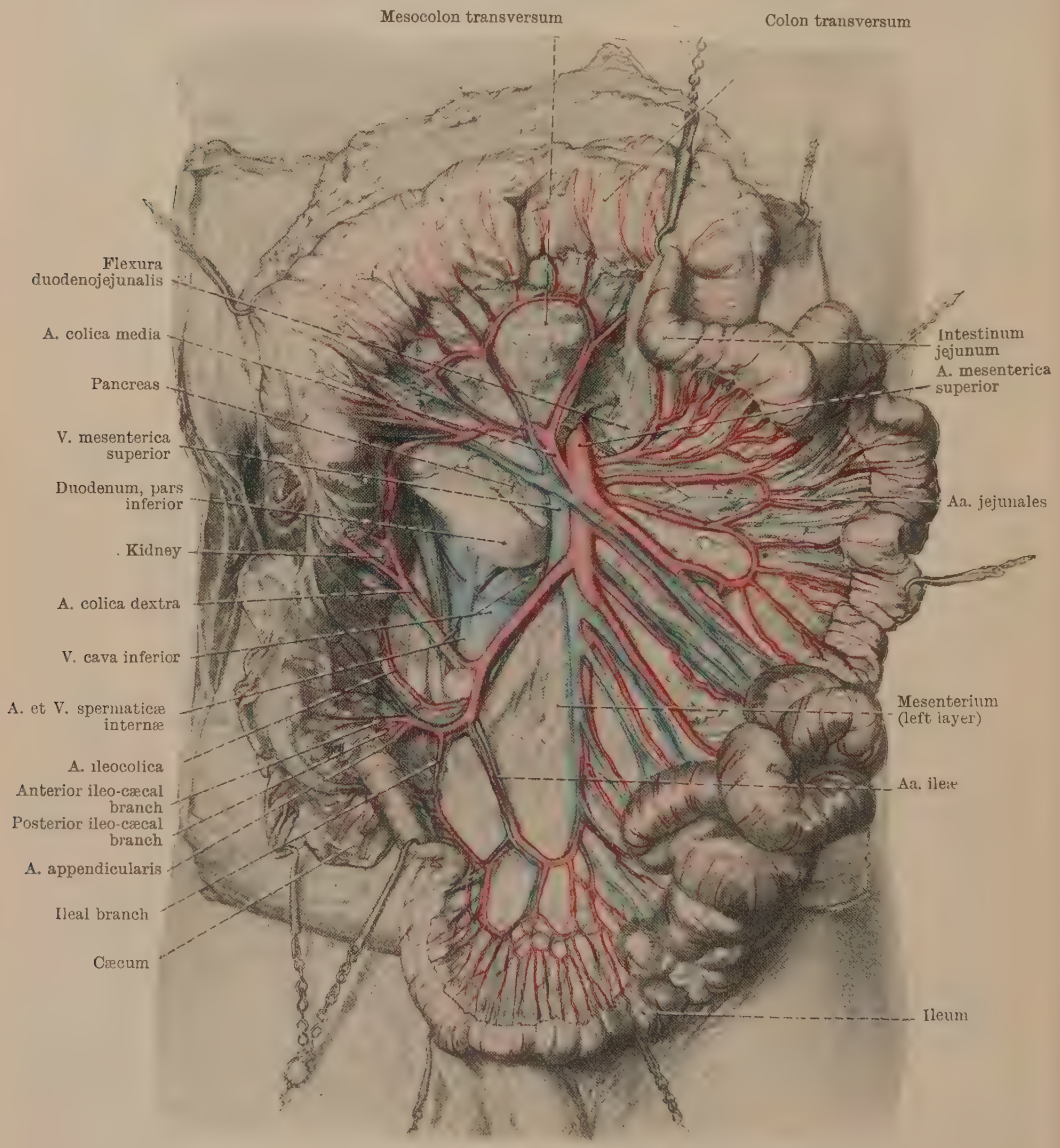

FIG. 747.—THE SUPERIOR MESENTERIC ARTERY AND ITS BRANCHES.

Note the difference in the number and arrangement of the loops formed by the jejunal branches as contrasted with the ileal branches.

part of the duodenum; opposite the latter it enters the root of the mesentery, in which it continues to descend, curving obliquely from above downwards and to the right, to the right iliac fossa, and crossing, in this part of its course, obliquely in front of the aorta, the lower part of the inferior vena cava, the right ureter, and the right psoas major muscle. At its origin it lies posterior to the neck of the pancreas and the splenic vein; where it passes in front of the duodenum it is crossed anteriorly by the transverse colon; and in the lower part of its extent it is behind the coils of small intestine.

Abnormalities.—The **superior mesenteric artery** may be double, and it may supply the whole of the alimentary canal from the second part of the duodenum to the end of the rectum, the inferior mesenteric artery being absent. In addition to its ordinary branches it may give off a hepatic, a splenic, a pancreatic, a gastric, a gastro-epiploic or a gastro-duodenal branch. Very rarely it gives off an omphalo-mesenteric branch, which passes to the region of the umbilicus and becomes connected with capillary vessels in the falciform ligament of the liver.

Branches.—It gives off numerous branches which supply the duodenum and the pancreas in part, the whole of the small intestine below the duodenum, and the large intestine nearly as far as the left colic flexure.

The branches are as follows:—

(*a*) The **intestinal** branches to the small intestine, varying from ten to sixteen in number, are separable into two groups, *jejunal* and *ileal*; they spring from the convexity of the superior mesenteric artery, and pass obliquely forwards and downwards, between the layers of the mesentery, each dividing into two branches which anastomose with adjacent branches to form a series of arcades, from which secondary branches are given off. This process of division and union is repeated three or four times in the case of the ileal arteries; thus four or five tiers of arches are formed, from the most distal of which terminal branches are given off to the walls of the jejunum and ileum. Branches from the successive arcades are also given off to the mesenteric lymph glands. The terminal branches anastomose together in the walls of the gut, forming a vascular network, which communicates above with the inferior pancreatico-duodenal artery and below with the terminal branch of the superior mesenteric trunk. The arterial loops and branches are accompanied by corresponding veins, lymphatics, and nerves.

(*b*) The **inferior pancreatico-duodenal artery**. This branch arises either from the trunk of the superior mesenteric, at the upper border of the third part of the duodenum, or from the first jejunal branch. It runs to the right, between the head of the pancreas and the third part of the duodenum, and terminates by dividing into two branches, anterior and posterior, which ascend, the former in front, and the latter behind the head of the pancreas; they supply the head of the pancreas, the descending and inferior parts of the duodenum, and they anastomose with the similar branches of the superior pancreatico-duodenal artery.

(*c*) The **middle colic artery** is a large branch which springs from the front of the superior mesenteric as it enters the root of the mesentery. It runs downwards and forwards, in the transverse mesocolon, and terminates by dividing into two branches, right and left, which anastomose respectively with the right and left colic arteries, forming arcades. Secondary and tertiary loops are sometimes formed and the terminal branches are distributed to the walls of the transverse colon.

(*d*) The **right colic artery** springs from the right or concave side of the superior mesenteric, either alone or in the form of a common trunk which divides into right colic and ileo-colic branches. It runs to the right, posterior to the peritoneum on the posterior wall of the abdomen, and in front of the right psoas major, the ureter, and the internal spermatic vessels, towards the ascending colon, near which it divides into an ascending and a descending branch. The former passes upwards, and anastomoses, in the transverse mesocolon, with the middle colic artery. The latter descends to anastomose with the upper branch of the ileo-colic, and from the loops thus formed branches are distributed to the walls of the ascending colon and the beginning of the transverse colon.

(*e*) The **ileo-colic artery** arises by a common trunk with the right colic, or separately from the right side of the superior mesenteric, and passes downwards and to the right, behind the peritoneum, towards the lower part of the ascending colon, where it terminates by dividing into an ascending branch which anastomoses with the lower branch of the right colic, and a descending branch which communicates with the colic terminal branches of the superior mesenteric trunk.

(*f*) **Terminal.**—The lower end of the superior mesenteric artery divides into five branches—(i.) ileal, (ii.) appendicular, (iii.) anterior ileo-cæcal, (iv.) posterior ileo-cæcal, and (v.) colic.

The **ileal branch** turns upwards and to the left in the lowest part of the mesentery, and anastomoses with the intestinal arteries. The **appendicular branch** passes behind the terminal portion of the ileum, and through the mesentery of the vermiform process to the vermiform process, upon which it ends. The **anterior ileo-cæcal** crosses the front of the ileo-cæcal junction in a fold of peritoneum; the **posterior ileo-cæcal** crosses the ileo-cæcal junction posteriorly, and the **colic** runs upwards to the ascending colon. The ileo-cæcal branches supply the walls of the cæcum, and, like the colic branch, anastomose with branches of the ileo-colic artery. In some cases the majority or all of the above terminal branches spring from the ileo-colic.

3. The **inferior mesenteric artery** (Fig. 748) arises from the front of the aorta towards the left side, 37 mm. above the bifurcation; it passes downwards and slightly to the left, lying posterior to the peritoneum and anterior to the left psoas major muscle, to the upper and left border of the left common iliac artery, where it becomes the superior hæmorrhoidal.

Abnormalities.—The **inferior mesenteric artery** may give hepatic, renal, or middle colic branches; occasionally it is absent, being replaced by branches of the superior mesenteric, and sometimes, as in ruminants and some rodents, its left colic branch does not anastomose with the middle colic artery.

All these variations of the unpaired visceral branches of the abdominal aorta are merely due to modifications of the usual processes by which the vessels are developed.

The hepatic, splenic, and left gastric arteries may arise directly from the aorta, a condition which is due to the retention of a greater number of the splanchnic arteries than usual. A double superior mesenteric artery results from the persistence of both the right and left splanchnic vessels from which the superior mesenteric artery is formed, these remaining separate instead of fusing together. All the other variations are the results of the obliteration of the usual channels, combined with the enlargement of anastomoses which exist both between the splanchnic arteries of adjacent segments and between the splanchnic and intermediate visceral arteries.

Branches.—(*a*) The **left colic artery** arises from the left side of the inferior mesenteric near its origin, and almost immediately divides into an upper and a lower branch. The *upper branch* runs upwards and to the left towards the left colic flexure, and to the lower pole of the left kidney, where it divides into (i.) a branch which enters the transverse mesocolon, and, turning medially, terminates by joining the left branch of the middle colic artery, and (ii.) a descending branch to the upper part of the descending colon. The *lower branch* passes to the left, behind the peritoneum, and divides into upper and lower divisions; the upper anastomoses with the descending division of the upper branch and supplies the lower part of the descending colon. The lower division supplies the iliac colon, and it anastomoses with the branches of the upper division and with the branches of the sigmoid arteries. Both branches of the left colic artery lie immediately behind the peritoneum, and each branch crosses anterior to the ureter and the internal spermatic vessels.

(*b*) The **sigmoid branches**, usually two in number, arise from the convexity of the inferior mesenteric, and pass downwards and to the left to the lower part of the iliac colon and to the pelvic colon. They lie posterior to the peritoneum, and anterior to the psoas major, the ureter, and the upper part of the iliacus. They terminate by dividing into branches which anastomose with the terminal twigs of the lower branch of left colic above and with branches of the superior hæmorrhoidal below, forming a series of arches from which branches are distributed to the lower part of the iliac colon and the pelvic colon.

(*c*) The **superior hæmorrhoidal artery** is the direct continuation of the inferior mesenteric. It enters the mesentery of the pelvic colon, crosses the front of the left common iliac artery, descends into the pelvis minor as far as the third piece of the sacrum, or, in other words, the junction between the pelvic colon and the rectum, and divides into two branches which pass downwards on the sides of the rectum. Half-way down the rectum each of the two terminal branches of the superior hæmorrhoidal artery divides into two or more branches which pass through the muscular coats and terminate in the submucous tissue, where they divide into numerous small branches which pass vertically downwards, anastomosing with one another, with offsets from the middle hæmorrhoidal branches of the interual iliac arteries, the inferior hæmorrhoidal branches of the internal pudic arteries, and with branches from the middle sacral artery.

The superior hæmorrhoidal artery supplies the mucous membrane of the pelvic colon and the rectum and the muscular coats of the pelvic colon.

Parietal Branches of the Abdominal Aorta.

1. The **inferior phrenic arteries** (Fig. 748), right and left, are of small size; they arise, either separately or by a common trunk, from the aorta, immediately below the diaphragm, to which they are distributed. Diverging from its fellow, each artery runs upwards and laterally, on the corresponding crus of the diaphragm —that on the right side passing posterior to the inferior vena cava, that on the left side posterior to the œsophagus—and just before reaching the central tendon of the diaphragm each divides into medial and lateral terminal branches. The *medial branch* runs forwards, and anastomoses with its fellow of the opposite side, forming an arch, convex forwards, along the anterior border of the central

tendon of the diaphragm. Offsets from this arch anastomose with the pericardiaco-phrenic, musculo-phrenic, and internal mammary arteries. The *lateral branch* passes laterally towards the lower ribs, and anastomoses with the musculo-phrenic and lower intercostal arteries.

In addition to supplying the diaphragm each inferior phrenic artery gives a **superior suprarenal branch**, to the suprarenal gland of its own side, and, occasionally,

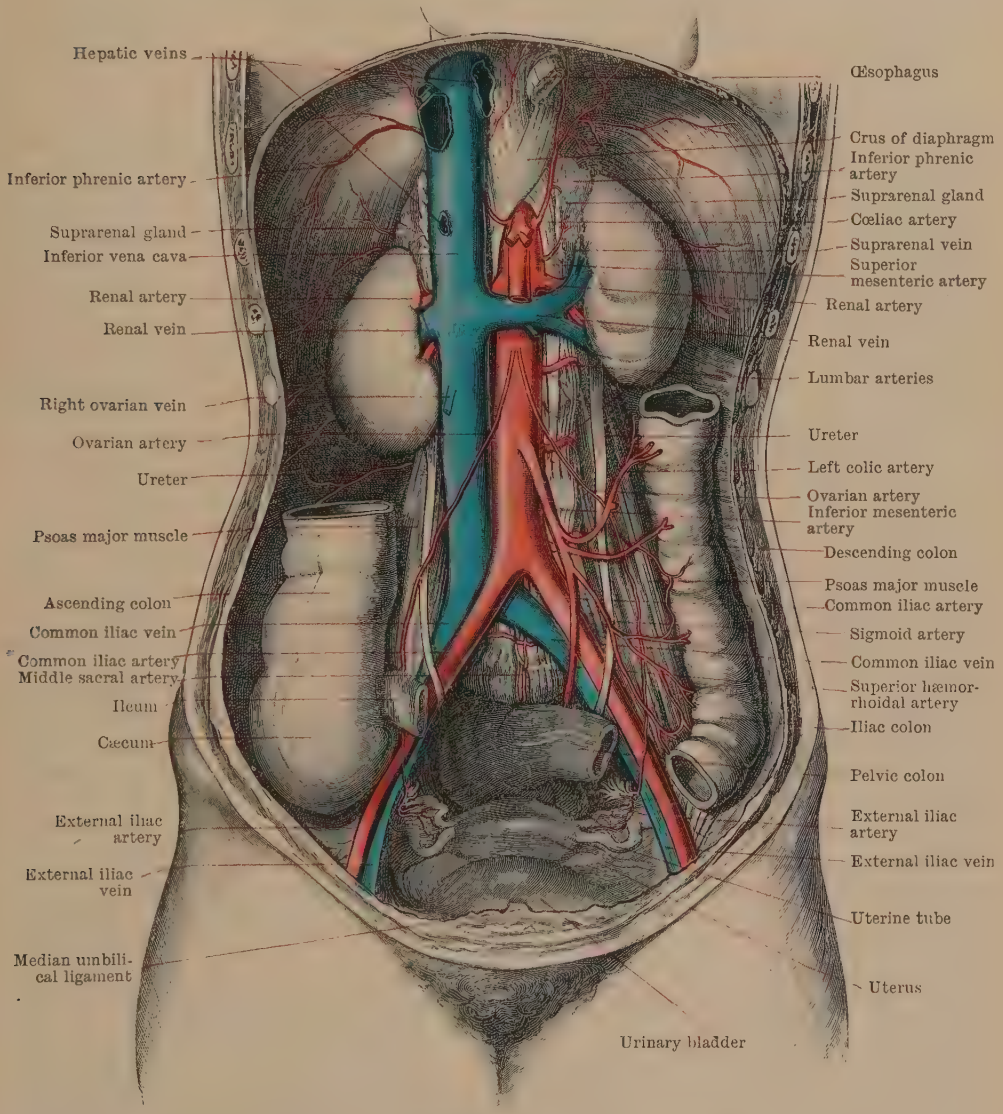

Fig. 748.—The Abdominal Aorta and its Branches.

small hepatic branches which pass through the coronary ligament to the liver. Further, the left artery gives œsophageal branches which anastomose with œsophageal branches of the aorta and of the left gastric artery, whilst from the artery of the right side minute branches pass to the inferior vena cava.

Abnormalities.—The **inferior phrenic arteries** are very variable; they may arise by a common trunk either from the cœliac artery or from the aorta; they may arise separately either from the aorta or from the cœliac artery and more commonly from the latter vessel; or again, one may spring from the aorta or cœliac artery, and the other from the coronary, renal, or even from the superior mesenteric artery.

2. The **lumbar arteries** correspond to the intercostal branches of the

thoracic aorta. They are in series with the intercostal arteries; their distribution is very similar; and, like the intercostals, they arise, either separately or by common trunks, from the posterior aspect of the aorta.

There are usually four pairs of lumbar arteries, but occasionally a fifth pair arises from or in common with the middle sacral artery.

From their origins the lumbar arteries pass laterally and posteriorly, across the front and sides of the bodies of the upper four lumbar vertebræ, to the intervals between the adjacent transverse processes, beyond which they are continued into the lateral part of the abdominal wall.

Each artery lies on the body of the corresponding lumbar vertebra. In its backward course, and while still in relation with the vertebral body, it is crossed by the sympathetic trunk, and then, after passing medial to and being protected by the fibrous arches from which the psoas major muscle arises, it runs behind the muscle and the lumbar plexus. The upper two arteries, on each side, also pass posterior to the crura of the diaphragm. Beyond the interval between the transverse processes of the vertebræ each artery turns laterally and crosses the quadratus lumborum—the last usually passing anterior to, and the others posterior to the muscle; it then pierces the aponeurosis of origin of the transversus, and proceeds forwards in the lateral abdominal wall, in the interval between the transversus and internal oblique muscles. The lumbar arteries anastomose with one another, with the lower intercostal and subcostal arteries, and with branches of the superior and inferior epigastric and of the deep circumflex iliac and ilio-lumbar arteries.

Fine twigs also pass from the lumbar arteries to the extra-peritoneal fat; these anastomose with corresponding branches from the inferior phrenic and ilio-lumbar arteries, and with small branches from the hepatic, renal, and colic arteries, to form the *subperitoneal plexus* of Turner.

The abdominal aorta is almost median in position, consequently the right lumbar arteries are scarcely longer than the left. On the right side the arteries pass behind the inferior vena cava, the upper two arteries being separated from that vessel by the right crus of the diaphragm. The upper two right arteries also pass posterior to the cisterna chyli and the lower end of the azygos vein.

Branches—Dorsal.—Each lumbar artery gives off, opposite the interval between the vertebral transverse processes, a dorsal branch of considerable size. It is analogous with and is distributed like the posterior branch of an aortic intercostal artery (p. 928). **Muscular branches** are given off, both from the main trunk and its dorsal branch, to the adjacent muscles.

Abnormalities. — Variations of the lumbar arteries are very similar to those of the intercostal arteries, and they are due to similar causes. The lumbar arteries of opposite sides may arise by common stems from the back of the aorta; and the last pair of lumbar arteries may arise in common with the middle sacral artery. Further, a lumbar artery may have its area of distribution extended into the adjacent segment.

3. The **middle sacral artery** (Fig. 748) is a single median vessel. It is commonly regarded as a caudal aorta and as the direct continuation of the abdominal aorta. It is, however, of small size, and almost invariably arises from the back of the aorta, about 12 mm. (half an inch) above its bifurcation. It descends, anterior to the lower two lumbar vertebræ and to the sacrum and coccyx, and ends, opposite the tip of the coccyx, by anastomosing with the lateral sacral arteries to form a loop from which branches pass to the coccygeal glomus. Opposite the fifth lumbar vertebra it is crossed, anteriorly, by the left common iliac vein, below which it is covered by peritoneum and coils of small intestine as far as the third segment of the sacrum, and in the rest of its extent it is posterior to the rectum. It is accompanied below by venæ comites, which, however, unite, above, to form a single middle sacral vein.

As it lies anterior to the last lumbar vertebra it gives off on each side a lumbar branch, the *arteria lumbalis ima*, which is distributed like an ordinary lumbar artery, and as it descends in front of the sacrum it distributes small parietal branches laterally which anastomose with the lateral sacral arteries. The

parietal branches usually give off small spinal offsets which enter the anterior sacral foramina. Small and irregular visceral branches pass to the rectum and anastomose with the superior and middle hæmorrhoidal arteries.

Abnormalities.—The **middle sacral artery** usually springs from the back of the aorta above its bifurcation; it may be considerably above, or more rarely it may spring directly from the bifurcation. Not infrequently it arises from the last lumbar artery or from a stem common to the two last lumbar arteries, and occasionally it arises from a common or internal iliac artery. Sometimes it gives off the last pair of lumbar arteries, and, in a few cases, an accessory, renal, or a hæmorrhoidal branch arises from it. The vessel is not always present, it may be double, entirely or in part, and it may bifurcate at its termination.

ARTERIÆ ILIACÆ COMMUNES.

4. The **common iliac arteries** (Figs. 748 and 752) are the terminal branches of the abdominal aorta. They commence opposite the middle of the body of the fourth lumbar vertebra a little to the left of the median plane. Each artery passes downwards and laterally, across the bodies of the fourth and fifth lumbar vertebræ and the intervening intervertebral fibro-cartilage, and it terminates, at the level of the lumbo-sacral articulation and anterior to the corresponding sacro-iliac joint, by dividing into external iliac and hypogastric branches.

The direction of each common iliac is indicated by a line drawn from the bifurcation of the aorta to a point midway between the symphysis pubis and the anterior superior spine of the ilium.

The right artery is a little longer than the left; the former being about 50 mm. (two inches) and the latter 43 mm. (one and three-quarter inches) in length.

Relations—*Anterior.*—Both arteries are covered anteriorly by peritoneum, and are separated by it from coils of the small intestine. Communicating branches between the aortic and hypogastric plexuses of the sympathetic pass in front of the arteries, each of which is often crossed, anteriorly, near its termination by the corresponding ureter.

The left artery is crossed, in addition, by the superior hæmorrhoidal vessels.

Posterior.—Behind the artery, of each side, are the bodies of the fourth and fifth lumbar vertebræ, and the intervening intervertebral fibro-cartilage, the sympathetic trunk, and the psoas major muscle. These relationships, however, are much closer on the left side than on the right. The right common iliac, except at its lower end, where it is in contact with the psoas major, is separated from the structures named by the terminations of the right and left common iliac veins and the commencement of the inferior vena cava. The left common iliac, which is not so separated, lies on the medial border of the psoas major. Somewhat deeply placed, in the areolar tissue between the psoas major and the lumbar vertebræ, are the obturator nerve, the lumbo-sacral trunk, and the ilio-lumbar artery, which form posterior relations to the common iliac artery of the corresponding side.

Lateral.—The lateral relations of each artery are coils of small intestine, and the commencement of the inferior vena cava lies to the lateral side of the upper part of the right artery.

Medial.—On the medial side of the right common iliac artery are the right common iliac vein, below, and the left common iliac vein, above. The last-named vein lies on the medial side of the left common iliac artery.

Branches.—The external iliac and the hypogastric are the only branches.

Abnormalities.—The **common iliac artery** may be longer or shorter than usual, a modification which is determined largely, though not altogether, by the point at which the bifurcation of the aorta takes place. If exceptionally long, it is usually tortuous. In rare cases in man the artery is absent. It occasionally gives off the middle or a lateral sacral artery, and ilio-lumbar, spermatic, or accessory renal branches may arise from it.

ARTERIA HYPOGASTRICA.

The **hypogastric artery** (O.T. **internal iliac**) (Figs. 748, 749, and 752) in the fœtus is the direct continuation of the common iliac trunk. It supplies numerous branches to the pelvis, runs upwards on the anterior abdominal wall to the umbilicus as the umbilical artery, and is prolonged through the umbilical cord to the placenta. One of its pelvic branches—the inferior gluteal (O.T. sciatic)—is

at first the main artery of the inferior extremity, but subsequently another branch is given off which becomes the chief arterial trunk of the lower limb. This branch is the external iliac artery; it soon equals and ultimately exceeds the hypogastric in size, and it is into these two vessels that the common iliac appears to bifurcate.

When the placental circulation ceases and the umbilical cord is severed, the umbilical part of the hypogastric trunk which extends from the pelvis minor to the umbilicus atrophies, and is afterwards represented almost entirely by a fibrous cord, known as the obliterated umbilical artery. It is only at its proximal end that the atrophied part remains pervious, and there it forms the commencement

9. Superficial perineal artery.
10. Artery to the bulb of the vestibule.

of the superior vesical artery. The permanent hypogastric is a comparatively short vessel. Owing to the arrangement of some of its branches it appears to end in an anterior and a posterior division, the former of which is to be regarded as the continuation of the vessel, whilst the latter is simply a common stem of origin for some of the branches.

With this explanation the artery may be described in the usual manner.

It arises from the common iliac opposite the sacro-iliac articulation and at the level of the lumbo-sacral articulation, and descends into the pelvis minor, to terminate, as a rule, opposite the upper border of the greater sciatic notch, in two divisions—anterior and posterior—from each of which branches of distribution are given off. The artery measures about 37 mm. (one and a half inches) in length.

Relations—*Anterior.*—Each hypogastric artery is covered antero-medially by

peritoneum, behind which the corresponding ureter descends along the anterior border of the artery. The pelvic colon crosses from the front to the medial side of the left artery, and the terminal part of the ileum bears the same relation to the right artery.

Posterior to it are the hypogastric vein and the commencement of the common iliac vein; still more posteriorly are the lumbo-sacral trunk and the sacro-iliac joint.

Lateral.—On its lateral side the external iliac vein separates it from the psoas major muscle, above. At a lower level the obturator nerve, embedded in a mass of fat, intervenes between the hypogastric artery and the lateral wall of the pelvis. On its medial side it is crossed by some of the tributaries of the hypogastric vein, and it is covered by peritoneum.

Branches.—The hypogastric artery supplies the greater part of the pelvic wall and contents, and its branches are distributed also to the buttock and thigh and to the external organs of generation.

All the branches may be given off separately from a single undivided parent trunk, but as a rule they arise in two groups corresponding to the two divisions in which the artery, under these circumstances, appears to end.

- **Posterior division**
  - **parietal**
    - Ilio-lumbar
    - Lateral sacral
    - Superior gluteal
- **Anterior division**
  - **parietal**
    - Obturator
    - Inferior gluteal
    - Internal pudendal
  - **visceral**
    - Umbilical
      - (Superior vesical)
    - Inferior vesical
    - Middle hæmorrhoidal.

In the female two additional branches are present—a *uterine* and a *vaginal.*

Branches of the Posterior Division.

The posterior terminal division gives off the ilio-lumbar and lateral sacral arteries, and is continued as the superior gluteal artery.

1. The **ilio-lumbar artery** runs upwards and laterally, across the upper margin of the pelvis minor, to the iliac fossa. It passes anterior to the sacro-iliac articulation, between the lumbo-sacral trunk and the obturator nerve, and posterior to either the lower part of the common or the upper part of the external iliac vessels, and the psoas and iliacus muscles.

In the iliac fossa it divides into an iliac and a lumbar branch. The **iliac branch** anastomoses with branches of the deep circumflex iliac and obturator arteries, it gives offsets to the iliacus, and supplies a large nutrient branch to the ilium. A **lumbar branch** ascends, behind the psoas major, to the crest of the ilium. It supplies the psoas and quadratus lumborum, and anastomoses with the lumbar and deep circumflex iliac arteries; it also gives off a *spinal branch,* which enters the intervertebral foramen between the fifth lumbar vertebra and the sacrum, and is distributed like the spinal branches of the lumbar and the aortic intercostal arteries.

2. **Lateral Sacral Arteries.**—There is sometimes only a single **lateral sacral artery** on each side; more commonly there are two, **superior** and **inferior.**

Both run downwards and medially, on the front of the sacrum. The inferior passes anterior to the piriformis and the sacral nerves, and descends, on the lateral side of the sympathetic trunk, to the coccyx, where it terminates by anastomosing with the middle sacral. The superior branch reaches only as far as the first or the second anterior sacral foramen; then it enters the sacral canal. It anastomoses with the lower branch and with the middle sacral artery. Branches are given off by the lateral sacral arteries to the piriformis, and to the sacral nerves. Spinal offsets are also given off, which pass through the anterior sacral foramina to the sacral canal; they supply the membranes of the spinal medulla, the roots of the sacral nerves, and the filum terminale, and anastomose with other spinal arteries. They

then pass through the posterior sacral foramina, and anastomose on the back of the sacrum with branches of the superior and inferior gluteal arteries.

3. **The Superior Gluteal Artery** (Figs. 751 and 755).—After giving off the ilio-lumbar and lateral sacral branches, the posterior division of the hypogastric artery is continued as the **superior gluteal artery.** This is a large vessel which pierces the pelvic fascia, and passes backwards, between the lumbo-sacral trunk and the first sacral nerve. It leaves the pelvis through the upper part of the greater sciatic foramen, above the piriformis muscle, and enters the buttock, where it divides, under cover of the glutæus maximus and between the adjacent borders of the piriformis and glutæus medius muscles, into superficial and deep branches.

(*a*) The **superficial branch** divides at once into numerous rami, some of which supply the glutæus maximus, whilst others pass through it, near its origin, to the overlying skin. The branches freely anastomose with branches of the inferior gluteal, internal pudendal, medial circumflex, deep circumflex iliac, and lateral sacral arteries.

(*b*) The **deep terminal branch**, accompanied by the superior gluteal nerve, runs forwards between the glutæus medius and minimus, and, after giving a nutrient branch to the ilium, subdivides into upper and lower branches. The *upper branch* runs forwards along the origin of the glutæus minimus from the anterior curved line of the ilium, and passes beyond the anterior margins of the glutæus medius and minimus to anastomose, under cover of the tensor fasciæ latæ, with the ascending branch of the lateral circumflex artery. It anastomoses with the deep circumflex iliac artery also, and it supplies muscular branches to the adjacent muscles. The *lower branch* passes more directly forwards, across the glutæus minimus, towards the trochanter major, along with the branch of the superior gluteal nerve which supplies the tensor fasciæ latæ. It supplies the gluteal muscles, and anastomoses with the ascending branch of the lateral circumflex artery.

Before leaving the pelvis the gluteal artery gives **muscular branches** to the pelvic diaphragm and the obturator internus, small **neural branches** to the roots of the sacral plexus, and **nutrient branches** to the hip-bone.

Branches of the Anterior Division.

The anterior division gives off both parietal and visceral branches, and is continued as the umbilical artery. The parietal branches are the obturator, the internal pudendal, and the inferior gluteal. The visceral branches include the superior and inferior vesical, and the middle hæmorrhoidal arteries in the male. In the female the anterior division of the hypogastric artery gives off similar visceral branches, and, in addition, a uterine and a vaginal branch.

Visceral Branches.

1. **The superior vesical artery** arises from the incompletely obliterated posterior part of the umbilical artery, as it lies at the side of the bladder. It passes medially to the upper part of the urinary bladder and divides into numerous branches which anastomose with the other vesical arteries, and it also gives small branches to the urachus, and often to the lower part of the ureter. It may in addition give off a middle vesical branch, and not infrequently the long slender *artery to the ductus deferens* arises from it.

2. **The Umbilical Artery.**—Atrophy of that portion of the **umbilical artery** which extends from the anterior division of the hypogastric to the umbilicus has already been referred to. The atrophy is complete between the umbilicus and the origin of the superior vesical artery, but between that origin and the apparent ending of the hypogastric in its two divisions it is incomplete, and the lumen of the vessel, though greatly diminished in size, remains patent. It is from the incompletely obliterated portion that the superior vesical artery arises. The completely obliterated part of the umbilical artery is reduced to a fibrous cord which runs along the side of the bladder to its apex, and then ascends, on the posterior surface of the anterior abdominal wall, to the umbilicus. In the latter part of its course it is known as the **ligamentum umbilicale laterale.** As it passes along the wall of the pelvis it is external to the peritoneum, and it is crossed by the ductus deferens in the male, and by the round ligament in the female.

3. The **inferior vesical artery** runs medially, upon the upper surface of the levator ani, to the base of the bladder. It also gives branches to the seminal vesicles, the ductus deferens, the lower part of the ureter and the prostate, and it anastomoses with its fellow of the opposite side, with the other vesical arteries, and with the middle hæmorrhoidal artery.

4. **Arteria Deferentialis.**—The **artery to the ductus deferens** may arise from either the superior vesical or the inferior. It is a long slender vessel which accompanies the ductus deferens to the testis, where it anastomoses with the testicular artery. It also anastomoses with the external spermatic branch of the inferior epigastric artery.

5. The **middle hæmorrhoidal artery** is an irregular branch which arises either directly from the anterior division of the internal iliac or from the inferior vesical branch; more rarely it springs from the internal pudendal artery. It runs medially, and is distributed to the muscular coats of the rectum; it also gives branches to the prostate, the seminal vesicle, and the ductus deferens, and it anastomoses with its fellow of the opposite side, with the inferior vesical, and with the superior and inferior hæmorrhoidal arteries.

6. The **vaginal artery** may arise either directly from the anterior division of the hypogastric or from a stem common to it and the uterine artery, and it may be represented by several branches.

It runs downwards and medially, on the floor of the pelvis, to the side of the vagina, and divides into numerous branches which ramify on the anterior and posterior walls of the passage. The corresponding branches of opposite sides anastomose and form anterior and posterior longitudinal vessels, the so-called *azygos arteries*. They also anastomose above with the cervical branches of the uterine artery, and below with the perineal branches of the internal pudendal. In addition to supplying the vagina, small branches are given to the bulb of the vestibule, to the base of the bladder, and to the rectum.

7. The **uterine artery** arises from the anterior division of the internal iliac, either separately or in common with the vaginal or middle hæmorrhoidal arteries. It runs medially and slightly forwards, upon the upper surface of the levator ani, to the lower border of the broad ligament, between the two layers of which it passes medially, and arches above the ureter about three-quarters of an inch from the uterus. It passes above the lateral fornix of the vagina to the side of the neck of the uterus, and then ascends towards the fundus, but at the level of the uterine tube it turns laterally, below the tube and between the layers of the broad ligament, and anastomoses with the ovarian artery. It supplies the uterus, the upper part of the vagina, the medial part of the uterine tube, and gives branches to the round ligament of the uterus. It anastomoses with its fellow of the opposite side, and with the vaginal, the ovarian, and the inferior epigastric arteries, along the round ligament of the uterus.

Parietal Branches of the Anterior Division.

1. The **obturator artery** (Figs. 749 and 752) runs anteriorly and downwards along the lateral wall of the pelvis minor, just below its upper margin, to the obturator foramen, through the upper part of which it passes. It terminates, immediately on entering the thigh, by dividing into anterior and posterior terminal branches, which skirt round the margin of the obturator foramen deep to the obturator externus muscle. It is accompanied, in the whole of its course, by the obturator nerve and vein, the nerve being above the artery and the vein below it.

To its lateral side is the pelvic fascia, which intervenes between it and the upper part of the obturator internus muscle, whilst on its medial side it is covered by peritoneum. The ureter intervenes between the posterior part of the artery and the peritoneum. When the bladder is distended it also comes into close relation with the lower and anterior part of the artery. In the female the ovarian vessels and the broad ligament form the medial relations of the obturator artery.

Branches.—All the branches except the terminal are given off before the artery leaves the pelvis. They include:—(*a*) **Muscular branches** to the obturator internus,

levator ani and ilio-psoas muscles. (*b*) A **nutrient branch** to the ilium, which passes deep to the ilio-psoas muscle, supplies the bone, and anastomoses with the ilio-lumbar artery. (*c*) A **vesical branch** or branches pass medially to the bladder beneath the lateral false ligament. (*d*) A **pubic branch** ascends on the posterior surface of the pubis, and anastomoses with its fellow of the opposite side and with the pubic branch of the inferior epigastric. It is given off just before the artery leaves the pelvis, and, in its upward course, it may pass either on the lateral or medial side of the external iliac vein, whilst not infrequently it runs on the medial side of the femoral ring. In the latter case it is important in relation to femoral hernia; this importance is emphasised when, as sometimes happens, the obturator artery arises as an enlarged pubic branch of the inferior epigastric artery instead of from the hypogastric. (*e*) **Terminal.**—The *anterior terminal branch* runs forwards, and the *posterior* backwards around the margin of the obturator foramen. They lie on the obturator membrane, under cover of the obturator externus, and they anastomose together at the lower margin of the foramen. Both give off offsets which anastomose with the medial circumflex artery, and twigs of supply to the adjacent muscles. The posterior branch also gives an acetabular branch to the hip-joint, which passes upwards, through the acetabular notch on the medial side of the transverse ligament, to supply the ligamentum teres and the head of the femur.

2. The **internal pudendal artery** (Figs. 749 and 750) arises from the anterior division of the hypogastric, close to the origin of the inferior gluteal artery, which slightly exceeds it in size. It runs downwards and backwards, to the lower part of the greater sciatic foramen, lying anterior to the piriformis muscle and the sacral plexus, from both of which it is separated by the pelvic fascia. At the lower border of the piriformis it pierces the pelvic fascia, passes between the piriformis and coccygeus muscles, and leaves the pelvis to enter the buttock. It is accompanied by venæ comites, the inferior gluteal vessels and nerves, the pudendal nerve, and the nerve to the obturator internus. In the buttock it lies on the spine of the ischium, under cover of the glutæus maximus, and between the pudendal nerve and the nerve to the obturator internus, the former being medial to it. It next passes through the lesser sciatic foramen and enters the perineum, in the anterior part of which it terminates by dividing into the profunda artery of the penis and the dorsal artery of the penis.

In the first part of its course *in the perineum* the artery lies in the lateral fascial wall of the ischio-rectal fossa, where it is enclosed in a canal in the fascia (Alcock's canal). This canal, which is situated about one and a half inches above the lower margin of the tuberosity of the ischium, contains also the pudendal veins and the terminal parts of the pudendal nerve, viz., the dorsal nerve of the penis, which lies above the artery, and the perineal division, which lies below the vessel. From the ischio-rectal fossa the internal pudendal artery is continued forwards between the two layers of the fascia of the urogenital diaphragm (O.T. triangular ligament of the urethra), and close to the ramus of the pubis. About half-an-inch below the arcuate ligament it turns somewhat abruptly forwards, pierces the inferior fascia of the urogenital diaphragm, and immediately divides into its terminal branches, viz., the profunda artery and the dorsal artery of the penis. The division sometimes takes place whilst the artery is still between the layers of the urogenital diaphragm.

Branches.—*In the pelvis* it gives small branches to the neighbouring muscles and to the roots of the sacral plexus.

In the buttock.—(*a*) **Muscular branches** are distributed to the adjacent muscles. (*b*) **Anastomotic branches** unite with branches of the superior and inferior gluteal, and medial circumflex arteries.

In the ischio-rectal fossa.—(*c*) The **inferior hæmorrhoidal artery** pierces the wall of the fascial canal, and runs obliquely forwards and medially. It soon divides into two or three main branches, which may arise separately from the pudendal; they pass across the space to the anal passage. The artery anastomoses in the walls of the anal passage with its fellow of the opposite side, and with the middle and superior hæmorrhoidal arteries; it anastomoses with the transverse perineal arteries also; and it supplies cutaneous twigs to the region of the anus, and others, which turn round the lower border of the glutæus maximus, to supply the lower part of the buttock.

(*d*) The **perineal artery** arises in the anterior part of the ischio-rectal fossa, pierces the base of the fascia of the urogenital diaphragm, and divides into long slender *posterior scrotal branches* in the male, and *posterior labial branches* in the female. Those branches are continued forwards, in the urethral triangle, to the scrotum or labium, deep to the superficial perineal fascia. They anastomose with their fellows of the opposite side, with the transverse perineal and the external pudendal arteries, and supply the muscles and subcutaneous structures of the urethral triangle.

(*e*) The **transverse perineal artery** is a small branch which arises either directly from the internal pudendal or from its perineal branch. It runs medially along the base of the fascia of the urogenital diaphragm (O.T. triangular lig.) to the central point of the perineum, where it anastomoses with its fellow of the opposite side, with the perineal artery, and with the inferior hæmorrhoidal arteries. It supplies the sphincter ani, the bulbo-cavernosus or sphincter vaginæ, and the anterior fibres of the levator ani.

In the urethral triangle.—(*f*) The **artery to the bulb**, a branch which is usually of

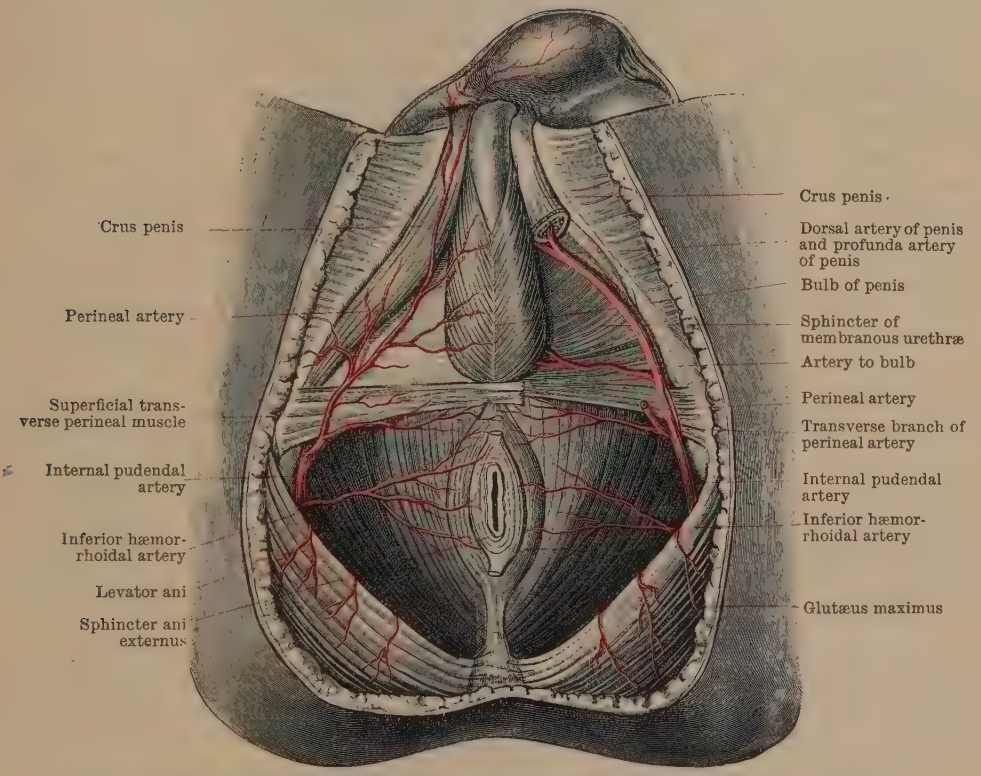

FIG. 750.—THE PERINEAL DISTRIBUTION OF THE INTERNAL PUDENDAL ARTERY IN THE MALE.

relatively large size, is given off between the fascial layers of the urogenital diaphragm. It runs transversely along the posterior border of the sphincter of the membranous urethræ, and then, turning forwards a short distance from the side of the urethra, it pierces the inferior fascia of the urogenital diaphragm and enters the substance of the bulb. It passes onwards in the corpus cavernosum urethræ to the glans, where it anastomoses with its fellow and with the dorsal arteries of the penis.

It supplies the sphincter of the membranous urethræ, bulbo-urethral gland (Cowper), the corpus cavernosum urethræ, and the penile part of the urethra. In the female this artery supplies the bulb of the vestibule.

(*g*) The **profunda artery of the penis** (O.T. **artery of the corpus cavernosum**) in the male, and **of the clitoris** in the female, is usually the larger of the two terminal branches. Immediately after its origin it enters the crus penis, and runs forwards in the corpus cavernosum penis, which it supplies.

(*h*) The **dorsal artery of the penis** in the male, and **of the clitoris** in the female, passes forwards between the layers of the suspensory ligament, and runs along the dorsal surface of the penis, with the dorsal nerve immediately to its lateral side, whilst it is separated from its fellow of the opposite side by the deep dorsal vein, which lies

in the median plane. It supplies the superficial tissues on the dorsal aspect of the penis, sends branches into the corpus cavernosum penis to anastomose with the profunda artery of the penis, and its terminal branches enter the glans penis, where they anastomose with the arteries to the bulb. It anastomoses also with the external pudendal branches of the femoral.

3. The **inferior gluteal artery** (O.T. **sciatic**) (Figs. 751 and 755) arises from the hypogastric artery, either separately or by a common trunk with the internal pudendal artery. It descends a little postero-lateral to the internal pudendal vessels, pierces the pelvic fascia, runs backwards between the first and second, or second and third sacral nerves, and, passing between the piriformis and coccygeus muscles, leaves the pelvis through the lower part of the greater sciatic foramen, and enters the buttock just below the piriformis. In the buttock it descends posterior and to the medial side of the sciatic nerve deep to the glutæus maximus, and posterior to the obturator internus, the two gemelli, the quadratus femoris, and upper part of the adductor magnus muscles, to the proximal part of the thigh.

Below the lower border of the glutæus maximus the artery is comparatively superficial, and having given off its largest branches, it runs distally, as a long slender vessel, with the posterior femoral cutaneous nerve.

Branches—*In the pelvis.*—Small and irregular branches supply the adjacent viscera and muscles and the sacral nerves; they anastomose with branches of the internal pudendal and lateral sacral arteries.

In the buttock.—(*a*) **Muscular branches** are given off to the muscles of the buttock and to the proximal parts of the hamstring muscles. They anastomose with the internal pudendal, medial circumflex, and obturator arteries. (*b*) The **coccygeal branch** arises immediately after the artery leaves the pelvis. It runs medially, pierces the sacro-tuberous ligament and the glutæus maximus, and ends in the soft tissues over the posterior aspect of the lower part of the sacrum and of the coccyx. It gives several branches to the glutæus maximus, and anastomoses with branches of the gluteal and lateral sacral arteries. (*c*) An **anastomotic branch** passes laterally, superficial or deep to the sciatic nerve, towards the greater trochanter of the femur. It anastomoses with branches of the gluteal, internal pudendal, medial and lateral circumflex, and the first perforating arteries, taking part in the formation of the so-called "crucial anastomosis." (*d*) **Cutaneous branches**, accompanying twigs of the posterior cutaneous nerve of the thigh, pass round the lower border of the glutæus maximus muscle to the integument. (*e*) The **a. comitans n. ischiadici** is a long slender branch which runs distally on the surface, or in the substance of the sciatic nerve. It supplies the nerve, and anastomoses with the perforating arteries and with the termination of the profunda femoris artery.

Abnormalities.—The **hypogastric artery** varies as regards length. It is usually longer, and arises at a higher level when the common iliac is short. In rare cases it has been found to arise from the aorta without the intervention of a common iliac. Frequently it does not, even in appearance, end in anterior and posterior divisions, but obviously forms a single trunk, as in the fœtus, from which the several branches are given off.

The visceral branches vary much in number and size, and the middle hæmorrhoidal may not be present, its place being taken by branches from the vesical arteries. A renal branch sometimes arises from the hypogastric artery.

The ilio-lumbar branch may arise from the common iliac instead of from the hypogastric artery; the superior gluteal and inferior gluteal arteries may arise by a common stem, or the superior gluteal may be absent, and its place taken by a branch from the femoral artery; the inferior gluteal artery may, as in the fœtus, constitute the main artery of the lower limb, and run distally to become continuous with the popliteal artery. Probably the arteria comitans nervi ischiadici represents the original continuity of the two vessels. Occasionally the lateral sacral arteries do not arise from the hypogastric trunks.

In some instances the **obturator artery** arises from the inferior epigastric artery instead of from the hypogastric. The condition is apparently due to obliteration of the usual origin of the obturator artery and to the subsequent enlargement of the anastomosing pubic branches of the obturator and inferior epigastric arteries. The course of the abnormal obturator artery is of importance. From its origin it descends into the pelvis minor, on the medial side of the external iliac vein, and in the majority of cases on the lateral side of the crural ring, but in three-tenths of the cases, and more frequently in males than in females, it descends on the medial side of the ring.

The obturator artery sometimes gives off an accessory pudendal branch which passes along the side of the prostate, pierces the urogenital diaphragm, and terminates by dividing into the profunda artery of the penis and the dorsal artery of the penis. When this occurs the internal pudendal artery is small, and it terminates in the artery to the bulb. Occasionally the accessory pudendal arises from the internal pudendal artery in the pelvis, or from one of the vesical arteries.

ARTERIES OF THE INFERIOR EXTREMITY.

The main artery of each lower limb is continued from the corresponding common iliac artery. It descends as a single trunk as far as the lower border of the

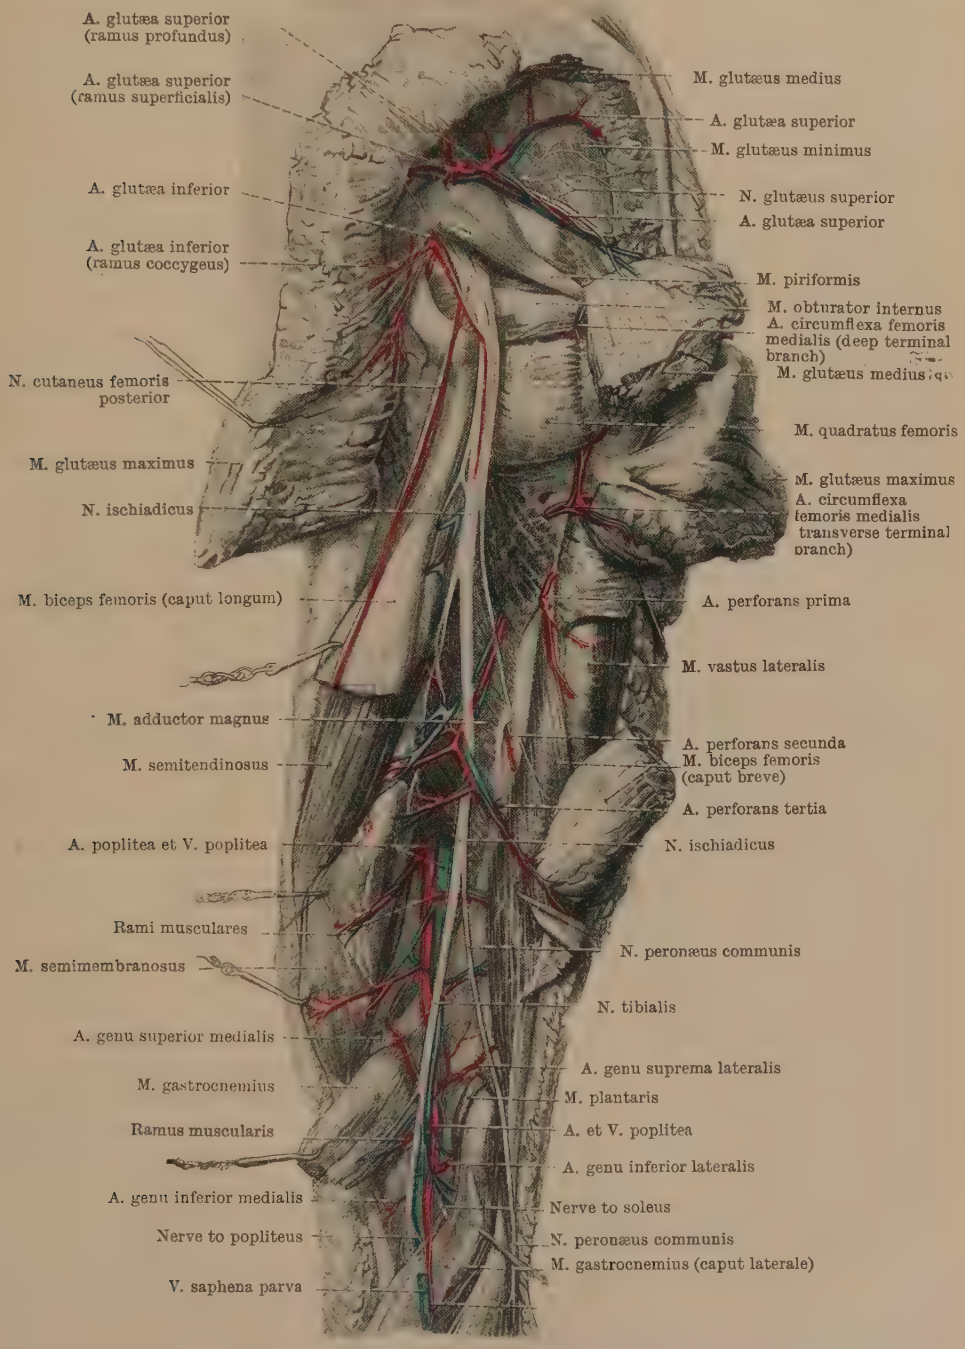

FIG. 751.—THE ARTERIES OF THE BUTTOCK AND THE POSTERIOR ASPECT OF THE THIGH AND KNEE.
NOTE.—In the specimen there was no anastomotic branch of the inferior gluteal artery, and the transverse terminal branch of the medial femoral circumflex artery pierced the upper part of the adductor magnus.

popliteus, and ends there by dividing into the anterior and posterior tibial arteries. Distinctive names are, however, applied to different parts of the artery, corresponding to the several regions through which it passes. Thus in the abdomen it is

called the **external iliac artery**, in the proximal two-thirds of the thigh it receives the name of the **femoral artery**, whilst its distal part, which is situated on the flexor aspect of the knee, is termed the **popliteal artery**.

ARTERIA ILIACA EXTERNA.

The **external iliac artery** (Figs. 748, 752) extends from a point opposite the sacro-iliac joint, at the level of the lumbo-sacral articulation, to a point below the inguinal ligament (Poupart's), midway between the anterior superior spine of the ilium and the symphysis pubis, where it becomes the femoral artery. Its length is about 87 to 100 mm. (three and a half to four inches), and in the adult it is usually somewhat larger than the hypogastric artery.

It runs downwards, forwards, and laterally, along the superior aperture of the pelvis minor, resting upon the fascia iliaca, which separates it, above, from the medial border, and, below, from the anterior surface of the psoas major muscle; and it is enclosed, with its accompanying vein, in a thin fascial sheath.

Relations—*Anterior.*—It is covered in front by peritoneum, which separates it on the left side from the iliac colon, and coils of small intestine, and on the right side from the terminal portion of the ileum, and sometimes from the vermiform process. The ureter, descending behind the peritoneum, sometimes crosses the front of the artery near its origin, and in the female the ovarian vessels cross the upper part of the artery. Near its lower end the artery is crossed anteriorly by the external spermatic branch of the genito-femoral nerve and by the deep circumflex iliac vein. In the male this part of the artery is crossed also by the ductus deferens, and in the female by the round ligament of the uterus. Several iliac lymph glands lie in front and at the sides of the external iliac artery, and almost invariably one of these is directly anterior to its termination.

Posterior.—The fascia iliaca and psoas major muscle lie behind the artery. Near its upper end the obturator nerve and the external iliac vein are posterior to the vessel.

Lateral.—On its lateral side is the genito-femoral nerve. *Medial.*—To the medial side of its lower part is the external iliac vein.

Branches.—In addition to small branches to the psoas major muscle and to the lymph glands, two named branches of considerable size spring from the external iliac artery, viz., the inferior epigastric and the deep circumflex iliac.

(1) The **inferior epigastric artery** (Figs. 749 and 752) arises, immediately above the inguinal ligament, from the front of the external iliac. It lies in the extra-peritoneal fat, it curves forwards from its origin, turns round the lower border of the peritoneal sac, and runs upwards and medially, along the medial side of the abdominal inguinal ring and along the lateral border of the medial inguinal fossa; it then pierces the transversalis fascia, passes over the semicircular fold (Douglas) and enters the sheath of the rectus abdominis muscle. For a short distance it ascends posterior to the rectus, but it soon penetrates the substance of the muscle, and breaks up into branches which anastomose with terminal offsets of the superior epigastric branch of the internal mammary artery and with the lower intercostal arteries. At the abdominal inguinal ring, in the male, the ductus deferens, the testicular vessels, and the external spermatic branch of the genito-femoral nerve hook round the front and lateral side of the artery, the ductus deferens turning medially behind it; whilst in the female the round ligament of the uterus and the external spermatic branch of the genito-femoral nerve occupy the corresponding positions.

Branches.—(*a*) **Muscular branches** supply the rectus, the pyramidalis, the transversus, and the oblique muscles of the abdominal wall, and anastomose with branches of the deep circumflex iliac, the lumbar, and the lower intercostal arteries. (*b*) **Cutaneous branches**, which pass from the front of the inferior epigastric, pierce the rectus abdominis and the anterior part of its sheath, and terminate in the subcutaneous tissues of the anterior abdominal wall, where they anastomose with corresponding branches of the opposite side and with branches of the superficial epigastric artery. (*c*) The **external spermatic** in the male (**artery of the round ligament of the uterus** in the female) is small. It descends through the inguinal canal and anastomoses with the external pudendal and the scrotal branches of the perineal artery, and in the male with the internal spermatic artery also. In the male it accompanies the spermatic funiculus,

supplying its coverings, including the cremaster. In the female it runs with the round ligament. (*d*) The **pubic branch** descends, either on the lateral or the medial side of the femoral ring, to anastomose with the pubic branch of the obturator artery; it anastomoses also with its fellow of the opposite side. Sometimes, when the obturator branch of the hypogastric artery is absent, the pubic branch of the inferior epigastric artery enlarges and becomes the obturator artery, which descends to the obturator foramen either on the lateral or the medial side of the femoral ring. In the latter case the artery may be injured in the operation for the relief of a strangulated femoral hernia.

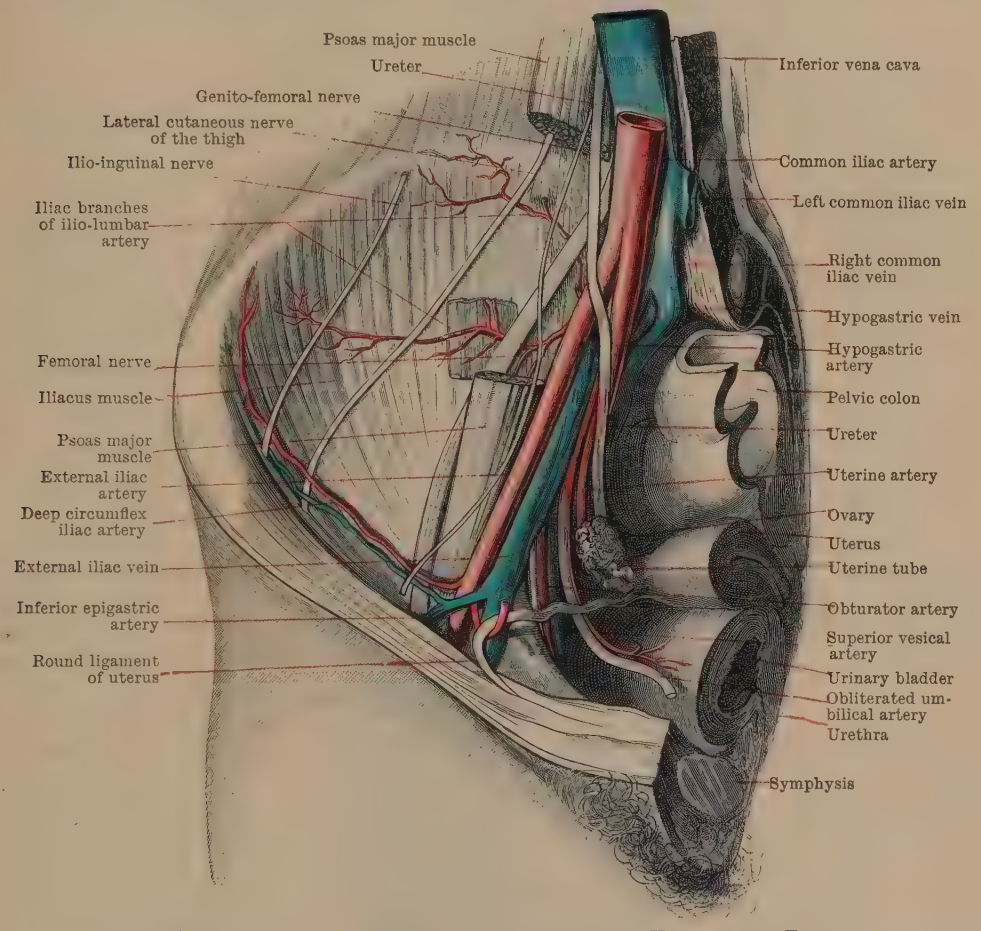

FIG. 752.—THE ILIAC AND HYPOGASTRIC ARTERIES AND VEINS IN THE FEMALE.

(2) The **deep circumflex iliac artery** (Figs. 752 and 753) springs from the lateral side of the external iliac artery, usually a little below the inferior epigastric, and immediately above the inguinal ligament. It runs laterally and upwards to the anterior superior spine of the ilium. In that part of its course it lies just above the lower border of the inguinal ligament, and is enclosed in a fibrous canal formed by the union of the transversalis and iliac fasciæ. A little beyond the anterior superior spine it pierces the transversus abdominis, and is continued between the transversus and the internal oblique, to terminate by anastomosing with branches of the ilio-lumbar artery.

Branches.—(*a*) **Muscular** to the upper parts of the sartorius and the tensor fasciæ latæ, and to the muscles of the abdominal wall. One of the latter branches is frequently of considerable size; it pierces the transversus muscle a short distance anterior to the anterior superior spine of the ilium, and ascends vertically, between the transversus and the internal oblique, anastomosing with the lumbar and the epigastric arteries. (*b*) **Cutaneous branches** pierce the muscles. They terminate in the skin over the crest of the ilium, and they anastomose with the superior gluteal, the superficial circumflex iliac, and the ilio-lumbar arteries.

Abnormalities.—The **external iliac artery** may be much smaller than usual, especially if the inferior gluteal artery persists as the main vessel of the lower limb. It may give off two deep circumflex iliac branches, a dorsal artery of the penis, a medial circumflex artery of the thigh, or a vas aberrans, and its deep circumflex iliac and inferior epigastric branches may arise at higher or lower levels than usual.

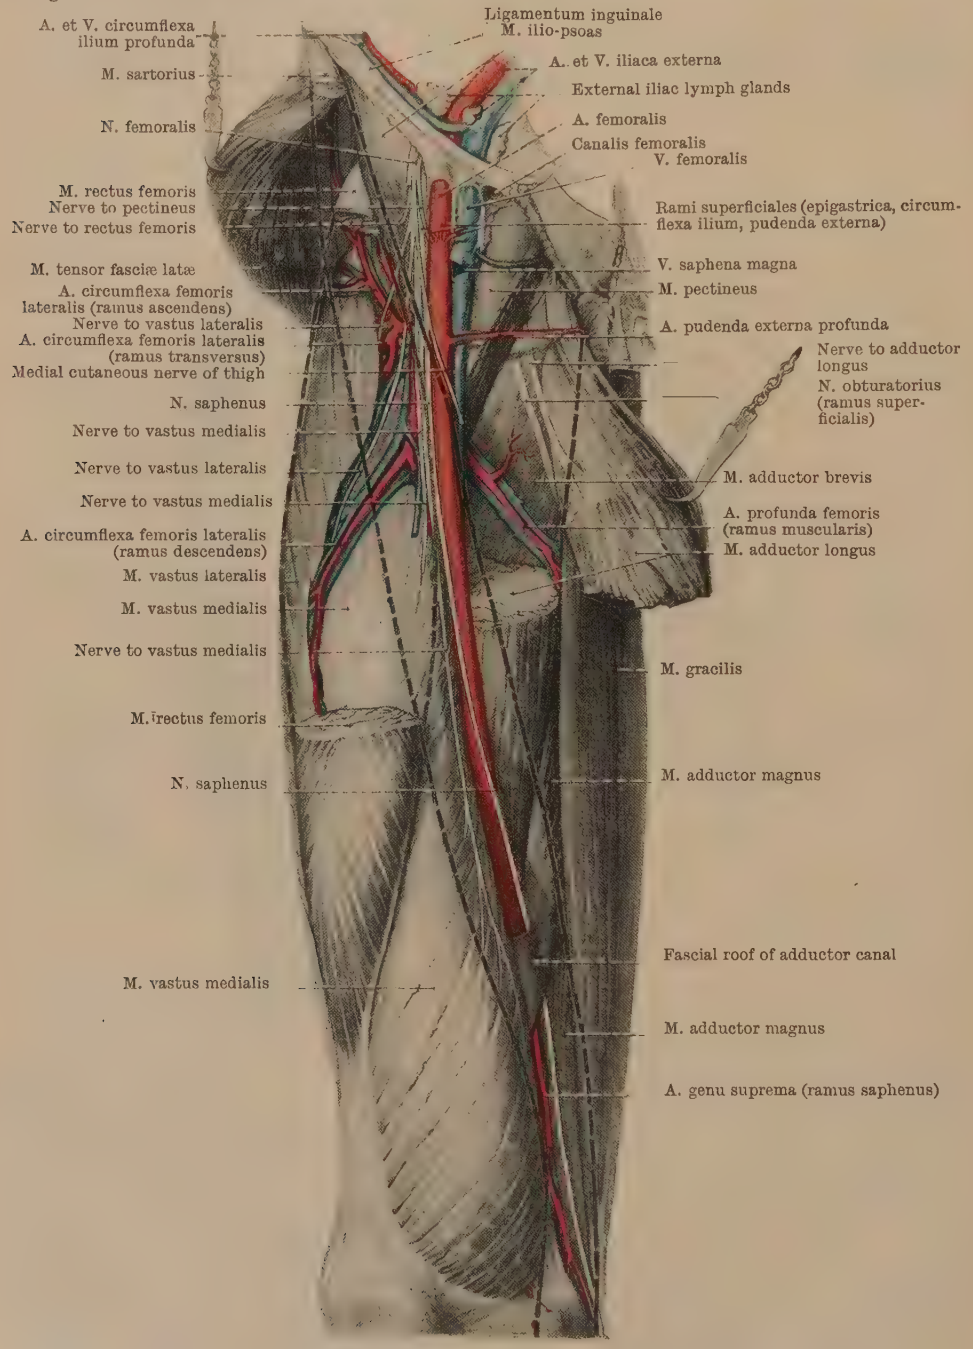

FIG. 753.—THE FEMORAL ARTERY AND ITS BRANCHES.

NOTE.—The outlines of the sartorius, the upper part of the rectus femoris, and the adductor longus are indicated by broken black lines.

ARTERIA FEMORALIS.

The **femoral artery** (Figs. 753 and 754) is the continuation of the external iliac into the thigh. It commences at the lower border of the inguinal ligament

(O.T. Poupart's), passes through the proximal two-thirds of the thigh, and terminates at the opening in the adductor magnus. At one time it was customary to speak of the first one and a half inches, as far as the origin of the profunda branch, as the common femoral, and to say that it divided into the superficial and deep femoral branches, of which the former was the direct continuation of the common trunk. The morphology and development of the vessel give no support for such terminology.

Course.—Its general direction is indicated by a line drawn from the point of origin, midway between the anterior superior spine of the ilium and the symphysis pubis, to the adductor tubercle, the thigh being flexed, abducted, and rotated laterally.

In its proximal half the femoral artery lies in the femoral trigone (Scarpa), and is comparatively superficial; at the apex of the trigone it passes deep to the sartorius, enters the adductor canal (Hunter's), and is thus more deeply placed.

At their entry into the femoral trigone both the artery and its vein are enclosed, for a distance of 31 mm. (one and a quarter inches), in a funnel-shaped fascial sheath formed of the fascia transversalis anteriorly and the fascia iliaca posteriorly. This is called the **femoral sheath**; it is divided, by antero-posterior septa, into three compartments, of which the lateral is occupied by the femoral artery and lumbo-inguinal branch of the genito-femoral nerve; the intermediate compartment contains the femoral vein; and the medial compartment constitutes the femoral canal.

Relations—*Anterior.*—In the femoral trigone the femoral artery is covered superficially by skin and fasciæ, by superficial sub-inguinal lymph glands and small superficial vessels. The anterior part of the femoral sheath and the fascia cribrosa are in front of the proximal part of the artery, and the fascia lata is in front of the distal part. Near the apex of the triangle the artery is crossed by the medial cutaneous nerve, and not infrequently by a tributary of the great saphenous vein. *Posterior.*—It is in relation, posteriorly, proximo-distally, with the posterior part of the femoral sheath, the pubic or pectineal portion of the fascia lata and the psoas major, the pectineus, and the proximal part of the adductor longus muscles. The nerve to the pectineus passes between the artery and the psoas major; the femoral vein and the profunda artery and vein intervene between it and the pectineus, and the femoral vein also separates it from the adductor longus.

The femoral vein, which lies on a plane posterior to the artery in the lower part of the femoral trigone, passes to its medial side above, where it is separated from the artery by the lateral septum of the femoral sheath. On the lateral side of the artery is the femoral nerve (O.T. anterior crural) proximally; more distally the saphenous nerve and the nerve to the vastus medialis are continued on the lateral side. The lumbo-inguinal branch of the genito-femoral nerve is anterior and to the lateral side, proximally, as it runs for a short distance in the femoral sheath.

In the *adductor canal* the artery has posterior to it the adductor longus and the adductor magnus, whilst anterior and to the lateral side is the vastus medialis. The femoral vein is also posterior to the artery, but lies to its lateral side distally and to its medial side proximally. Anterior to the artery is the fascial roof of the canal, with the obturator or sub-sartorial plexus of nerves and the sartorius muscle. The saphenous nerve enters the adductor canal with the artery, and runs first on its lateral side, then anterior, and lastly on its medial side.

Branches.—The femoral artery gives off the following branches:—

(1) Superficial branches.
  (*a*) The superficial circumflex iliac.
  (*b*) The superficial epigastric.
  (*c*) The superficial external pudendal.
(2) Muscular.
(3) The deep external pudendal.
(4) The profunda.
(5) The arteria genu suprema.

(*a*) The **superficial circumflex iliac artery** springs from the front of the femoral artery, just below the inguinal ligament. It pierces the femoral sheath and the fascia lata, lateral to the fossa ovalis, and runs, in the superficial fascia, as

far as the anterior superior spine of the ilium. It supplies the lateral set of sub-inguinal glands and the skin of the groin, and it sends branches, through the fascia lata, which anastomose with branches of the deep circumflex iliac artery, and supply the upper parts of the sartorius and tensor fasciæ latæ muscles.

(*b*) The **superficial epigastric artery** arises near the preceding. It pierces the femoral sheath and the fascia cribrosa, and passes upwards and medially between the superficial and deep layers of the superficial fascia of the abdominal wall, towards the umbilicus. It supplies the sub-inguinal glands and the integument, and anastomoses with its fellow of the opposite side, with the inferior

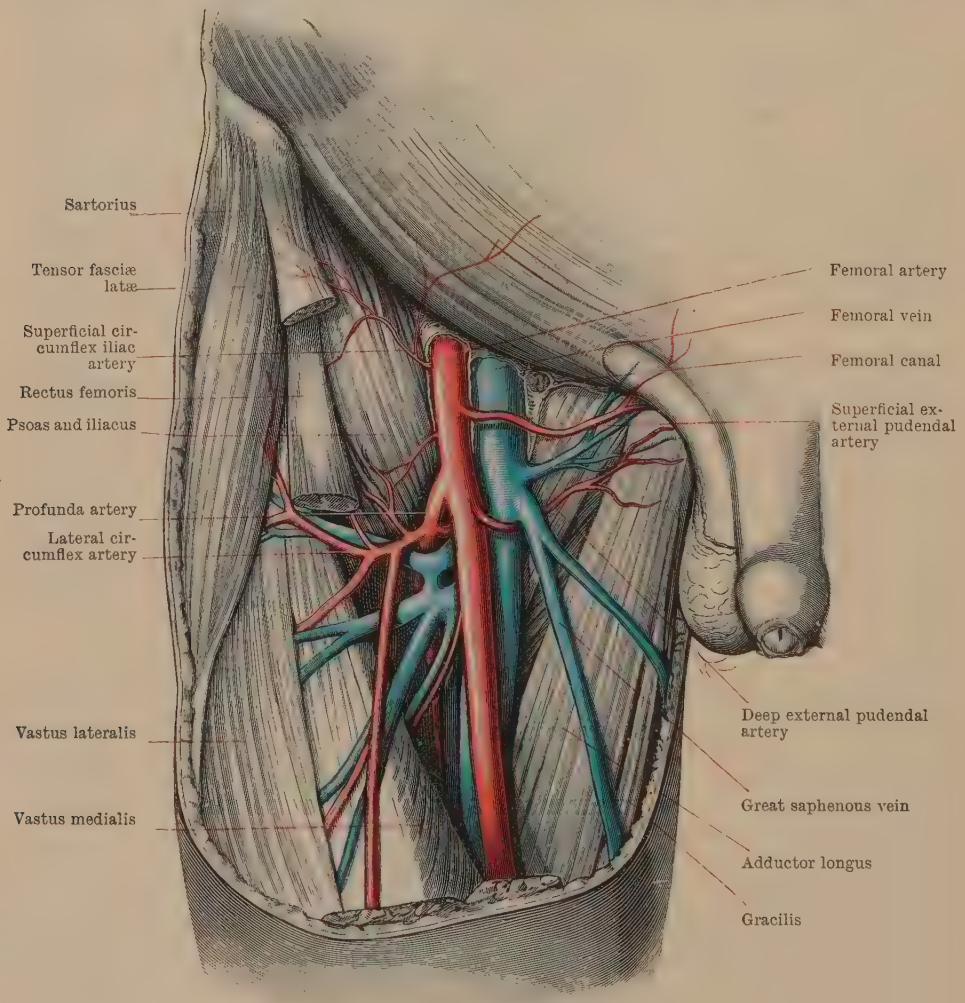

Fig. 754.—The Femoral Vessels in Femoral Trigone.

epigastric, and with the superficial circumflex iliac and superficial external pudendal arteries.

(*c*) The **superficial external pudendal artery** also springs from the front of the femoral artery, and, after piercing the femoral sheath and the fascia cribrosa, runs upwards and medially towards the pubic tubercle, where it crosses superficial to the spermatic cord and divides into terminal *anterior scrotal* or *labial branches* according to the sex. It supplies the integument of the lower part of the abdominal wall, the root of the dorsum of the penis in the male, and the region of the mons Veneris in the female, and it anastomoses with its fellow of the opposite side, with the deep external pudendal, with the dorsal artery of the penis, and with the superficial epigastric artery.

(2) The **muscular branches** are distributed to the pectineus and the adductor muscles on the medial side, and to the sartorius and the vastus medialis on the lateral side.

(3) The **deep external pudendal artery** arises from the medial side of the femoral. It runs medially, anterior to the pectineus, and either anterior or posterior to the adductor longus, to the medial side of the thigh; it then pierces the deep fascia, and terminates in the scrotum, where it anastomoses with the posterior scrotal branches of the perineal and the anterior scrotal branches of the superficial external pudendal arteries, and with the external spermatic branch of the inferior epigastric artery. In the female it terminates in the labium majus.

(4) The **profunda artery** (Fig. 754) is the largest branch of the femoral artery. It arises about 37 mm. (an inch and a half) distal to the inguinal ligament, from the lateral side of the femoral artery. It curves backwards and medially, passes posterior to the femoral artery, and runs distally, close to the medial aspect of the femur, to the distal third of the thigh, where it perforates the adductor magnus and passes to the back of the thigh. Its termination is known as the *fourth perforating artery*. As the profunda descends it lies anterior to the iliacus, the pectineus, the adductor brevis, and the adductor magnus. It is separated from the femoral artery by its own vein, by the femoral vein, and by the adductor longus muscle.

Branches.—(*a*) **Muscular branches** are given off from the profunda, both in the femoral trigone and whilst it lies between the adductor muscles; many of them terminate in the adductors, others pass through the adductor magnus, and terminate in the hamstrings, where they anastomose with the transverse branch of the medial circumflex and with the proximal muscular branches of the popliteal artery.

(*b*) The **lateral circumflex artery** (Figs. 753 and 754) springs from the lateral side of the profunda, or occasionally from the femoral artery proximal to the origin of the profunda. It runs laterally, anterior to the iliacus and between the superficial and deep branches of the femoral nerve, to the lateral border of the femoral trigone; then, passing posterior to the sartorius and the rectus femoris, it terminates by dividing into three terminal branches —the ascending, the transverse, and the descending. Before its termination it supplies branches to the muscles mentioned and to the proximal part of the vastus intermedius.

(i.) The **ascending terminal branch** runs proximally and laterally, posterior to the rectus femoris and the tensor fasciæ latæ, along the linea intertrochanterica, to the anterior borders of the glutæi, medius and minimus, between which it passes to anastomose with the deep branches of the superior gluteal artery. It supplies twigs to the neighbouring muscles, anastomoses with the gluteal, the deep circumflex iliac, and the transverse branch of the lateral circumflex arteries, and, as it ascends along the linea intertrochanterica, it gives off a branch which passes, between the two limbs of the ilio-femoral ligament, into the hip-joint. (ii.) The **transverse terminal branch** is small; it runs laterally, between the vastus intermedius and the rectus femoris, passes into the substance of the vastus lateralis, winds round the femur, and anastomoses with the ascending and descending branches, with the perforating branches of the profunda, and with the inferior gluteal and medial circumflex arteries. (iii.) The **descending terminal branch** runs distally, posterior to the rectus and along the anterior border of the vastus lateralis, accompanied by the nerve to the latter muscle. It anastomoses with the transverse branch, with twigs of the inferior perforating arteries, with the arteria genu suprema of the femoral, and with the superior lateral genicular branch of the popliteal artery.

(*c*) The **medial circumflex artery** springs from the medial and posterior part of the profunda, at the same level as the lateral circumflex, and runs backwards, through the floor of the femoral trigone, passing between the psoas major and the pectineus; then it crosses the upper border of the adductor brevis, and continuing backwards, below the neck of the femur, it passes between the adjacent borders of the obturator externus and the adductor brevis to the upper border of the adductor magnus, where it divides into two terminal branches, a transverse and a profunda branch.

Branches.—(i.) An **acetabular branch** is given off as the artery passes below the neck of the femur. It ascends to the acetabular notch where it anastomoses with twigs from the posterior branch of the obturator artery, and it sends branches into the acetabular fossa and along the ligamentum teres to the head of the femur. (ii.) **A superficial branch,** which passes medially, anterior to the pectineus and between the adductors brevis and longus. (iii.) **Muscular branches** are given off to the neighbouring muscles. The largest of these branches usually arises immediately before the termination of the artery; it runs distally, on the anterior aspect of the adductor magnus, and anastomoses with the muscular branches of the profunda artery. (iv.) The **profunda terminal branch** (ascending) passes upwards and laterally, between the obturator externus and the quadratus femoris to the trochanteric fossa of the femur, where it anastomoses

with branches of the superior and inferior gluteal arteries. (v.) The **transverse terminal branch** runs backwards to the hamstring muscles, usually between the lower border of the quadratus femoris and the upper border of the adductor magnus, but it may pierce the upper part of the adductor magnus. It anastomoses, in front of the distal part of the glutæus maximus, with the inferior gluteal and first perforating arteries and with the transverse branch of the lateral circumflex, and, in the substance of the hamstrings, with the muscular branches of the profunda.

(*d*) The **perforating arteries** (Fig. 755), including the terminal branch of the profunda, are four in number. They curve posterolaterally, round the posterior aspect of the femur, lying close to the bone and anterior to the well-marked tendinous arches which interrupt the continuity of muscular attachments; their terminal branches enter the vastus lateralis and anastomose, in its substance, with one another, with the descending branch of the lateral circumflex, with the arteria genu suprema, and with the superior lateral genicular branch of the popliteal.

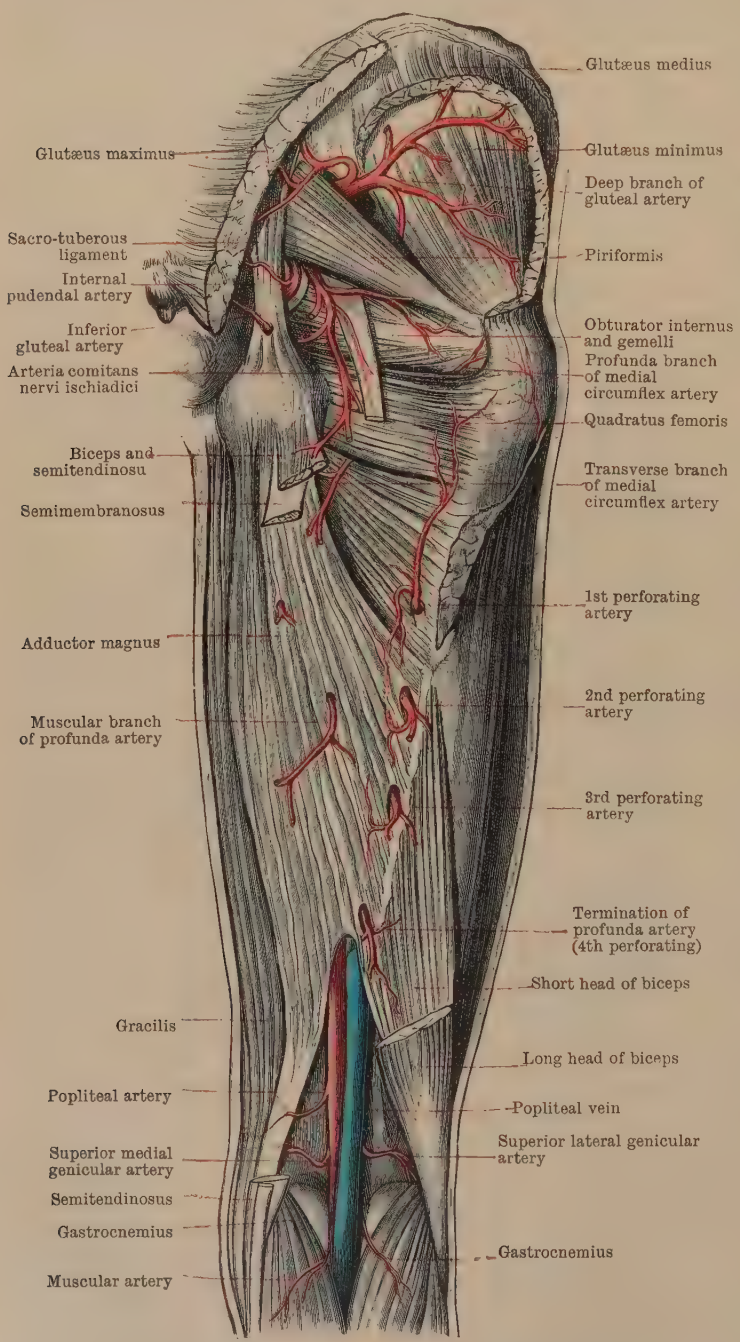

FIG. 755.—THE ARTERIES OF THE BUTTOCK AND THE POSTERIOR ASPECT OF THE THIGH AND KNEE.

The **first perforating artery** pierces the insertions of the adductors brevis and magnus, and some of its branches anastomose, anterior to the gluteus maximus, with the inferior glutæal, with the transverse branch of the medial circumflex, and with the transverse branch of the lateral circumflex, forming what is known as the crucial anastomosis.

The **second perforating artery** pierces the adductors brevis and magnus, and then passes between the glutæus maximus and the short head of the biceps femoris into the vastus lateralis. It anastomoses with its proximal and distal fellows, and with the medial circumflex and the proximal muscular branches of the popliteal artery.

The **third** and **fourth perforating arteries** pass through the adductor magnus and the short

head of the biceps femoris into the vastus lateralis. Their anastomoses are similar to those of the second perforating.

A **nutrient branch** to the femur is given off either from the second or third perforating artery, usually the former; an additional nutrient branch may also be supplied by the first or fourth perforating arteries.

(5) The **arteria genu suprema** arises near the termination of the femoral artery, in the distal part of the adductor canal, and divides, almost immediately, into a superficial, saphenous, and a deep (musculo-articular) branch; indeed, very frequently the two branches arise separately from the femoral trunk.

(*a*) The **saphenous branch** passes through the distal end of the adductor canal with the saphenous nerve, and appears superficially, on the medial side of the knee, between the gracilis and the sartorius. It gives twigs to the integument of the proximal and medial part of the leg, and it anastomoses with the inferior medial genicular artery. (*b*) The **musculo-articular branch** runs towards the knee, in the substance of the vastus medialis, along the anterior aspect of the tendon of the adductor magnus. It anastomoses with the superior medial genicular artery, and it sends branches laterally, one on the surface of the femur and another along the proximal border of the patella, to anastomose with the descending branch of the lateral circumflex, the fourth perforating artery, the superior lateral genicular, and the anterior tibial recurrent.

Abnormalities.—The **femoral artery** is small, and ends in the profunda and circumflex branches, when the inferior gluteal artery forms the principal vessel of the lower limb. The profunda branch, which arises usually from the lateral side of the femoral trunk, about 37 mm. (1½ in.) distal to the inguinal ligament, may commence at a more proximal or a more distal level, and from the back or the medial side of the femoral trunk. In rare cases when the profunda arises at a more proximal level than usual it may cross anterior to the femoral vein, above the entrance of the great saphenous vein, after which it passes distally and laterally posterior to the femoral vessels (Johnston, *Anat. Anz.*, Bd., 42, 1912). Absence of the profunda has been noted, and in those cases the branches usually given off by it spring directly from the femoral artery.

The femoral artery may be double for a portion of its extent, or it may be joined by a vas aberrans given off from the external iliac artery. In addition to its ordinary branches, it may furnish one or both of the circumflex arteries of the thigh, and sometimes it gives off, near the origin of the profunda, a great saphenous artery, such as exists normally in many mammals. This vessel runs distally through femoral trigone and the adductor canal, and accompanies the saphenous nerve to the medial side of the foot.

The deep circumflex iliac, the obturator, and the inferior epigastric arteries are occasionally given off from the femoral.

ARTERIA POPLITEA.

The **popliteal artery** is the direct continuation of the femoral. It commences at the medial and proximal side of the popliteal fossa, under cover of the semimembranosus, and terminates at the distal border of the popliteus muscle, and on a level with the distal part of the tuberosity of the tibia, by dividing into the anterior and the posterior tibial arteries.

From its origin the artery passes distally, with a lateral inclination, to the interspace between the condyles of the femur, whence it is continued vertically to its termination.

Relations—*Anterior.*—It is in contact in front and proximo-distally with the popliteal surface of the femur, the posterior part of the capsule of the knee-joint, and the fascia covering the posterior surface of the popliteus.

Posterior.—The artery is overlapped behind, in the proximal part of its extent, by the lateral border of the semimembranosus; it is crossed, about its middle, by the popliteal vein and the tibial (O.T. internal popliteal) nerve, the vein intervening between the artery and the nerve; whilst, in the distal part of its extent, it is overlapped by the adjacent borders of the two heads of the gastrocnemius, and is crossed by the nerves to the soleus and popliteus and by the plantaris muscle.

Lateral.—On its lateral side it is in relation, proximally, with the tibial nerve and the popliteal vein, then with the lateral condyle of the femur, and, distally, with the lateral head of the gastrocnemius and the plantaris.

Medial.—On the medial side it is in relation, proximally, with the semimembranosus, in the middle with the medial condyle of the femur, and, distally, with the tibial nerve, the popliteal vein, and the medial head of the gastrocnemius. Popliteal lymph glands are arranged irregularly around the artery.

Branches.—(1) **Muscular branches** are given off in two sets, proximal and distal.

The *proximal muscular branches* are distributed to the distal parts of the hamstring muscles, in which they anastomose with branches of the profunda artery.

The distal muscular, or *sural*, arteries enter the proximal parts of the gastrocnemius, the plantaris, the soleus, and the popliteus muscles, and they anastomose with branches of the posterior tibial artery and the lower genicular arteries.

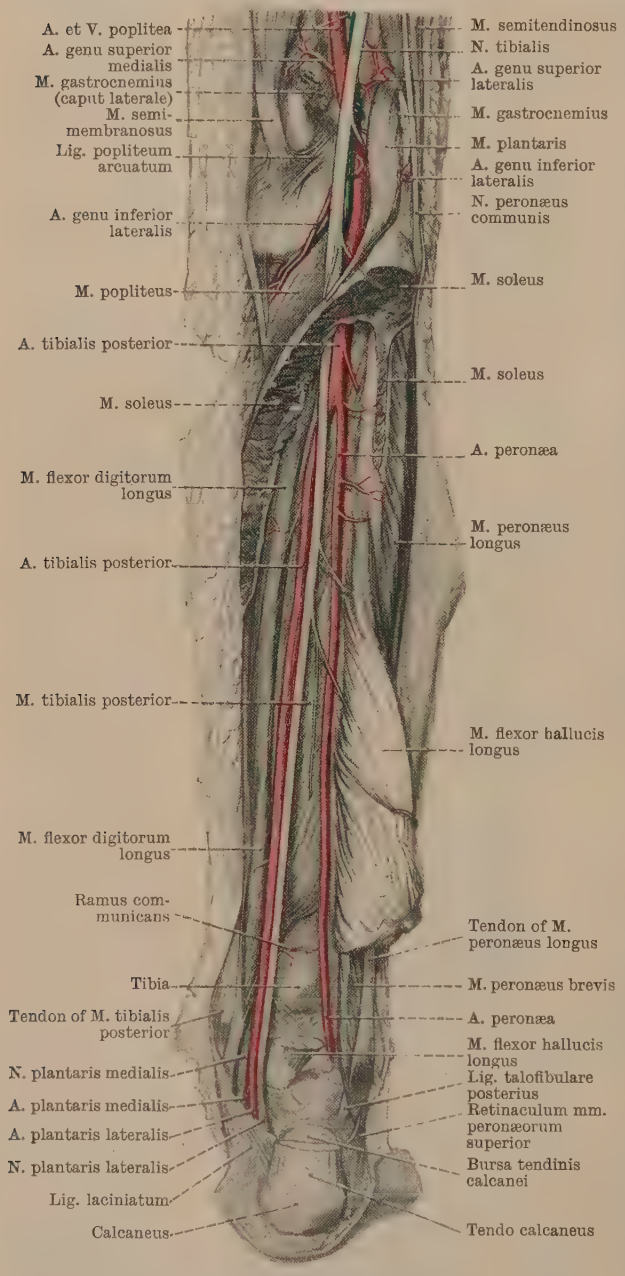

FIG. 756.—THE POPLITEAL AND POSTERIOR TIBIAL ARTERIES AND THEIR BRANCHES.

(2) The **genicular branches** are five in number—viz., superior and inferior lateral, superior and inferior medial, and a middle branch.

(*a*) The **superior lateral genicular artery** passes laterally, proximal to the lateral condyle, behind the femur and in front of the biceps tendon, into the vastus lateralis, where it anastomoses with the arteria genu suprema, the descending branch of the lateral circumflex, and the fourth perforating artery; it also sends branches distally to anastomose with the inferior lateral genicular and with the anterior tibial recurrent.

(*b*) The **superior medial genicular artery** passes medially, proximal to the medial condyle, behind the femur, and anterior to the tendon of the adductor magnus, into the vastus medialis. It anastomoses with branches of the arteria genu suprema and of the superior lateral genicular artery.

(*c*) The **inferior lateral genicular artery** runs laterally, across the popliteus muscle and anterior to the plantaris and the lateral head of the gastrocnemius; then, turning forwards, it is joined by the inferior lateral genicular nerve, and passes to the medial side of the fibular collateral ligament. It terminates by anastomosing with its fellow of the opposite side and with the superior lateral genicular and anterior tibial recurrent arteries.

(*d*) The **inferior medial genicular artery** passes medially, distal to the medial condyle of the tibia, along the proximal border of the popliteus and in front of the medial head of the gastrocnemius, to the medial side of the knee, where it turns forwards, between the bone and the tibial collateral ligament, and terminates anteriorly by anastomosing with its fellow of the opposite side, with the recurrent branch of the anterior tibial artery, and with the superior medial genicular artery.

(*e*) The **arteria genu media** passes directly forwards from the front of the popliteal artery, pierces the central part of the posterior surface of the capsule of the knee-joint,

and enters the intercondylar fossa. It supplies branches to the crucial ligaments and to the synovial membrane, and is accompanied by the medial genicular branch of the tibial nerve, and sometimes by the genicular branch of the obturator nerve.

(3) **Cutaneous branches** are distributed to the skin over the popliteal fossa. One of these, the *superficial sural artery*, runs along the middle of the back of the calf with the vena saphena parva.

Abnormalities.—The **popliteal artery** may exceptionally form the direct continuation of the inferior gluteal artery. It sometimes divides at a more proximal or more distal level than usual, and the division may be into either two or three branches; if three terminal branches are present, they are the anterior and posterior tibial and the peroneal arteries, and if only two, either the anterior and posterior tibial, or the anterior tibial and the peroneal arteries.

Occasionally the artery is double for a short portion of its course, and it has been found to cross, first posterior to the medial head of the gastrocnemius to the medial side of the knee, and then anterior to the medial head of the gastrocnemius to regain the popliteal fossa. The number of its branches may be reduced, or they may be increased by the addition of a vas aberrans which connects it with the posterior tibial artery. Its superficial sural branch may enlarge to form a well-marked small saphenous artery.

Arteria Tibialis Posterior.

The **posterior tibial artery**, the larger of the two terminal branches of the popliteal, commences at the distal border of the popliteus and terminates midway between the tip of the medial malleolus and the most prominent part of the heel, at the distal border of the laciniate ligament (O.T. internal annular). It ends by dividing into the medial and the lateral plantar arteries, which pass onwards to the sole of the foot.

The posterior tibial artery runs distally and medially, in the posterior part of the leg, between the superficial and deep layers of muscles and covered, posteriorly, by the deep intermuscular fascia which intervenes between them.

Relations—*Anterior.*—It is in contact anteriorly, and proximo-distally, with the tibialis posterior, the flexor digitorum longus, the posterior surface of the tibia, and the posterior ligament of the ankle-joint.

Posterior.—The artery is crossed about 37 mm. (an inch and a half) distal to its origin by the tibial nerve. Elsewhere it is in contact with the intermuscular fascia which binds down the deep layer of muscles. More superficially the proximal half of the artery is covered by the fleshy parts of the soleus and gastrocnemius muscles, between which is the plantaris; the distal half of the artery is much nearer the surface, and is covered only by skin and fasciæ, except at its termination, where it lies deep to the laciniate ligament.

Lateral and Medial.—The artery is accompanied by two venæ comites, one on each side. The tibial nerve lies at first on the medial side of the vessel, then crosses posterior to it, and is continued distally on its lateral side. In the most distal part of its course the artery is separated from the medial malleolus by the tendons of the tibialis posterior and the flexor digitorum longus, whilst the tendon of the flexor hallucis longus lies postero-lateral to it.

Branches.—The posterior tibial gives off numerous branches, the largest of which, the peroneal, forms one of the chief arteries of the leg. The branches include—

(1) Large **muscular branches** which are distributed to the soleus, the tibialis posterior, the flexor digitorum longus, and the flexor hallucis longus. They anastomose with the deep sural branches of the popliteal artery and the lower medial genicular artery.

(2) A **fibular branch** passes laterally, to the neck of the fibula, where it anastomoses with the inferior lateral genicular and the deep sural arteries, and supplies the adjacent muscles.

(3) The **peroneal artery** (Fig. 756) is the largest branch of the posterior tibial. It arises about 25 mm. (an inch) below the distal border of the popliteus, curves laterally across the proximal part of the tibialis posterior to the medial crest of the fibula, along which it passes to the distal part of the interosseous space. About 25 mm. (an inch) proximal to the ankle-joint it gives off a perforating branch and then passes, posterior to the tibio-fibular syndesmosis and lateral malleolus, to the lateral side of the heel and the foot. It supplies the ankle, the tibio-fibular syndesmosis, and the talo-calcanean joint, and anastomoses with the medial calcanean branch of the lateral plantar artery, and with the tarsal and arcuate branches of the dorsalis pedis.

As the peroneal artery passes laterally from its origin it lies posterior to the tibialis posterior, and is covered posteriorly by the deep intermuscular fascia and by the soleus.

As it descends along the medial crest of the fibula it lies in a fibrous canal between the tibialis posterior in front and the flexor hallucis longus behind. The peroneal artery is accompanied by two venæ comites, and is crossed anteriorly and posteriorly by communicating branches between them.

Branches.—(*a*) **Muscular branches** are distributed to the soleus, tibialis posterior, flexor hallucis longus, and the peroneal muscles. Some pass through the interosseous membrane and supply the anterior muscles of the leg.

(*b*) **A nutrient branch** enters the nutrient foramen of the fibula.

(*c*) **A communicating branch** passes across the back of the distal end of the shaft of the tibia, about 25 mm. (an inch) above the tibio-fibular syndesmosis, to anastomose with the posterior tibial artery.

(*d*) The **perforating branch** passes forwards at the junction of the distal border of the interosseous membrane and the interosseous tibio-fibular ligament, and runs, in front of the ankle, to the dorsum of the foot, where it anastomoses with the lateral malleolar branch of the anterior tibial artery and with the tarsal branch of the dorsalis pedis; it also supplies branches to the tibio-fibular syndesmosis, to the ankle-joint, and to the peronæus tertius.

(4) The **nutrient branch**, the largest of the nutrient group of arteries to long bones, springs from the proximal part of the posterior tibial, pierces the tibialis posterior, and enters the nutrient foramen on the posterior surface of the tibia. In the interior of the bone it divides into proximal and distal branches, the former passing towards the proximal extremity of the bone, and the latter towards the distal extremity. Before entering the tibia the nutrient artery gives small muscular branches.

(5) A **communicating branch** unites the posterior tibial to the peroneal artery about 25 mm. (an inch) above the tibio-fibular syndesmosis. It passes posterior to the shaft of the tibia and anterior to the flexor hallucis longus.

(6) **Cutaneous branches** are distributed to the skin of the medial and posterior part of the leg.

(7) A **posterior medial malleolar branch** is distributed to the medial surface of the medial malleolus, anastomosing with a corresponding branch of the anterior tibial artery.

Abnormalities.—The **posterior tibial artery** may be small or altogether absent, its place being taken by branches of the peroneal artery; again, it may be longer or shorter than usual, in conformity with the more proximal or more distal division of the popliteal trunk. The peroneal artery is large, if either the anterior or the posterior tibial artery is small. The perforating branch of the peroneal is almost invariably large when the anterior tibial artery is small; in some cases, indeed, it replaces the whole of the dorsalis pedis continuation of the latter vessel; in others, however, only the lateral tarsal and arcuate branches are so replaced. The peroneal sometimes arises from a stem common to it and the anterior tibial artery.

Plantar Arteries.

(8) The **medial** and **lateral plantar arteries** are the terminal branches of the posterior tibial artery. They arise, under cover of the origin of the ligamentum laciniatum, midway between the tip of the medial malleolus and the most prominent part of the medial side of the os calcis (Figs. 756, 757).

The **medial plantar artery** is the smaller of the two terminal branches of the posterior tibial artery. It passes forwards, along the medial side of the foot in the interval between the abductor hallucis and the flexor digitorum brevis, to the head of the first metatarsal bone, where it terminates by uniting with the plantar digital branch of the dorsalis pedis, which is distributed to the medial side of the great toe. In its course forwards it gives off a *superficial branch*, which ramifies on the superficial surface of the abductor hallucis; branches to the adjacent muscles and articulations, and to the subjacent skin; it also gives three *digital branches* which anastomose, at the roots of the three medial interdigital clefts, with the medial plantar metatarsal arteries. Some of the cutaneous branches of the medial plantar artery anastomose, round the medial border of the foot, with the medial cutaneous branches of the dorsalis pedis artery.

The **lateral plantar artery** is the larger of the two terminal branches of the posterior tibial artery. It runs forwards and laterally, first between the flexor digitorum brevis superficially and the quadratus plantæ deeply, and then, in the interval between the flexor digitorum brevis and the abductor digiti quinti, to the medial side of the base of the fifth metatarsal bone, where it turns abruptly medially and, gaining a deeper plane, passes across the bases of the metatarsal

bones and the origins of the interossei, and above the oblique head of the adductor of the great toe, to the lateral side of the base of the first metatarsal bone, where it terminates by anastomosing with the dorsalis pedis artery. The last part of the artery is convex forwards and forms the *plantar arch*, which is completed by the profunda branch of the dorsalis pedis.

Branches.—Between its origin and the base of the fifth metatarsal the lateral plantar artery gives off (*a*) the **medial calcanean branch**, which is distributed to the skin and the subcutaneous tissue of the heel.

(*b*) **Muscular branches** to the abductor hallucis, flexor digitorum brevis, quadratus plantæ, and abductor digiti quinti.

(*c*) **Cutaneous branches** to the skin of the lateral side of the foot.

Between the base of the fifth metatarsal bone and the first interosseous space it forms the **plantar arch**, and gives off (*d*) four **plantar metatarsal branches**; (*e*) three **posterior perforating arteries** to the dorsal metatarsal arteries; and (*f*) **articular branches** to the tarsal joints.

The **fifth** or most lateral **metatarsal branch** runs along the lateral side of the little toe, supplying the skin, joints, and the flexor tendons with their synovial sheaths. The three medial **plantar metatarsal branches, second, third,** and **fourth,** run forwards on the plantar surfaces of the interossei, the medial two lying dorsal to the oblique head of the adductor of the great toe, and all three passing dorsal to the transverse head of the adductor. At the bases of the interdigital clefts the second, third, and fourth plantar metatarsal arteries divide into plantar digital arteries which run along the plantar aspects of adjacent toes, and supply skin, joints, and the flexor tendons and sheaths. Opposite the last phalanx of each toe the digital arteries of opposite sides of the toe anastomose together.

Transverse head of adductor hallucis

FIG. 757.—THE PLANTAR ARTERIES AND THEIR BRANCHES.

The **posterior perforating arteries** are three in number; they pass dorsalwards through the three lateral inter-metatarsal spaces, between the heads of the dorsal interosseous muscles, and terminate by uniting with the corresponding dorsal metatarsal arteries. **Anterior perforating branches** which communicate with the dorsal metatarsal arteries are given off from two or three of the plantar metatarsal arteries just before they divide.

The **articular branches** are numerous and irregular; they supply the joints and ligaments of the tarsus on its plantar aspect.

Abnormalities.—The **medial plantar artery** is sometimes very small, and it may be absent; its place is taken by branches of the dorsalis pedis or lateral plantar arteries. The lateral

plantar artery also may be small or absent, the plantar arch being formed entirely by the dorsalis pedis.

Arteria Tibialis Anterior.

The **anterior tibial artery**, the smaller of the two terminal divisions of the popliteal, commences opposite the distal border of the popliteus muscle, and terminates in front of the ankle, where it is continued into the dorsal artery of the foot.

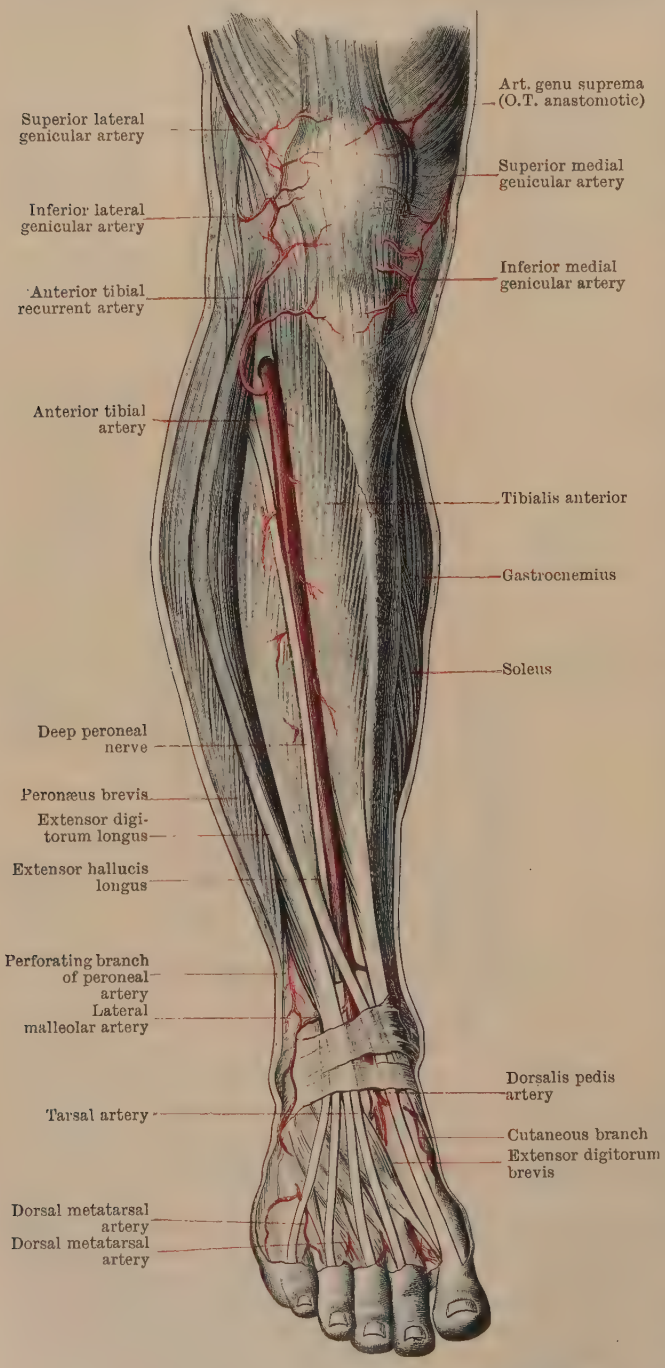

Fig. 758.—The Anterior Tibial Artery and its Branches.

Course and Relations.—From its origin, at the back of the leg, the artery passes anteriorly, between the two slips of the proximal part of the tibialis posterior and above the proximal border of the interosseous membrane. It then runs distally, resting, in the proximal two-thirds of its course, against the anterior surface of the interosseous membrane and, subsequently, on the distal part of the tibia and the anterior ligament of the ankle-joint. In the proximal third of the anterior compartment of the leg it lies between the extensor digitorum longus laterally and the tibialis anterior medially; in the middle third it is between the extensor hallucis longus and the tibialis anterior; in the distal third the extensor hallucis longus crosses in front of the artery and reaches its medial side, and the most distal part of the vessel lies between the tendon of the extensor hallucis longus on the medial side and the most medial tendon of the extensor digitorum longus on the lateral side.

The deep peroneal nerve is at first well to the lateral side of the artery, but it soon passes in front of the vessel, and it lies in front of the middle third of the artery; more distally the nerve is usually found on the

lateral side again, and at the ankle it intervenes between the artery and the most medial tendon of the extensor digitorum longus.

Two venæ comites, with numerous intercommunications, accompany the artery.

Obviously the anterior tibial artery is, at least in its proximal part, deeply placed; moreover, its lateral muscular boundaries overlap it. In the distal two-thirds of its extent it is, however, easily accessible from the surface; and beyond being covered by the nerve and crossed by the tendon, as already described, is only covered, in addition, by skin, fascia, and the transverse crural ligament.

Branches.—Close to its origin the artery gives off fibular and posterior tibial recurrent branches; after it reaches the front of the leg it gives off anterior tibial recurrent, muscular, cutaneous, medial malleolar, and lateral malleolar branches.

(1) The **fibular branch** is a small vessel which may arise separately from the anterior tibial artery, or by a common stem with the posterior tibial recurrent; occasionally it springs from the lower end of the popliteal artery, or from the posterior tibial. It runs upwards and laterally, behind the neck of the fibula and through the fibres of the soleus, and it terminates in branches which supply the soleus, the peronæus longus, and the skin of the proximal and lateral part of the leg. It anastomoses with the inferior lateral genicular artery.

(2) The **posterior tibial recurrent branch**, also small, and not always present, runs upwards, anterior to the popliteus muscle, to the back of the knee-joint. It anastomoses with the inferior genicular branches of the popliteal, and gives branches to the popliteus muscle and the proximal tibio-fibular articulation.

(3) The **anterior tibial recurrent branch** arises from the anterior tibial artery in front of the interosseous membrane. It runs proximally and medially, between the proximal part of the tibialis anterior and the lateral condyle of the tibia, accompanied by the recurrent articular branch of the common peroneal nerve, and, after supplying the tibialis anterior and the proximal tibio-fibular articulation, it pierces the deep fascia of the leg; it is connected with the anastomoses round the knee-joint, formed by the genicular branches of the popliteal artery, the descending branch of the lateral circumflex artery, and the arteria genu suprema.

(4) The **muscular branches** are distributed to the muscles of the front of the leg, and a few small branches also pass backwards to the deep surface of the tibialis posterior muscle.

(5) The **cutaneous branches** supply the skin of the front of the leg.

(6) The **medial anterior malleolar branch** arises from the lower part of the anterior tibial artery, and is smaller than its companion on the lateral side. It runs medially, posterior to the tibialis anterior tendon, ramifies over the medial malleolus, anastomosing with branches of the posterior tibial artery, and is distributed to the skin and to the ankle-joint.

(7) The **lateral anterior malleolar branch**, more constant and larger than the medial, passes laterally, posterior to the extensor digitorum longus and peronæus tertius, towards the lateral malleolus. It anastomoses with the perforating branch of the peroneal artery and with the tarsal artery, and supplies the ankle-joint and the adjacent articulations.

Dorsalis Pedis Artery.—The **dorsal artery of the foot** is the direct continuation of the anterior tibial; it commences opposite the front of the ankle-joint, and extends to the posterior extremity of the first interosseous space, where it divides into the first dorsal metatarsal and the profunda branch.

It is covered superficially by skin and fascia, including the cruciate ligament, and it is crossed, just before it reaches the first interosseous space, by the tendon of the extensor hallucis brevis. It rests upon the anterior ligament of the ankle, the head of the talus, the talo-navicular ligament, the dorsum of the navicular bone, and the dorsal naviculo-cuneiform and the inter-cuneiform ligaments between the first and second cuneiform bones. On its lateral side is the medial terminal branch of the deep peroneal nerve, which intervenes between it and the extensor digitorum brevis and the most medial tendon of the extensor digitorum longus. On its medial side it is in relation with the tendon of the extensor hallucis longus. Two venæ comites, one on each side, accompany the artery.

Branches.—On the dorsum of the foot the dorsalis pedis artery gives off cutaneous branches, lateral and medial tarsal branches, the arcuate branch, and the first dorsal metatarsal and the profunda branch.

(1) **Cutaneous branches**, two or three in number, are distributed to the skin on the

dorsum and medial side of the foot; they anastomose with branches of the medial plantar artery.

(2) **The tarsal branches, medial and lateral.**—The medial tarsal branches are small vessels given off from the medial side of the artery. They pass to the medial border of the foot and anastomose with branches of the medial plantar artery. The lateral tarsal branch is given off opposite the head of the talus; it runs laterally, deep to the extensor hallucis brevis and the extensor digitorum brevis, supplying those muscles and the tarsal joints, and it anastomoses with the perforating branch of the peroneal, the arcuate, and lateral plantar arteries, and with the lateral malleolar artery.

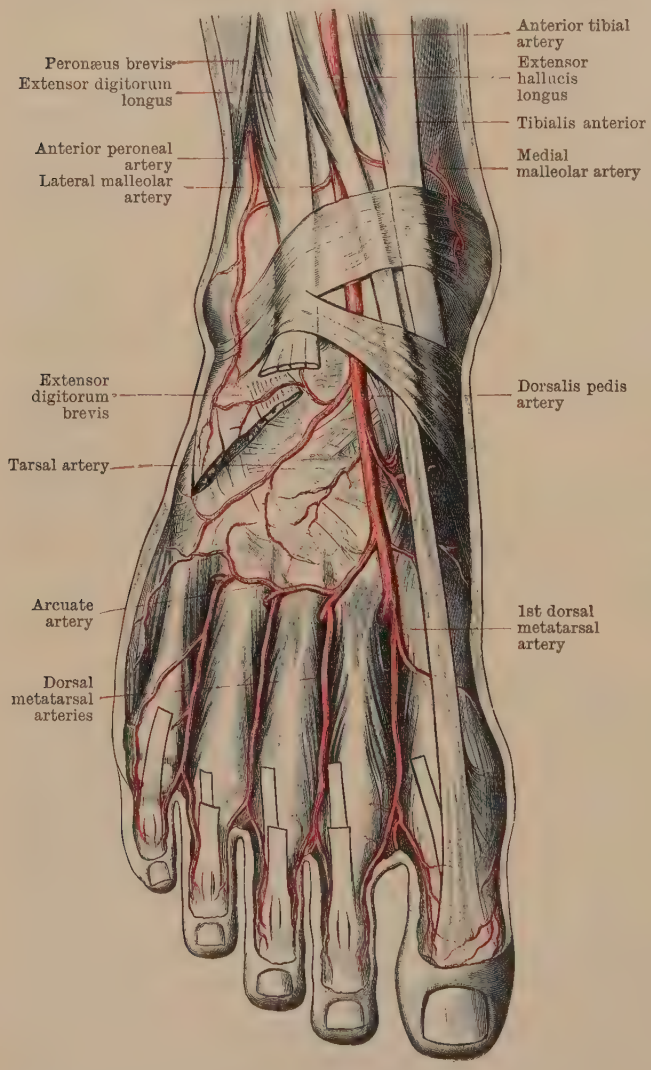

FIG. 759.—THE DORSALIS PEDIS ARTERY AND ITS BRANCHES.

(3) The **arcuate artery** arises opposite the first cuneiform bone. It runs laterally, on the bases of the metatarsal bones, deep to the long and short extensor tendons, supplies the extensor hallucis brevis and the extensor digitorum brevis, and anastomoses with branches of the lateral tarsal and lateral plantar arteries. It gives off three **dorsal metatarsal arteries**, second, third, and fourth, which run forwards on the muscles which occupy the three lateral interosseous spaces to the clefts of the toes, where each divides into two *dorsal digital branches* for the adjacent sides of the toes bounding the cleft to which it goes. The lateral side of the little toe receives a branch from the most lateral dorsal metatarsal artery. Each dorsal metatarsal artery gives off a *posterior perforating branch*, which passes through the posterior part of the intermetatarsal space, between the heads of the dorsal interosseous muscle, to anastomose with the plantar arch, and an *anterior perforating branch*, which passes through the anterior part of the space to anastomose with the corresponding plantar metatarsal artery.

(4) The **first dorsal metatarsal artery** is continued forwards from the dorsal artery of the foot, and runs on the dorsal surface of the first dorsal interosseous muscle. It ends by dividing into dorsal digital branches for the adjacent sides of the first and second toes. Before it divides it usually gives off a *dorsal digital branch* which passes, deep to the tendon of the extensor hallucis, to the medial side of the great toe.

(5) The **profunda branch** passes through the posterior end of the first intermetatarsal space, between the two heads of the first dorsal interosseous muscle, to the plantar aspect of the foot, where it unites with the lateral plantar artery and completes the plantar arch. As it unites with the lateral plantar artery it gives off the first plantar metatarsal artery (O.T. arteria magna hallucis), which passes forwards, along the first intermetatarsal space, to the base of the first interdigital cleft, where it divides into plantar digital arteries

for the adjacent sides of the great and second toes; before it divides it gives off a *plantar digital artery* to the medial side of the great toe.

Abnormalities.—The **anterior tibial artery** may be absent, its place being taken by branches of the posterior tibial and peroneal arteries. It is longer than normal when the popliteal artery divides at a more proximal level than usual, and in those cases it may pass either posterior or anterior to the popliteus muscle. Occasionally the anterior tibial artery and its dorsalis pedis continuation are larger than normal, and the terminal part of the dorsalis pedis takes the place, more or less completely, of the lateral plantar artery.

VENÆ.

Veins commence at the terminations of the capillaries. They converge towards the heart, and unite with one another to form larger and still larger vessels, until, finally, seven large trunks are formed which open into the atria of the heart. Three of the trunks, the **superior vena cava**, the **inferior vena cava**, and the **coronary sinus**, belong to the *systemic circulation*; they contain venous blood, and open into the right atrium. The remaining four, the **pulmonary veins**, belong to the *pulmonary circulation*; they return oxygenated blood from the lungs, and open into the left atrium.

In addition to the systemic and pulmonary veins, there is also a third group of veins, constituting the **portal system**, in which blood from the abdominal part of the alimentary canal, and from the spleen and pancreas, is conveyed to the liver. The portal system is further peculiar in that it both begins and ends in capillaries. From its terminal capillaries in the liver the *hepatic veins* arise, and as these open into the inferior vena cava the blood of the portal system is finally poured into the general systemic circulation. The hepatic veins also receive blood supplied to the liver by the hepatic arteries.

VENÆ PULMONALES.

The terminal **pulmonary veins** (Figs. 721 and 727), two on each side, open into the left atrium of the heart. Their tributaries arise in capillary plexuses in the walls of the pulmonary alveoli. By the union of the smaller veins larger vessels are formed which run along the anterior aspects of the bronchial tubes, and, uniting together, ultimately form a single efferent vessel in each lobe, which passes into the root of the lung. Thus there are five main pulmonary veins, but, immediately after entering the root of the lung, the vessels from the upper and middle lobes of the right lung join together, and so only four terminal pulmonary veins open into the left atrium of the heart. Neither the main stems nor their tributaries possess valves.

Relations.—In the root of the lung the upper pulmonary vein, on each side, lies below and in front of the pulmonary artery. The lower pulmonary vein, on each side, is in the lowest part of the root, and it is in a plane posterior to that in which the upper vein lies.

On the right side the upper pulmonary vein passes behind to the superior vena cava, and the lower passes behind the right atrium. They both terminate in the upper and posterior part of the left atrium close to the interatrial septum.

On the left side both upper and lower pulmonary veins cross anterior to the descending aorta, and they terminate in the upper and posterior part of the left atrium near its left border.

All four pulmonary veins perforate the fibrous layer of the pericardium, and receive partial coverings of the serous layer before they enter the atrium.

SYSTEMIC VEINS.

The **systemic veins** return blood to the right atrium of the heart through the superior vena cava, the inferior vena cava, and the coronary sinus. The two first-named receive blood from the veins of the body and limbs and from most of the abdominal and pelvic viscera. The coronary sinus receives blood from the veins of the walls of the heart alone.

General Arrangement.—The veins of the body wall and limbs form two groups —(1) the superficial veins; (2) the deep veins.

The **superficial veins** lie in the superficial fascia; they commence in the capillaries of the skin and subcutaneous tissues, and are very numerous. They frequently anastomose with one another, and they also communicate with the deep veins, in which, after piercing the deep fascia, they terminate. They may or may not accompany superficial arteries.

The **deep veins** accompany arteries, and are known as *venæ comites*. The large arteries have only one accompanying vein, but with the medium-sized and small arteries there are usually two venæ comites, which anastomose freely with each other by short transverse branches of communication.

Visceral veins usually accompany the arteries which supply viscera in the head, neck, thorax, and abdomen. As a rule there is only one vein with each visceral artery, and, with the exception of those which enter into the formation of the portal system, they terminate in the deep systemic veins.

SINUS CORONARIUS ET VENÆ CORDIS.

The **coronary sinus** (Fig. 721) is a short, but relatively wide, venous trunk which receives the majority of the veins of the heart. It lies in the inferior portion of the coronary sulcus, between the left atrium and the left ventricle, and it is covered superficially by some of the muscular fibres of the atrium.

It terminates in the lower and posterior part of the right atrium, between the orifice of the inferior vena cava on the right, and the right atrio-ventricular orifice anteriorly; an imperfect valve, consisting of one cusp, called the **valve of the coronary sinus (Thebesius)**, is situated at the right margin of the opening of the sinus into the atrium.

The apertures of the tributaries of the coronary sinus, except those of the great and small cardiac veins, are not provided with valves, and the valves of the two veins mentioned are often incompetent.

Tributaries.—(1) The **great cardiac vein** (Fig. 722) commences at the apex of the heart. It ascends, in the anterior interventricular sulcus, to the coronary sulcus; it then turns to the left, and, passing round the left margin of the heart, into the inferior part of the coronary sulcus, terminates in the left extremity of the coronary sinus. It receives tributaries from the walls of both ventricles and from the wall of the left atrium. It receives also the *left marginal vein*; that vein commences at the lower extremity of the left margin of the heart, along which it ascends to its termination.

(2) The **small cardiac vein** is very variable; as a rule it commences at the inferior margin of the heart and passes to the right to the coronary sulcus in which it turns to the left, on the inferior surface of the heart, and terminates in the right extremity of the coronary sinus. It receives tributaries from the walls of the right atrium and the right ventricle.

(3) The **oblique vein of the left atrium (Marshall)** (Fig. 721) is a small venous channel which descends obliquely, on the posterior wall of the left atrium, and terminates in the coronary sinus. Its orifice is not provided with a valve. It is of special interest, inasmuch as it represents the left superior vena cava of some other mammals, and is developed from the left duct of Cuvier.

(4) The **inferior cardiac vein of the left ventricle** runs along the inferior surface of the left ventricle and ends in the coronary sinus.

(5) The **middle cardiac vein** commences at the apex of the heart, and, passing posteriorly, in the inferior interventricular sulcus, terminates in the coronary sinus near its right extremity. It receives tributaries from the inferior parts of the walls of both ventricles.

Veins of the Heart which do not end in the Coronary Sinus.—(*a*) The **anterior cardiac veins** are two or three small vessels which ascend on the anterior wall of the right ventricle to the coronary sulcus, where they either end in the right atrium or terminate in the small cardiac vein. (*b*) The **venæ minimæ cordis.**—A number of small veins, which commence in the substance of the walls of the heart and terminate directly in its cavities, principally in the atria; some few, however, open into the ventricles.

VENA CAVA SUPERIOR AND ITS TRIBUTARIES.

The **superior vena cava** (Figs. 727 and 760) returns the blood from the head and neck, the upper extremities, the thoracic wall, and a portion of the upper part of the wall of the abdomen. It is formed, at the lower border of the first right costal cartilage, by the union of the two innominate veins, and it descends, with

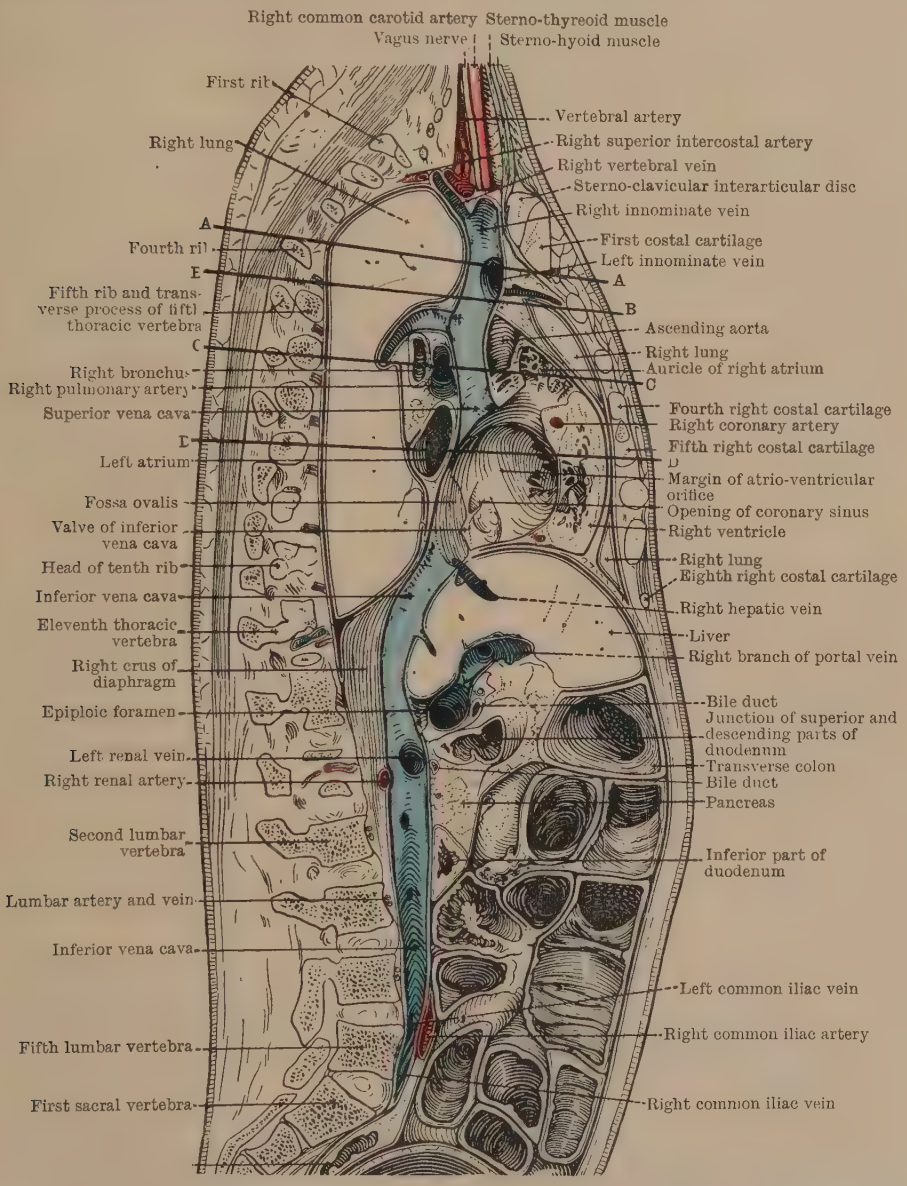

Fig. 760.—A Sagittal Lateral Section of the Body of a Young Male along the Lines of the Superior and the Inferior Venæ Cavæ.

a slight convexity to the right, to the level of the third right costal cartilage, where it opens into the upper and posterior part of the right atrium. It is about 75 mm. (three inches) long; in the lower half of its extent it is enclosed within the fibrous layer of the pericardium, and it is covered in front and on each side by the serous layer.

Relations.—It is overlapped *anteriorly* by the margins of the right lung and pleural

sac and by the ascending aorta. The lung and pleura intervene between it and the second and third costal cartilages, the internal intercostal muscles in the first and second intercostal spaces, and the internal mammary vessels. It is in relation *posteriorly* with the right margin of the trachea, the right vagus nerve, the vena azygos, which opens into it at right angles, the right bronchus, the right pulmonary artery, and the upper right pulmonary vein. On its *left side* are the ascending portion of the aorta, and the commencement of the innominate artery, whilst on the *right side* it is in close relation with the right pleura, the phrenic nerve and the pericardiaco-phrenic vessels intervening.

Tributaries.—In addition to the two innominate veins, by the union of which it is formed, the superior vena cava receives only one large tributary, viz., the vena azygos; but several small pericardial and mediastinal veins open into it.

Abnormalities.—The **superior vena cava** may develop on the left side instead of on the right. This peculiarity is due to the persistence of the left duct of Cuvier instead of that on the right side, and it is associated with absence of the coronary sinus, which is replaced by the lower part of the left superior vena cava. An exceptional case is recorded in which the opening of the coronary sinus into the heart was obliterated, and the cardiac veins terminated in a trunk which passed upwards to the left innominate vein. This trunk was obviously formed by enlargement of the left duct of Cuvier and the lower part of the left precardinal vein. Not very uncommonly, as the result of the persistence of both ducts of Cuvier, there are two superior venæ cavæ, the transverse anastomosis which usually forms the left innominate vein being small or entirely absent. In such cases the left innominate vein descends in the left part of the superior mediastinum, crosses the aortic arch, is joined by the left superior intercostal vein, and becomes the left superior vena cava; which descends anterior to the root of the left lung, and terminates in the lower and back part of the right atrium. It receives the great cardiac vein, and, turning to the back of the heart, replaces the coronary sinus. This arrangement is normal in many mammals. Occasionally in man the left superior vena cava terminates in the left atrium, and the coronary sinus, which represents a part of the sinus venosus, has been seen to have a similar ending; both these abnormal endings must be the result of malposition of the interatrial septum.

Vena Azygos and its Tributaries.

The **vena azygos** (Fig. 775) commences either from the posterior aspect of the inferior vena cava, at the level of the right renal vein, or as the direct upward continuation of an anastomosing channel which connects together the lumbar veins of the right side, and which is known as the *right ascending lumbar vein*. It ascends through the aortic orifice of the diaphragm, and is continued upwards through the posterior mediastinum. In the upper part of its course, it first passes posterior to the root of the right lung, and then arches anteriorly, above the root, to its termination in the posterior part of the superior vena cava, immediately before the latter vessel pierces the pericardium and at the level of the second costal cartilage. It frequently possesses imperfect valves.

Relations.—*In the abdomen* it lies on the anterior surfaces of the bodies of the upper lumbar vertebræ, posterior to the right crus of the diaphragm and the inferior vena cava, and to the right side of the cisterna chyli.

In the thorax it lies on the anterior surfaces of the bodies of the lower eight thoracic vertebræ, the intervening fibro-cartilages, and the anterior longitudinal ligament; and anterior to the right aortic intercostal arteries. In the lower part of the posterior mediastinum the right pleura and lung lie anterior to it; at a higher level it is overlapped by the right margin of the œsophagus, and immediately before its termination it is crossed by the root of the right lung.

On its left side it is in relation, in the greater part of its extent, with the thoracic duct and, as it arches anteriorly over the root of the lung, with the right vagus nerve and the trachea. About the level of the eighth thoracic vertebra it receives the accessory hemiazygos vein, whilst at the level of the ninth thoracic vertebra the hemiazygos vein opens into it.

In addition to the two veins last mentioned it receives the right posterior intercostal veins, except that from the first space but including the right superior intercostal vein, the right subcostal vein, and, through the ascending lumbar vein, the upper right lumbar veins. It also receives the right bronchial veins and some small œsophageal, pericardial, and mediastinal tributaries.

Tributaries.—(1) The **vena hemiazygos accessoria** is formed by the union of the fourth, fifth, sixth, seventh, and eighth left posterior intercostal veins. It lies on the left sides of the bodies of the fifth, sixth, and seventh thoracic vertebræ, and the corresponding intercostal arteries. It crosses the vertebral column, from left to right,

opposite the body of the eighth thoracic vertebra, passing posterior to the aorta, œsophagus, and thoracic duct; and it terminates either in the vena azygos or in the vena hemiazygos. In addition to its intercostal tributaries it receives the left bronchial veins, and some small posterior mediastinal veins, and it communicates with the left superior intercostal vein.

(2) The **vena hemiazygos** commences in the epigastric region of the abdomen. At its origin it is connected either with the left ascending lumbar vein or with the left renal vein. After piercing the left crus of the diaphragm it ascends, on the left sides of the bodies of the lower thoracic vertebræ, and, opposite the eighth or ninth thoracic vertebra, it turns to the right, crosses the front of the vertebral column, posterior to the aorta, œsophagus, and thoracic duct, and terminates in the vena azygos. As it ascends, on the bodies of the vertebræ, it lies lateral to the aorta, and medial to the roots of the splanchnic nerves, and anterior to the lower left intercostal arteries. Through the left ascending lumbar vein it receives blood from the upper lumbar veins of the left side; the left subcostal vein, the lower three posterior intercostal veins, and small mediastinal tributaries also terminate in it.

Abnormalities.—The **vena azygos** may be formed on the left side; it then arches over the root of the left lung, and terminates in the left end of the coronary sinus. This is the normal arrangement in some mammals, and it is due to the persistence of the cephalic end of the left postcardinal vein, the thoracic part of the left supracardinal vein, and the left duct of Cuvier.

Occasionally the azygos vein is the only vessel by which blood is returned to the heart from the lower limbs and the lower parts of the body walls. In such cases that portion of the inferior vena cava which usually extends from the right renal vein to the heart is absent and the azygos vein is the direct continuation of the inferior vena cava. This condition probably results from the absence of those parts of the inferior vena cava which are usually formed from the right vitelline and the right subcardinal veins, and to the enlargement of the whole of the right supracardinal vein.

The **hemiazygos** and the **accessory hemiazygos veins** may be absent. In such cases each left intercostal vein opens separately into the vena azygos. On the other hand the hemiazygos and the accessory hemiazygos veins may form a continuous trunk which may open by a transverse anastomosis into the azygos vein, or it may join the left innominate vein. When the hemiazygos and the accessory hemiazygos veins form a single trunk, which receives the left intercostal veins and opens into the left innominate vein, the condition is due to the persistence of the whole of the thoracic part of the left supracardinal vein and of the lower part of the left postcardinal vein.

Cases also occur in which the thoracic part of the postcardinal vein is represented by three instead of two stems, either the hemiazygos or the accessory hemiazygos vein being represented by two vessels.

(3) The **bronchial veins** do not quite correspond to the bronchial arteries, and they are not found on the walls of the smallest bronchi. On each side the tributaries run, anterior or posterior to the bronchial tubes to reach the root of the lung, where they unite, as a rule, into two small trunks; those of the right side open into the vena azygos, and those of the left into the accessory hemiazygos vein, or into the left superior intercostal vein. On both sides they are joined by tracheal and posterior mediastinal veins. Some few small bronchial veins, including most of those from the smaller tubes, open into the pulmonary veins.

(4) **Venæ Intercostales.**—There are two sets of **intercostal veins**, the anterior and the posterior.

The **anterior intercostal veins** are tributaries of the internal mammary or of the musculo-phrenic veins, and are described with those vessels (pp. 968, 969).

The **posterior intercostal veins** (Fig. 775) are eleven in number on each side. A single vein runs in each intercostal space; it is situated in the costal groove, above the corresponding artery.

On the right side the posterior intercostal vein of the first space accompanies the superior intercostal artery across the front of the neck of the first rib, and terminates in the vertebral or innominate vein. The second, third, and fourth posterior intercostal veins of the right side unite together to form a common trunk, the **right superior intercostal vein**, which terminates by joining the vena azygos. The fifth to the eleventh posterior intercostal veins of the right side open separately into the vena azygos.

On the left side the first posterior intercostal vein follows a course similar to that taken by the corresponding vein on the right side, and terminates in the left vertebral or innominate vein. The second, third, and sometimes the fourth posterior intercostal veins of the left side unite to form the **left superior intercostal vein**, which runs from behind forwards along the left or anterior aspect of the aortic arch. It passes obliquely between the left vagus and phrenic nerves, crosses the root of the left subclavian artery, and ends in the lower border of the left innominate vein. The fifth, sixth, seventh, and eighth, and

sometimes the fourth posterior intercostal veins of the left side terminate in the accessory hemiazygos vein, and the ninth, tenth, and eleventh end in the hemiazygos vein.

Each posterior intercostal vein is provided with valves, both at its termination and along its course, which prevent the blood flowing towards the anterior aspect of the thoracic wall. Its tributaries are derived from the adjacent muscles and bones, and a short distance from its termination it receives a posterior tributary which passes to it between the transverse processes of the vertebræ. This posterior vessel is formed by the union of small veins which issue from the muscles of the back, from the anterior and posterior spinal plexuses which lie respectively in front of the bodies and behind the arches of the vertebræ, and by venous channels which issue through the intervertebral foramina; the latter vessels commence in the vertebral canal, where they are connected with the anterior and posterior spinal veins.

Venæ Anonymæ.

The **innominate veins** (Figs. 760 and 727) are two in number, right and left. They return blood from the head and neck, the upper extremities, the upper part of the posterior wall of the thorax, the anterior wall of the thorax, and the upper part of the anterior wall of the abdomen. Each innominate vein commences behind the medial end of the clavicle of the corresponding side, and is formed by the union of the internal jugular and subclavian veins; the two innominate veins terminate by uniting together, at the lower border of the first costal cartilage of the right side, to form the superior vena cava. To reach that point the left vein has to pass from left to right behind the manubrium sterni, and it is therefore about three times as long as the right vein. The innominate veins do not possess valves.

The **right innominate vein** is a little more than 25 mm. (1 inch) in length. It descends almost vertically to the lower border of the first costal cartilage, and terminates in the superior vena cava.

Relations.—It is in relation, anteriorly, with the medial end of the clavicle and the sterno-hyoid and sterno-thyreoid muscles. It partly overlaps the innominate artery, which lies to its left side, and it is in front of the internal mammary artery, the right vagus nerve, and the upper end of the right pleural sac. The phrenic nerve and the accompanying vessels run along its right side, and intervene between it and the right pleural sac.

Tributaries.—In addition to the veins by the union of which it is formed, the right innominate vein receives the right vertebral and internal mammary veins, the first right posterior intercostal vein, and sometimes the right inferior thyreoid vein. The right lymphatic duct also opens into it.

The **left innominate vein** passes from left to right, with a slight obliquity downwards, behind the upper part of the manubrium sterni, to the lower border of the first right costal cartilage, where it terminates in the superior vena cava. It is about 60 to 75 mm. (3 inches) long.

Relations.—It is covered anteriorly, in the greater part of its extent, by the sterno-hyoid and sterno-thyreoid muscles, but at its right extremity it is slightly overlapped by the right pleura, and in the median plane the remains of the thymus intervene between it and the posterior surface of the sternum. It rests, posteriorly, upon the left pleura, the left internal mammary artery, the left subclavian artery, the left phrenic, and the left vagus nerves, the left superior cardiac branch of the sympathetic, the inferior cervical branch of the left vagus, the left common carotid artery, the trachea, and the innominate artery.

Its lower border is in relation with the arch of the aorta, and on its upper border it receives the inferior thyreoid vein of one or both sides.

Tributaries.—It receives the vertebral, internal mammary, inferior thyreoid, superior intercostal veins of its own side, the first left posterior intercostal vein, and some pericardial, thymic, anterior bronchial, and anterior mediastinal veins. Sometimes the right inferior thyreoid vein joins it, but not uncommonly that vessel terminates in the right innominate vein or in the commencement of the superior vena cava.

The thoracic duct opens into it just at the angle of junction of the internal jugular and subclavian veins.

The Internal Mammary Veins.—Each internal mammary artery is accompanied by venæ comites; they commence by the union of the venæ comites of the superior epigastric and musculo-phrenic arteries, between the sixth costal cartilage and the trans-

versus thoracis; and at the upper part of the thorax they fuse into a single vessel which enters the superior mediastinum and ends in the innominate vein of the same side.

The tributaries of the internal mammary veins are—(*a*) The **venæ comites** of the **superior epigastric** and **musculo-phrenic arteries**, which in their turn receive tributaries which correspond with the branches of the arteries they accompany. (*b*) Six **anterior perforating veins** which accompany the corresponding arteries, one lying in each of the upper six intercostal spaces. (*c*) Twelve **anterior intercostal veins** from the upper six intercostal spaces, two veins lying in each space with the corresponding branches of the internal mammary artery. (*d*) Small and irregular **pleural, muscular, mediastinal,** and **sternal veins.**

The internal mammary veins are provided with numerous valves which prevent the blood from flowing downwards.

The Superior Epigastric Veins.—The venæ comites of the superior epigastric artery receive tributaries from the substance of the rectus abdominis, the sheath of the muscle, and the superjacent skin and fascia; they pass, with the artery, between the sternal and costal origins of the diaphragm, and terminate in the internal mammary veins.

Musculo-phrenic Veins.—The venæ comites of the musculo-phrenic artery commence in the abdomen, pass through the diaphragm with the musculo-phrenic artery, and terminate in the internal mammary veins. They receive as tributaries the anterior intercostal veins of the seventh, eighth, and ninth intercostal spaces, and small venules from the substance of the diaphragm and walls of the abdomen.

The **vertebral veins** correspond only to the extra-cranial parts of the vertebral arteries. Each commences by the union of offsets from the intraspinal venous plexuses, and, issuing from the vertebral canal, passes across the posterior arch of the atlas, with the vertebral artery, to the foramen in the transverse process of the atlas. In the foramina in the cervical transverse processes, a plexus of venous channels surrounds the artery. At the lower part of the neck efferents from the plexus unite to form a single trunk which issues from the foramen in the transverse process of the sixth cervical vertebra, and descends, in the interval between the longus colli and scalenus anterior muscles, to terminate in the upper and posterior part of the innominate vein; at its termination there is a uni- or bi-cuspidate valve.

Relations.—In the first part of its course the vein lies in the sub-occipital triangle. The second, plexiform portion, is in the canal formed by the foramina in the transverse processes of the cervical vertebræ, and, with the artery, which it surrounds, lies anterior to the trunks of the cervical spinal nerves. The third part, in the root of the neck, is between the longus colli and scalenus anterior muscles, in front of the first part of the vertebral artery, and behind the internal jugular vein.

Tributaries.—In addition to the offsets from the intraspinal venous plexuses by the union of which it is formed, each vertebral vein receives the following tributaries: (*a*) Small vessels which issue from the muscles, ligaments, and bones of the deeper parts of the neck, and the lower and posterior part of the head. (*b*) Offsets from the intraspinal venous plexuses which pass out of the vertebral canal by the intervertebral foramina. (*c*) The **ascending cervical vein**, a vessel which is formed by the union of tributaries which issue from a venous plexus on the anterior aspects of the bodies and roots of the transverse processes of the cervical vertebræ. This vessel accompanies the ascending cervical artery, and terminates in the lower part of the vertebral vein, immediately after the latter has issued from the foramen in the sixth cervical transverse process. (*d*) The **deep cervical vein**; this commences in the sub-occipital triangle from a venous plexus with which the vertebral and occipital veins communicate. It descends, posterior to the transverse processes of the cervical vertebræ, in company with the profunda cervicis artery, turns forwards at the root of the neck, between the transverse processes of the sixth and seventh cervical vertebræ or between the latter and the neck of the first rib, and opens into the vertebral vein. It receives blood from the muscles, ligaments, and bones of the back of the neck. (*e*) The **posterior intercostal vein** from the first intercostal space sometimes opens into the vertebral vein.

Occasionally the venous plexus around the vertebral artery ends below in two terminal trunks, anterior and posterior, instead of one. In those cases the second terminal vessel lies behind the lower part of the vertebral artery, passes through the foramen in the transverse process of the seventh cervical vertebra, and turns forwards on the lateral side

of the artery to join the anterior trunk, thus forming a common terminal vein which ends in the usual manner.

The **inferior thyreoid vein** commences by the union of tributaries which issue from the isthmus and the corresponding lobe of the thyreoid gland. The two veins descend, along the front of the trachea, into the superior mediastinum, where the right inferior thyreoid vein terminates either in the right innominate vein or in the junction of the two innominate veins, and the left in the upper border of the left innominate vein; or the two veins unite to form a single trunk, which ends, usually, in the left innominate vein, but, occasionally, in the right. As they descend in the neck the inferior thyreoid veins anastomose together, and sometimes the anastomoses are so frequent that a venous plexus is formed in front of the lower cervical portion of the trachea.

VEINS OF THE HEAD AND NECK.

Vena Jugularis Interna (Figs. 727, 732, 763, 774 and 775).—Each **internal jugular vein** commences, in the posterior compartment of the jugular foramen, as the direct continuation of the transverse sinus, and terminates, behind the medial part of the clavicle, by uniting with the subclavian vein of the same side to form the innominate vein.

Its commencement, which is dilated, forms the *superior bulb* of the jugular vein. In the upper part of the neck it lies postero-lateral to the internal carotid artery and the last four cerebral nerves. As it descends it accompanies first the internal and then the common carotid artery. It inclines forwards as it descends, and gradually passes from its original position, behind and to the lateral side of the internal carotid artery, until it lies more completely to the lateral side of the internal and common carotid arteries, and, indeed, somewhat overlaps the latter anteriorly. This is more especially the case on the left side, for both internal jugular veins trend slightly towards the right as they descend; consequently, at the root of the neck, the right vein is separated from the right common carotid artery by a small interval filled with areolar tissue, whilst the left vein is more directly in front of the corresponding common carotid artery.

A dilatation, the *inferior bulb*, is present at the inferior extremity of the vein; it is bounded, either above or below, by a valve of two or three semilunar cusps. Sometimes both the superior and inferior ends of the bulb are bounded by valves.

Relations.—The vein lies anterior to the transverse processes of the cervical vertebræ, the rectus capitis lateralis, longus capitis, and scalenus anterior muscles, the ascending cervical artery, which runs upwards in the interval between the attachments of the two latter muscles, and the phrenic nerve; the transverse scapular and the transverse cervical arteries intervene between it and the scalenus anterior. At the root of the neck the vein lies in front of the first part of the subclavian artery and the origins of the vertebral artery and the thyreo-cervical trunk, and on the left side it is anterior to the terminal part of the thoracic duct.

On the antero-medial side of the internal jugular vein, immediately below the skull, are the internal carotid artery and the last four cerebral nerves; in the rest of its extent it is in relation, medially, first with the internal and then with the common carotid artery, whilst to its medial side and somewhat posteriorly, between it and the large arteries, lies the vagus nerve.

Each internal jugular vein is covered, superficially, in the whole of its length, by the sterno-mastoid muscle; near its upper end it is crossed by the styloid process, the stylo-pharyngeus and stylo-hyoid muscles, and the posterior belly of the digastric, whilst in its lower half, the omo-hyoid, the sterno-hyoid, and the sterno-thyreoid muscles are superficial to it, under cover of the sterno-mastoid. Just below the transverse process of the atlas, and under cover of the sterno-mastoid, the vein is crossed, on its lateral side, by the accessory nerve and by the occipital artery; about the middle of its course it is crossed by the communicans cervicis nerve, and near its lower end by the anterior jugular vein; the latter vessel, however, is separated from it by the sterno-hyoid and sterno-thyreoid muscles. Superficial to the vein are numerous deep cervical lymph glands.

Abnormalities.—The **internal jugular vein** may be either smaller or larger than normal. In either case compensatory changes in size occur in the transverse sinus and internal jugular vein of the opposite side, or in the external and anterior jugular veins of the same side.

Tributaries.—(*a*) A vein from the **cochlea** and (*b*) the **inferior petrosal sinus** join it near its commencement. (*c*) **Pharyngeal branches** from the venous plexus on the wall of the pharynx. (*d*) **Emissary veins** from the cavernous sinus. (*e*) The **common facial vein**, which receives the anterior and posterior facial veins. (*f*) The **lingual veins**, which return part of the blood from the tongue. (*g*) The **vena comitans hypoglossi**, which accompanies the hypoglossal nerve. (*h*) The **superior thyreoid vein**, which accompanies the corresponding artery. (*i*) The **middle thyreoid vein**, which passes backwards from the corresponding lobe of the thyreoid gland and crosses the middle of the lateral aspect of the common carotid artery. (*j*) The **occipital vein** occasionally terminates in the internal jugular vein. In many cases, however, it ends in the sub-occipital plexus, which is drained by the vertebral and deep cervical veins (see p. 969).

The **common facial vein** is formed by the union of the **anterior** and **posterior facial veins**. It accompanies the first part of the external maxillary artery in the carotid triangle, and terminates in the anterior border of the internal jugular vein. Just before it disappears beneath the sterno-mastoid, the common facial vein frequently gives off a large branch which descends along the anterior border of the sterno-mastoid to the supra-sternal fossa, where it joins the anterior jugular vein.

The **anterior facial vein** (Fig. 761) commences at the medial commissure of the eyelids as the *angular vein*, which is formed by the union of the supra-orbital and frontal veins. It passes downwards and backwards in the face, to the lower and anterior part of the masseter muscle, which it crosses, lying in the same plane as the external maxillary artery, but following a much straighter course. After crossing the lower border of the mandible it passes across the submaxillary triangle, superficial to the submaxillary gland, and separate from the external maxillary artery, which there lies in a deeper plane. It terminates, a short distance below the angle of the mandible, by uniting with the posterior facial vein to form the common facial vein.

The anterior facial vein receives tributaries corresponding with all the branches of the external maxillary artery, except the ascending palatine and the tonsillar, which have no accompanying veins, the blood from the region which they supply being returned for the most part through the pharyngeal plexus. The anterior facial vein also communicates with the pterygoid plexus around the external pterygoid muscle, by means of an anastomosing channel, called the **deep facial vein**, which passes posteriorly, between the masseter and buccinator muscles, into the infra-temporal fossa.

The **posterior facial vein**, see p. 974.

The **inferior thyreoid veins** have already been described (see p. 970).

Venæ Subclaviæ.—The **subclavian vein**, of each side, is the direct continuation of the main vein of the upper extremity, *i.e.* the axillary vein; but through its tributary, the external jugular vein, it receives blood both from the head and from the superficial parts of the neck.

From its commencement, at the external border of the first rib, it runs medially, below and anterior to the corresponding artery, from which it is separated by the lower part of the scalenus anterior muscle, and it terminates, behind the medial end of the clavicle, in the innominate vein of the corresponding side. As it passes medially it forms a slight curve, the convexity of which is directed upwards.

Each subclavian vein possesses a single bicuspid valve which is situated immediately to the distal side of the opening of the external jugular vein.

Relations.—The subclavian vein is in relation *anteriorly* with the posterior layer of the costo-coracoid membrane, which separates it from the subclavius muscle, and the nerve to the subclavius, and with the back of the medial end of the clavicle, from which it is partly separated, however, by the fibres of the sterno-hyoid and sterno-thyreoid muscles.

It is closely attached, anteriorly, to the posterior surface of the costo-coracoid membrane; consequently it is expanded when the clavicle is moved forwards, an arrangement which constitutes a distinct danger when operations are being performed in the neighbourhood of the vein; for, in the event of the vessel being wounded, forward movement of the clavicle may cause air to be sucked into the vein, with fatal results.

Posterior to the vein, and on a higher plane, is the first part of the subclavian artery,

but it is separated from the second part by the scalenus anterior. As soon as it reaches the medial border of the anterior scalene the subclavian vein unites with the internal jugular vein, immediately anterior to the internal mammary artery.

The upper surface of the first rib is *below* the vein.

Tributaries.—Whilst the subclavian vein is the direct continuation of the axillary vein, and receives, therefore, the blood from the upper extremity, it has, as a general rule, only one named tributary, viz., the external jugular vein.

Vena Jugularis Externa.—The **external jugular vein** (Fig. 761) is formed on the superficial surface of the sterno-mastoid muscle, a little below and posterior to

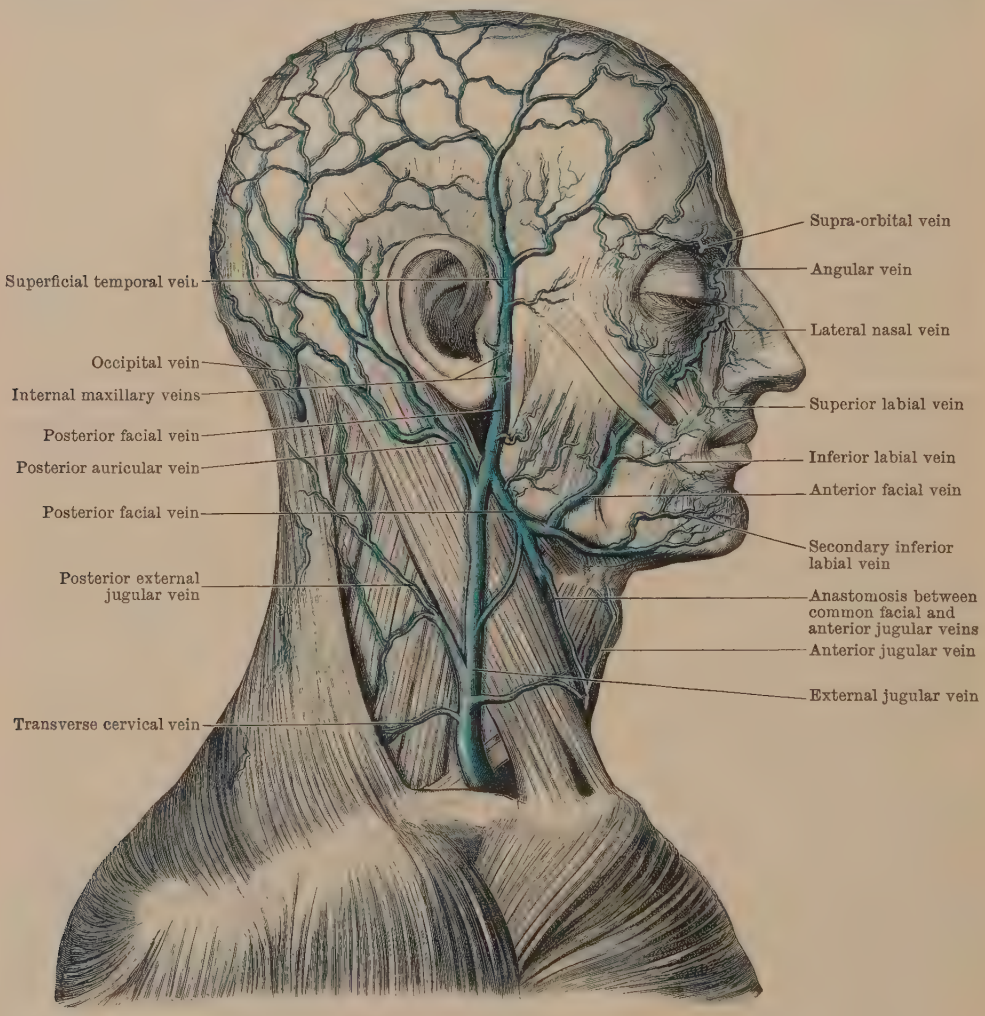

Fig. 761.—Superficial Veins of the Head and Neck.

the angle of the mandible, by the union of the posterior auricular vein with a branch from the posterior facial vein. In many cases the branch from the posterior facial vein is so preponderantly large that it is more correct to describe the external jugular vein as commencing as a branch of the posterior facial vein. After its formation the external jugular vein descends, with a slight obliquity backwards, to the anterior part of the subclavian portion of the posterior triangle of the neck, where it pierces the deep fascia, crosses in front of the third part of the subclavian artery, and terminates in the subclavian vein.

Whilst on the surface of the sterno-mastoid muscle it is covered by the superficial fascia, and platysma muscle, and it lies parallel with the great auricular nerve; after crossing the nervus cutaneus colli it reaches the posterior border of

the sterno-mastoid, where it receives a tributary called the **posterior external jugular vein**, which commences in the superficial tissues of the upper and back part of the neck, and runs downwards and forwards, across the roof of the upper part of the posterior triangle, to its termination in the external jugular vein.

As the external jugular vein pierces the deep cervical fascia in the subclavian triangle, its wall is closely attached to the margin of the opening through which it passes; and as it is crossing in front of the third part of the subclavian artery it is joined by the transverse scapular, transverse cervical, and anterior jugular veins.

There are usually two valves in the lower part of the vein—one, at its termination, which is generally incompetent, and a second at a higher level.

Abnormalities.—The **external jugular vein** is sometimes absent, or it may be smaller than usual; in both cases either the anterior or the internal jugular vein is enlarged. In some of the cases in which the external jugular vein is small it receives no communication from the posterior facial vein, but is merely the continuation of the posterior auricular vein. On the other hand, it may be enlarged, and receive the whole of the posterior facial vein.

Tributaries.—In addition to the posterior auricular vein and the branch from the posterior facial vein by which it is formed, the external jugular vein receives the posterior external jugular vein, which has already been described, the transverse cervical and transverse scapular veins from the region of the shoulder, and the anterior jugular vein. Occasionally the cephalic vein also opens into it.

The **posterior auricular vein** (Fig. 761) receives tributaries from the posterior parts of the parietal and temporal regions and from the medial surface of the auricle. It is considerably larger than the posterior auricular artery, which it accompanies only in the scalp. At the base of the scalp it leaves the artery and descends in the superficial fascia, over the upper part of the sterno-mastoid, to join the external jugular vein.

The **transverse cervical** and **transverse scapular veins** accompany the corresponding arteries; not infrequently they open directly into the subclavian vein.

The **anterior jugular vein** commences in the submental region, and is formed by the union of small veins from the lower lip and chin. It descends, in the superficial fascia, at a variable distance from the median plane, perforates the superficial layer of the deep fascia, a short distance above the sternum, and enters the suprasternal space (Burns) between the first and second layers of the deep fascia. In the space it anastomoses with its fellow of the opposite side and receives a communication from the common facial vein. Then it turns laterally, between the sterno-mastoid superficially and the sterno-hyoid, sterno-thyreoid, and scalenus anterior muscles deeply, and terminates in the external jugular vein at the posterior border of the sterno-mastoid.

Abnormalities.—The **anterior jugular vein** may be absent, or it may be unusually large, especially in the lower part of its extent, and after it has received an occasional tributary from the common facial vein.

The external jugular vein sometimes receives the occipital vein or a communication from it.

The Veins of the Scalp.

The veins which drain the blood from the superficial parts of the scalp are the frontal, the supra-orbital, the superficial temporal, the posterior auricular, and the occipital. The blood from the deeper part of the scalp, in the region of the temporal fossa, on each side, passes into the deep temporal veins, which are tributaries of the pterygoid plexus.

The **frontal** and **supra-orbital veins** receive blood from the medial and anterior part of the scalp. They unite together, near the medial commissure of the eyelids, to form the *angular vein*; before the union is effected the supra-orbital vein sends a branch backwards, through the supra-orbital notch, into the orbital cavity, where it terminates in the ophthalmic vein, and as this branch passes through the notch it receives the frontal diploic vein (p. 975).

The **superficial temporal vein** (Figs. 732, 761) is formed by frontal and parietal tributaries which accompany the corresponding branches of the superficial temporal artery. They drain the lateral frontal, the superficial part of the temporal, and the anterior part of the parietal region of the scalp, and unite to form a single trunk which descends to the upper border of the zygoma, immediately anterior to the auricle, where it terminates in the posterior facial vein (see p. 974).

The **posterior auricular vein** drains the posterior portions of the temporal and parietal areas of the scalp (see above).

The **occipital vein** (Figs. 732, 761) receives tributaries from the parietal and occipital regions. As a rule it pierces the occipital origin of the trapezius, and, passing into the sub-occipital triangle, terminates in a plexus of veins which is drained by the vertebral and deep cervical veins. It sometimes communicates with the external jugular vein, and occasionally an offset from it accompanies the corresponding artery and ends in the internal jugular vein.

It generally receives the mastoid emissary vein; one of its tributaries receives the parietal emissary vein, and occasionally an emissary vein from the confluens sinuum (O.T. torcular Herophili) opens into it.

The Veins of the Orbit, the Nose, and the Infra-temporal Region.

The veins of these three regions are closely associated together; for although the orbital blood is returned, for the most part, to the cavernous sinus by the ophthalmic vein, the latter vein is closely connected with the pterygoid plexus, which lies in the infra-temporal region.

Veins of the Orbit.—The veins of the orbit correspond, with the exception of the naso-frontal vein, with the branches of the ophthalmic artery, and they gradually converge, as they pass backwards in the orbit, until they form two main trunks, a **superior ophthalmic vein** and an **inferior ophthalmic vein**. The two trunks terminate separately, or by a single stem, in the anterior end of the cavernous sinus, to which they pass through the superior orbital fissure, and between the two heads of the lateral rectus muscle.

The superior ophthalmic vein communicates, at the supero-medial angle of the orbit, with the angular vein, and it receives the naso-frontal vein which accompanies the frontal nerve. The inferior ophthalmic vein communicates, through the inferior orbital fissure, with the pterygoid plexus.

Veins of the Nose.—The veins of the walls of the nasal cavity end partly in the ethmoidal tributaries of the superior ophthalmic vein, partly in the septal affluent of the superior labial and in the lateral nasal veins, both of which are tributaries of the anterior facial vein; but the majority of the veins of the nose, both from the septal and lateral walls, join together to form a spheno-palatine vein which passes through the spheno-palatine foramen and the pterygo-palatine fossa, and terminates in the pterygoid plexus.

The Pterygoid Plexus and the **Internal Maxillary Vein.**—The **pterygoid plexus** of veins lies in the infra-temporal and pterygoid fossæ. It covers the lateral surface of the internal pterygoid muscle, and surrounds the external pterygoid. It receives tributaries which correspond with and accompany the branches of the internal maxillary artery—viz., spheno-palatine, pharyngeal, vein of pterygoid canal, infra-orbital, posterior superior alveolar, descending palatine, buccinator, two or three deep temporal, pterygoid, masseteric, and inferior alveolar veins, and the middle meningeal vein. It communicates, superiorly, with the cavernous sinus through the foramen ovale; anteriorly with the inferior ophthalmic vein through the inferior orbital fissure; and between the masseter and the buccinator with the anterior facial vein by the deep facial anastomosing branch. It also communicates posteriorly and medially, on the medial side of the internal pterygoid, with the pharyngeal plexus, and it terminates posteriorly in the internal maxillary vein.

The **internal maxillary vein** is a short vessel which accompanies the first part of the internal maxillary artery, between the spheno-mandibular ligament and the neck of the mandible. Between the neck of the mandible and the antero-medial surface of the parotid gland it joins the upper part of the posterior facial vein. Occasionally the internal maxillary vein is double, and sometimes it is represented by several channels.

The **posterior facial vein** is formed, immediately above the zygomatic arch, by the union of the superficial and middle temporal veins. It crosses the zygomatic arch, dips deep to the upper part of the parotid gland, and, whilst lying between the

antero-medial surface of the gland and the posterior border of the mandible, it receives the internal maxillary vein or veins. Then it descends, through the substance of the parotid, and, emerging from its lower end at the angle of the mandible, it passes forwards and downwards to unite with the anterior facial vein in the formation of the common facial vein.

Whilst it is in the substance of the parotid it gives off a comparatively large branch, which emerges from the lower and posterior part of the gland and forms one of the two commencing tributaries of the external jugular vein.

Abnormalities.—The **posterior facial vein** may terminate entirely in the common facial vein, or in the external or the internal jugular vein. It may be very small, and occasionally it is absent.

VENOUS SINUSES AND VEINS OF THE CRANIUM AND OF ITS CONTENTS.

The venous channels met with in the cranial walls and cranial cavity are:—

(1) The diploic veins, which lie in the spongy tissue between the outer and inner tables of the cranial bones.

(2) The meningeal veins, which accompany the meningeal arteries in the outer layer of the dura mater.

(3) The veins of the brain, which lie between the folds of pia mater and in the subarachnoid space.

(4) The cranial venous sinuses, channels which are situated between the outer and inner layers of the dura mater; they receive the blood from the terminal cerebral veins.

Diploic and Meningeal Veins.

The **diploic veins** are anastomosing spaces in the spongy tissue of the flat

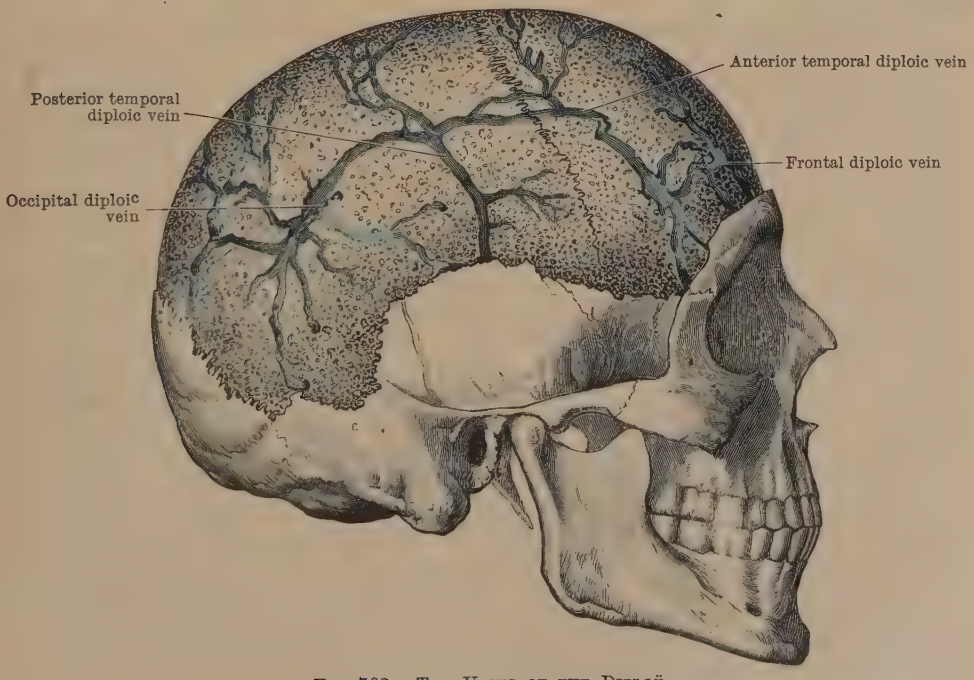

Fig. 762.—The Veins of the Diploë.

bones of the skull; they are lined with endothelium. The number of efferent vessels which emerge from the diploic spaces is not constant, but usually there are at least four on each side—viz., a frontal, two temporal, anterior and posterior, and an occipital.

The **frontal diploic vein** is one of the most constant; it drains the anterior part

of the frontal bone, passes through a small aperture in the upper margin of the supra-orbital notch, and terminates in the supra-orbital vein.

The **anterior temporal diploic vein** drains the posterior part of the frontal bone and the anterior part of the parietal bone; it pierces the great wing of the sphenoid, and terminates either in the spheno-parietal sinus or in the anterior deep temporal vein.

The **posterior temporal diploic vein** drains the posterior part of the parietal bone; it runs downwards to the posterior inferior angle of the parietal bone and terminates in the transverse sinus, to which it passes either through a foramen in the inner table of the parietal bone or through the mastoid foramen.

The **occipital diploic vein** is usually the largest of the series; it drains the occipital bone, and terminates either externally in the occipital vein or internally in the lateral sinus.

Venæ Meningeæ.—The **meningeal veins** commence in two capillary plexuses, a deep and a superficial. The deep plexus is a wide-meshed network in the inner layer of the dura mater. Its efferent vessels terminate in the superficial plexus. The superficial plexus lies in the outer layer of the dura mater. It consists of numerous vessels of uniform calibre which frequently anastomose together, and terminate in two sets of efferents; of these, one set ends in the cranial blood sinuses, and the other accompanies the meningeal arteries. The efferent meningeal veins are peculiar, inasmuch as they do not alter much in size as they approach their terminations. They lie external to the arteries in the grooves in the inner wall of the cranium, and are very liable to be torn when the bones are fractured (Wood Jones).

Veins of the Brain.

The veins of the brain include the veins of the cerebrum, of the mid-brain, of the cerebellum, of the pons, and of the medulla oblongata. They do not possess valves.

The Veins of the Cerebrum.—The **cerebral veins** are arranged in two groups, (*a*) the deep and (*b*) the superficial.

The deep veins issue from the substance of the brain. The superficial veins lie upon its surface in the pia mater and the subarachnoid space. The terminal trunks of both sets pierce the arachnoid membrane and the inner layer of the dura mater, and open into the cranial venous sinuses.

(*a*) The **deep cerebral veins** are the chorioid veins, the venæ terminales, the internal cerebral veins, the great cerebral vein (Galen), the vein of the septum pellucidum and the inferior striate veins.

Each **chorioid vein** is formed by the union of tributaries which issue from the chorioid plexus in the body and inferior horn of a lateral ventricle. It ascends, along the lateral border of the tela chorioidea of the third ventricle (O.T. velum interpositum), and passes forwards, in the lateral border of that fold of pia mater, to the interventricular foramen (Monro), where it receives efferents from the chorioid plexus of the third ventricle, and unites with the vena terminalis to form the internal cerebral vein (Galen).

The **vena terminalis** (O.T. **vein of corpus striatum**), on each side, is formed by the union of tributaries which issue from the corpus striatum and from the thalamus. It runs forwards between the thalamus and the caudate nucleus, in a groove in the floor of the lateral ventricle, and, after receiving tributaries from the walls of the anterior horn of the ventricle, and the vein of the septum pellucidum, it terminates at the apex of the tela chorioidea, where it joins the chorioid vein to form the internal cerebral vein (Galen).

Each **internal cerebral vein** (Galen) commences at the apex of the tela chorioidea, near the interventricular foramen (Monro), by the union of the vena terminalis with the chorioid vein. The two veins run backwards between the layers of the tela, receiving tributaries from the chorioid plexuses of the third ventricle and from the fornix and corpus callosum, and they terminate, beneath the splenium of the corpus callosum, by uniting to form the great cerebral vein (Galen).

The **great cerebral vein (Galen)** passes backwards and slightly upwards from its origin, and ends in the anterior extremity of the straight sinus. In addition to the two internal cerebral veins, by the union of which it is formed, it receives tributaries from the posterior parts of the gyrus cinguli of each side, from the pineal and quadrigeminate bodies, from the medial and inferior surfaces of the occipital lobes of the brain, and from the upper surface of the cerebellum. It also receives the basal vein of each side (see below).

An **inferior striate vein** descends, on each side, from the substance of the corpus striatum, and, after passing through the anterior perforated substance, ends in the basal vein, which, as already stated, is a tributary of the great cerebral vein.

(*b*) The **superficial cerebral veins** are more numerous and of larger calibre than the cerebral arteries. They lie upon the surface of the cerebrum, drain blood from the cerebral cortex, and they are divisible into two sets, the superior and the inferior.

The **superior cerebral veins**, twelve or more in number, lie in the pia mater and subarachnoid space on the upper and lateral aspect of the cerebral hemispheres. They run upwards and medially, to the margin of the longitudinal fissure where they receive tributaries from the medial surface of the hemisphere, and they terminate in the superior sagittal sinus or in the lateral lacunar expansions of the sinus. The anterior veins of this set are small and run transversely, but the posterior are large and run obliquely forwards and medially; they are embedded for some distance in the wall of the sinus, and their orifices are directed forwards against the blood stream.

The **inferior cerebral veins** lie on the lower and lateral aspects of the cerebral hemispheres; they run downwards and medially, and terminate in the sinuses which lie at the base of the skull—viz., the cavernous, the superior petrosal, and the transverse sinuses. One of these veins, the **superficial middle cerebral vein**, runs along the posterior horizontal branch and the stem of the lateral fissure (Sylvius) to the cavernous sinus; occasionally it is united by an anastomotic loop, known as the **great anastomotic vein** (Trolard), with the superior sagittal sinus, and sometimes by the **inferior anastomotic vein** with the transverse sinus.

The **anterior cerebral vein** of each side lies in the longitudinal fissure, and accompanies the corresponding anterior cerebral artery; it receives tributaries from the corpus callosum and the gyrus cinguli. Turning downwards, round the genu of the corpus callosum, it reaches the base of the brain, and terminates in the basal vein.

The **deep middle cerebral vein** lies deeply in the lateral fissure (Sylvius); it anastomoses freely with the superficial middle vein, receives tributaries from the insula and the adjacent opercula, and terminates in the basal vein.

The **basal vein** commences at the anterior perforated substance; it is formed by the union of the anterior cerebral vein with the deep middle vein and with the inferior striate vein. Passing backwards round the pedunculus cerebri, it terminates in the great cerebral vein (Galen). Its tributaries are derived from the tuber cinereum, the corpus mamillare, the posterior perforated substance, the uncus, the inferior cornu of the lateral ventricle, and the pedunculus cerebri.

Veins of the Mid-brain.—The veins of the mid-brain terminate for the most part either in the great cerebral vein (Galen) or in the basal veins.

Cerebellar Veins.—These veins also are divisible into two groups, the superficial and the deep. The former are quite independent of and much more numerous than the arteries. They form two sets, the superior and the inferior.

The **superior superficial cerebellar veins** terminate in a single median or vermian efferent vessel which is sometimes double, and in several lateral efferents. The superior vermian vein runs anteriorly and ends in the great cerebral vein (Galen). The lateral superior cerebellar veins terminate in the transverse sinuses or in the superior petrosal sinuses.

The **inferior superficial cerebellar veins** also form a small vermian and numerous lateral efferents; the former runs backwards and joins either the straight sinus or one of the transverse sinuses, and the latter end in the inferior petrosal and occipital sinuses.

The **deep cerebellar veins** issue from the substance of the cerebellum and terminate in the superficial veins.

Veins of the Pons.—The deep veins from the substance of the pons pass forwards to its anterior surface, where they become superficial, and, anastomosing together, form a plexus which is drained by superior and inferior efferent veins. The superior efferent veins join the basal vein; the inferior efferent veins either unite with the cerebellar veins, or they open into the superior petrosal sinus.

Veins of the Medulla Oblongata.—Deep veins of the medulla oblongata issue from its substance and end in a superficial plexus. This plexus is drained by an anterior and a posterior median vein and by radicular veins.

The **anterior median vein** is continuous below with the corresponding vein of the spinal medulla; it communicates above with the plexus on the surface of the pons.

The **posterior median vein** is continuous below with the posterior median vein of the spinal medulla, from which it ascends to the lower end of the fourth ventricle, where it divides into two branches which join the inferior petrosal sinus or basilar plexus.

The **radicular veins** issue from the lateral parts of the plexus and run with the roots of the last four cerebral nerves; they end in the inferior petrosal and occipital sinuses or in the upper part of the internal jugular vein.

Sinus Duræ Matris.

The **venous sinuses** of the cranium are spaces between the layers of the dura mater; and they are lined with an endothelium which is continuous with the endothelium of the veins. They receive the veins of the brain, communicate frequently with the meningeal veins and with veins external to the cranium, and terminate directly or indirectly in the internal jugular vein. Some of the cranial blood sinuses are unpaired, others are paired.

Unpaired Sinuses.—These are the superior sagittal, the inferior sagittal, the straight, the anterior and posterior intercavernous, and the basilar.

The **superior sagittal sinus** commences in the anterior fossa of the cranium, at the crista galli, where it communicates, through the foramen cæcum, with the veins of the nasal cavity or with the angular vein. It passes backwards in the convex margin of the falx cerebri, grooving the frontal, both the parietal bones, and upper part of the occipital. As it descends along the occipital bone it usually passes slightly to the right side, and it ends, at the level of the internal occipital protuberance, by becoming the right transverse sinus. Instead of passing to the right, it occasionally turns to the left, and ends in the left transverse sinus, and in some cases it bifurcates and ends in both transverse sinuses. When it ends wholly in the right or the left transverse sinus its termination is associated with a well-marked dilatation, the *confluens sinuum*, which is lodged in a depression at one side of the internal occipital protuberance. The confluens sinuum is connected, across the protuberance, by an anastomosing channel, with a similar dilatation which marks the junction of the straight sinus with the lateral sinus of the opposite side. Opening into the superior sagittal sinus are the superior cerebral veins, and it communicates on each side by small openings with a series of spaces in the dura mater, the **lacunæ laterales**, into which the arachnoideal granulations project. It also communicates, by emissary veins, which pass through the foramen cæcum and through each parietal foramen, with the veins on the exterior of the cranium. Its cavity, which is triangular in transverse section, is crossed by several fibrous strands called the **chordæ Willisii.**

The **inferior sagittal sinus** lies, usually, in the posterior two-thirds of the lower free margin of the falx cerebri. It terminates posteriorly by joining with the great cerebral vein (Galen) to form the straight sinus. It receives tributaries from the falx cerebri and from the medial surface of the middle third of each cerebral hemisphere.

Sinus Intercavernosi.—The **anterior intercavernous sinus** is a small transverse channel which crosses from one cavernous sinus to the other in the anterior border of the diaphragma sellæ.

The **posterior intercavernous sinus** also connects the two cavernous sinuses together. It lies in the posterior border of the diaphragma sellæ.

The anterior and posterior intercavernous sinuses and the intervening parts of the cavernous sinuses form collectively the **circular sinus.**

The **basilar plexus** is situated in the dura mater on the basilar part of the occipital bones. It connects the posterior ends of the cavernous or the anterior ends of the inferior petrosal sinuses together, and communicates below with the anterior spinal veins.

The **straight sinus** is formed by the union of the inferior sagittal sinus with the great cerebral vein (Galen). It runs downwards and backwards, along the line

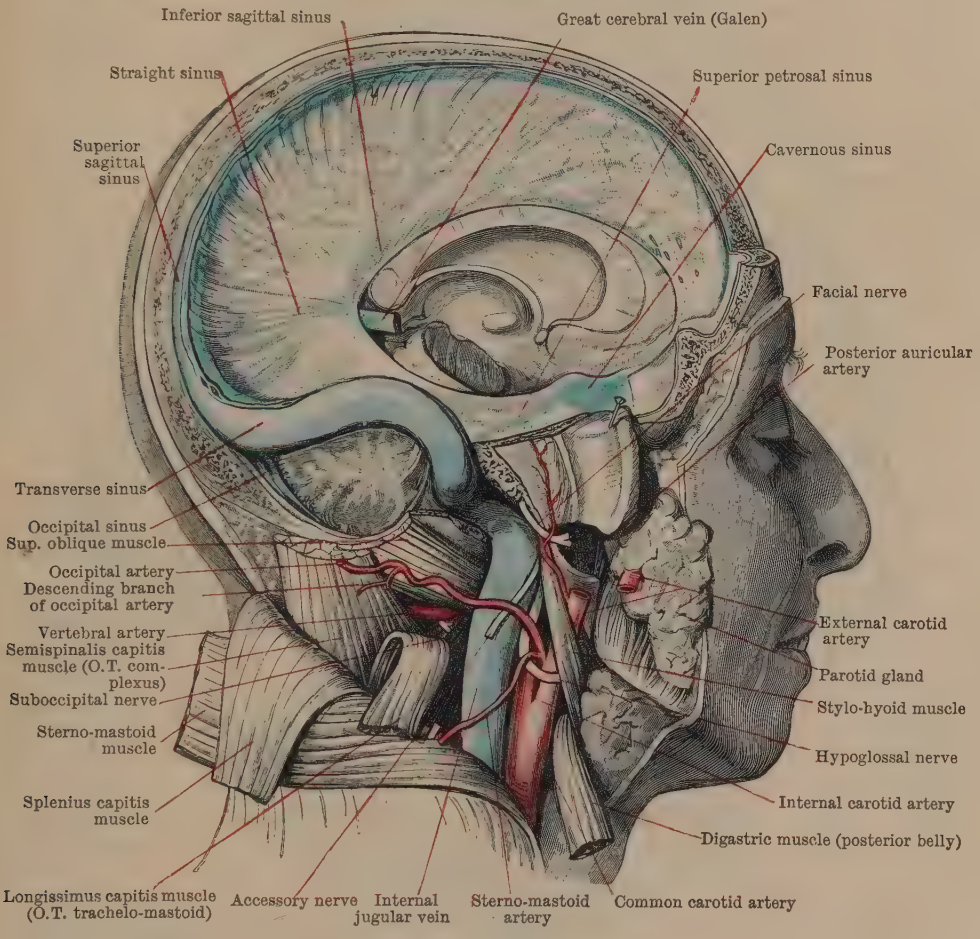

FIG. 763.—DISSECTION OF THE HEAD AND NECK, showing the cranial blood sinuses and the upper part of the internal jugular vein.

of union between the falx cerebri and the tentorium cerebelli. As a general rule it turns to the left at the internal occipital protuberance, dilates somewhat, and becomes continuous with the left transverse sinus, its dilatation being united with the corresponding dilatation on the lower end of the superior sagittal sinus, the "confluens sinuum," by a transverse anastomosing channel. Occasionally the straight sinus terminates in the right lateral sinus; in that case the superior sagittal sinus ends in the left transverse sinus; and sometimes it bifurcates to join both transverse sinuses. It receives some of the superior cerebellar veins and a few tributaries from the falx cerebri.

Paired Sinuses.—There are six pairs of sinuses, viz., the transverse, the occipital, the cavernous, the superior petrosal, the inferior petrosal, and the spheno-parietal.

Transverse Sinuses.—Each **transverse sinus** commences at the internal occipital protuberance, the right usually as the continuation of the superior sagittal, and the left as the continuation of the straight sinus. Each passes laterally in the postero-lateral part of the attached border of the tentorium cerebelli and in a groove in the occipital bone. From the lateral angle of the occipital bone it passes to the posterior inferior angle of the parietal bone, which it grooves;

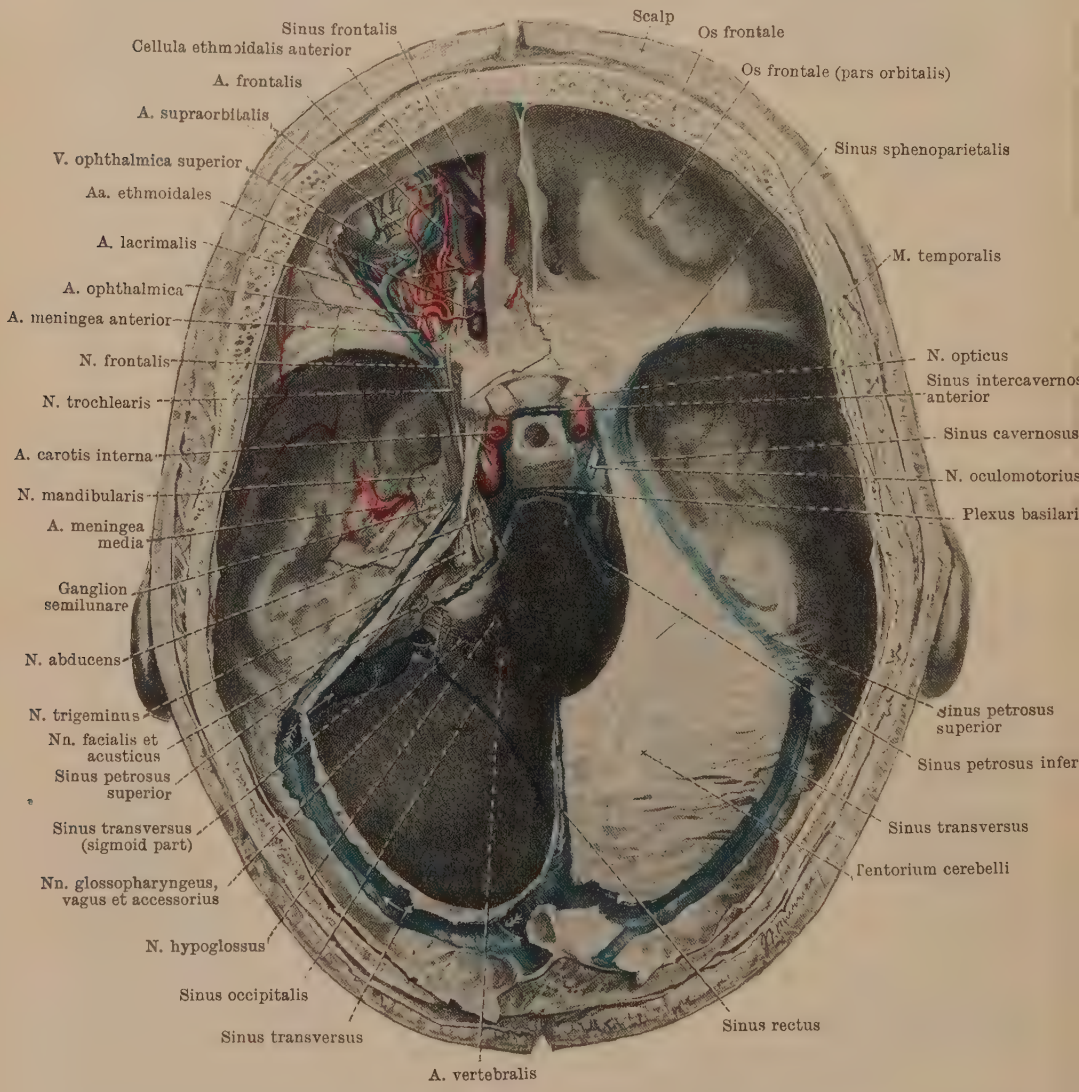

FIG. 764.—THE LOWER BLOOD SINUSES OF THE DURA MATER.

In the specimen represented the superior sagittal sinus opened into both transverse sinuses and chiefly into the left. The straight sinus also opened into both transverse sinuses. The medial part of the left transverse sinus was divided by a horizontal septum into upper and lower parts. The arrow in the figure passes below the septum.

then it leaves the tentorium and turns downwards on the inner surface of the mastoid portion of the temporal bone; from the latter it passes to the upper surface of the jugular process of the occipital bone, and turns forwards and then downwards into the jugular foramen, where it becomes continuous with the internal jugular vein. The part which descends on the temporal bone and turns forwards on the jugular process of the occipital is called the sigmoid sinus.

Its tributaries are some of the superior and inferior cerebellar veins, a posterior diploic vein, and the superior petrosal sinus. It is connected with the veins out-

side the cranium by emissary veins which pass through the mastoid foramen and the condyloid canal.

The **occipital sinuses** lie in the attached border of the falx cerebelli and in the dura mater along the postero-lateral boundaries of the foramen magnum; frequently they unite above and open by a single channel into the commencement of either the right or the left transverse sinus, but their upper extremities may remain separate, and then each communicates with the commencement of the transverse sinus of its own side. On the other hand, either the right or the left sinus may be absent. Each opens below into the terminal part of the corresponding transverse sinus, and both communicate with the posterior spinal veins. Each occipital sinus is an anastomosing channel between the upper and lower extremities of the transverse sinus of the same side, and each receives a few inferior cerebellar veins.

The **cavernous sinuses** lie at the sides of the body of the sphenoid bone. Each sinus commences, anteriorly, at the medial end of the superior orbital fissure, where it receives the corresponding ophthalmic veins, and it terminates, at the apex of the petrous portion of the temporal bone, by dividing into the superior and the inferior petrosal sinuses. Its cavity, which is irregular in size and shape, is so divided by numerous fibrous strands that it assumes the appearance of cavernous tissue; and in its lateral wall are embedded the internal carotid artery with its sympathetic plexus, the oculo-motor, the trochlear, the ophthalmic and maxillary divisions of the trigeminal and the abducent nerves. Its tributaries are the ophthalmic vein, the spheno-parietal sinus and the inferior cerebral veins, including the middle cerebral vein. It communicates with the opposite cavernous sinus by means of the anterior and posterior intercavernous sinuses; with the pterygoid plexus, in the infra-temporal fossa, by an emissary vein which passes either through the foramen ovale or through the foramen Vesalii; with the internal jugular vein by small venous channels which accompany the internal carotid artery through the carotid canal, and by the inferior petrosal sinus; with the transverse sinus by the superior petrosal sinus; and through the superior ophthalmic vein with the angular vein.

The **spheno-parietal sinuses** are lodged in the dura mater on the under surfaces of the small wings of the sphenoid bone close to their posterior borders. Each sinus communicates with the middle meningeal veins, receives veins from the dura mater, and terminates in the anterior part of the corresponding cavernous sinus.

The Superior Petrosal Sinuses.—Each **superior petrosal sinus** commences at the apex of the petrous portion of the temporal bone, in the posterior end of the corresponding cavernous sinus, and it runs backwards and laterally, in the attached margin of the tentorium cerebelli, above the trigeminal nerve. It grooves the superior angle of the petrous portion of the temporal bone, at the lateral end of which it terminates in the transverse sinus, at the point where the latter is turning downwards on the medial surface of the mastoid portion of the temporal bone. It receives inferior cerebral, superior cerebellar, tympanic, and diploic veins.

The Inferior Petrosal Sinuses.—An **inferior petrosal sinus** commences at the posterior end of each cavernous sinus; it runs backwards, laterally, and downwards, in the posterior fossa of the cranium, in a groove formed by the lower angle of the petrous part of the temporal bone and the adjacent border of the basilar part of the occipital bone, to the anterior compartment of the jugular foramen of the same side, through which it passes. It crosses the last four cerebral nerves either on their lateral or on their medial sides, and it terminates in the internal jugular vein. Its tributaries include inferior cerebellar veins and veins from the internal ear, which pass to it through the internal acoustic meatus, the aquæductus cochleæ, and the aquæductus vestibuli.

Abnormalities.—Variations of the **cranial blood sinuses** are not numerous. One transverse sinus may be absent or very small, when, as a rule, that of the opposite side is enlarged. The inferior sagittal, the occipital, or the spheno-parietal sinuses may be absent, and there may be an additional petro-squamous tributary to the transverse sinus. The petro-squamous sinus, when present, is the remains of a sinus which crossed the temporal bone, passed through the post-condyloid foramen, and terminated in the lateral cerebral vein. In the human adult, in rare cases, it pierces the skull behind the condyle of the mandible, and terminates in the posterior facial vein. This is the normal arrangement in some mammals.

Vv. Emissariæ.—The **emissary veins** are veins which convey blood from the blood sinuses in the interior of the cranium to the veins which lie outside the walls of the cranium. They may be single veins, or plexiform channels surrounding other structures which are passing through the walls of the cranium.

(1) **Frontal.**—In the child, and sometimes in the adult, an emissary vein passes from the anterior end of the superior sagittal sinus through the foramen cæcum. Its lower end divides into two channels which either terminate in the veins of the roof of the nasal cavities or they perforate the nasal bones and join the angular veins.

(2) **Parietal.**—The parietal emissary veins, one on each side, pass through the parietal foramina, from the superior sagittal sinus to the occipital veins.

(3) **Occipital.**—An occipital emissary vein is only occasionally present. It passes from the "confluens sinuum" through the occipital protuberance to one of the tributaries of an occipital vein, and it receives the occipital diploic vein.

(4) **Condyloid.**—When the condyloid canals are present in the occipital bone each is traversed by a condyloid emissary vein, which connects the lower end of the corresponding transverse sinus with the plexus of veins in the sub-occipital triangle.

(5) **Emissary Plexus of the Foramen Ovale.**—This plexus surrounds the mandibular nerve, as it passes through the foramen ovale, and connects the cavernous sinus with the corresponding pterygoid plexus in the infratemporal fossa. If the foramen Vesalii is present, the plexus of the foramen ovale is replaced or supplemented by an emissary vein which passes through that foramen.

(6) **Internal Carotid Plexus.**—The internal carotid plexus accompanies the internal carotid artery through the carotid canal of the temporal bone, and connects the cavernous sinus either with the pharyngeal plexus or with the upper part of the internal jugular vein.

(7) **Plexus of the Hypoglossal Canal.**—As the hypoglossal nerve passes through the hypoglossal canal (O.T. anterior condyloid foramen) it is accompanied either by a venous plexus or by a large vein which connects the veins of the medulla oblongata and the lower part of the occipital sinus with the upper end of the internal jugular vein, or with the extra-cranial part of the inferior petrosal sinus.

Vertebral Veins.

The vertebral veins include—

(1) The basi-vertebral veins.
(2) The external vertebral plexuses.
  (*a*) anterior „ „
  (*b*) posterior „ „
(3) The internal vertebral plexus.
(4) Vertebral longitudinal sinuses.
(5) Intervertebral veins.

The **basi-vertebral veins** are venous channels, enclosed by endothelial walls, which lie in the interiors of the bodies of the vertebræ. They communicate anteriorly with the plexuses of veins on the anterior surfaces of the bodies of the vertebræ, and they converge, radially, towards the posterior surfaces of the bodies of the vertebræ where they open into the transverse anastomoses between the longitudinal vertebral sinuses.

The **external vertebral plexuses**, (*a*) *anterior* and (*b*) *posterior*.

(*a*) The **anterior external vertebral plexuses** are formed by anastomosing venous channels which lie on the anterior surfaces of the vertebræ. They communicate with the basi-vertebral veins and with the intervertebral veins.

(*b*) The **posterior external vertebral plexuses** lie around the postero-lateral aspects of the vertebræ, in the vertebral grooves, around the spines, the articular and the transverse processes of the vertebræ. They communicate with the internal plexuses and with the intervertebral veins, and they open into the vertebral, intercostal, and lumbar veins.

The Longitudinal Vertebral Sinuses. — The veins in the interior of the vertebral canal form a network, the *vertebral venous network*, which lies external to the dura mater and covers the internal surfaces of the arches and the posterior surfaces of the bodies of the vertebræ. The network communicates laterally with the intervertebral veins, posteriorly with the posterior external venous plexuses, whilst anteriorly it receives the basi-vertebral veins. In the anterior part of the network, on the posterior surfaces of the bodies of the vertebræ, at the sides of the posterior longitudinal ligament, there are two large longitudinal channels, the *anterior longitudinal vertebral sinuses*. Two less marked longitudinal channels, the *posterior longitudinal vertebral sinuses*, can sometimes be distinguished on the internal surfaces of the vertebral arches.

The anterior longitudinal vertebral sinuses communicate above with the basilar plexus, the terminal parts of the transverse sinuses, and with the network of veins which accompanies each hypoglossal nerve through the hypoglossal canal.

The posterior longitudinal vertebral sinuses, when they are well established, communicate above with the occipital sinuses.

The Intervertebral Veins.—The internal vertebral venous network is drained not only above into the cranial venous sinuses by the longitudinal vertebral sinuses, but also by a series of intervertebral veins which pass through the intervertebral foramina. In the cervical region the intervertebral veins open externally into the vertebral veins, in the thoracic region into the intercostal veins, in the lumbar region into the lumbar veins, and in the sacral region into the lateral sacral veins. The intervertebral veins convey blood both from the internal vertebral venous plexus and also from the anterior and the posterior external vertebral plexuses.

The Veins of the Spinal Medulla.

The **veins of the spinal medulla** issue from the substance of the spinal medulla, and terminate in a plexus in the pia mater. In that plexus there are six longitudinal channels—one *antero-median*, along the anterior fissure, two *antero-lateral*, immediately behind the anterior nerve-roots, two *postero-lateral*, immediately posterior to the posterior nerve-roots, and one *postero-median*, dorsal to the posterior septum. Radicular efferent vessels issue from the plexus, and pass along the nerve roots to communicate with the internal vertebral venous network. The veins of the spinal medulla vary very much in size, but they are largest on the lower and on the posterior portions.

The postero-median and antero-median veins are continued above into the corresponding veins of the medulla oblongata.

The antero-lateral and postero-lateral veins pour their blood partly into the median veins and partly into the radicular veins; indeed, the greater part of the blood from the spinal medulla is returned by the radicular veins.

THE VEINS OF THE SUPERIOR EXTREMITY.

The veins of each upper limb are divisible into two sets—viz., **superficial** and **deep**. Both sets open eventually into a common terminal trunk which is known as the **axillary vein**. That vein is, therefore, the chief efferent vein of the upper extremity. It is continued as the subclavian vein to the innominate vein, through which its blood, together with that from the corresponding side of the head and neck, reaches the superior vena cava.

The Deep Veins of the Upper Extremity.

The deep veins of the upper limb, with the exception of the axillary vein, are arranged in pairs, **venæ comites**, which accompany the different arteries and are similarly named. So far as these veins are concerned it will be sufficient to state that they are provided with valves, that they are situated one on each side of the artery with which they are associated, and that they are usually united together by numerous transverse anastomoses which cross the line of the artery. The axillary vein, however, requires more detailed consideration.

Vena Axillaris.

The **axillary vein** (Figs. 732 and 741) commences, as the direct continuation of the basilic vein, opposite the lower border of the teres major muscle. It passes upwards and medially, through the axilla, along the medial side of the axillary artery, and terminates, at the external border of the first rib, by becoming the subclavian vein. It possesses one or more bicuspid valves of which one is usually situated opposite the lower border of the subscapularis muscle.

Relations.—Its anterior relations are similar to those of the axillary artery, but, in addition, the vein is crossed anteriorly, under cover of the clavicular part of the pectoralis major, by the pectoral branches of the thoraco-acromial artery, and by branches of the medial anterior thoracic nerve, and it receives anteriorly, just above the upper border of the pectoralis minor, the termination of the cephalic vein.

Posterior to it are the muscles which form the posterior wall of the axilla, the axillary fat, and the first serration of the serratus anterior. The long thoracic nerve intervenes between it and the serratus anterior, and the subscapular and thoraco-dorsal nerves and the subscapular artery pass between it and the subscapularis.

It is separated from the third part of the axillary artery by the ulnar nerve and medial cutaneous nerves of the forearm; from the second part of the axillary artery by the medial cord of the brachial plexus; and in the proximal part of the axilla, behind the costo-coracoid membrane, it is separated from the first part of the artery by the medial anterior thoracic nerve. To its medial side lie the lateral set of axillary glands, and, in the distal part of the axilla, the medial cutaneous nerve of the arm.

Tributaries.—In addition to tributaries corresponding with the branches of the axillary artery, it receives the venæ comites of the brachial artery, at the lower border of the subscapularis; and the cephalic vein, which joins it above the upper border of the pectoralis minor muscle.

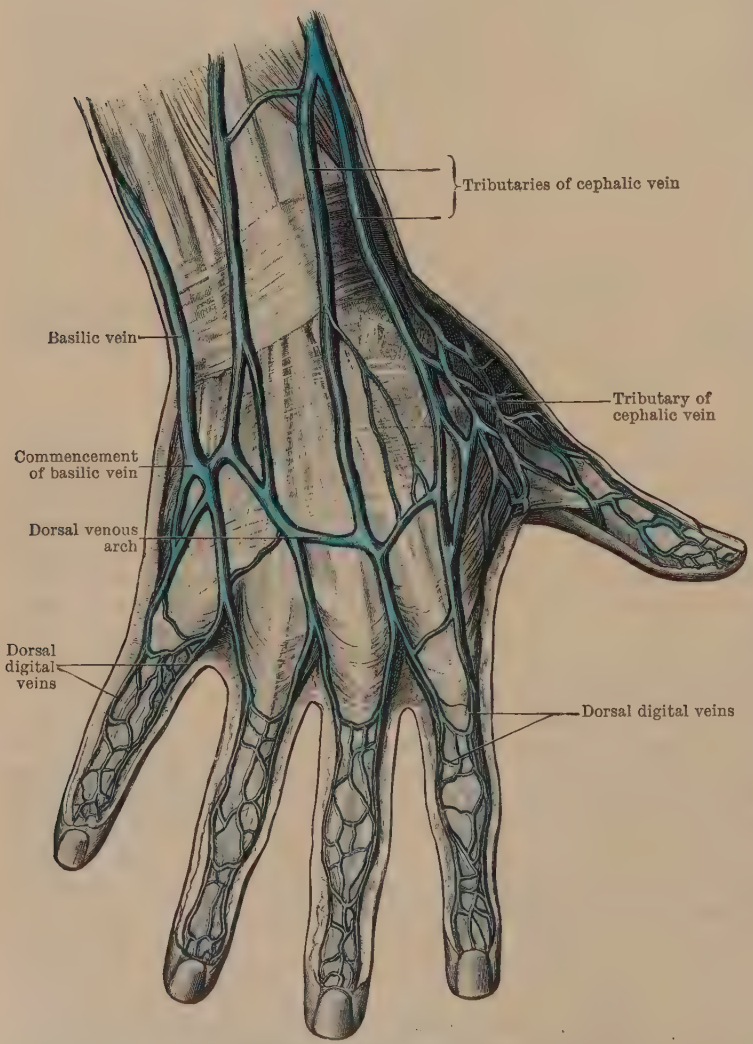

Fig. 765.—Superficial Veins on the Dorsum of the Hand and Digits.

The Superficial Veins of the Superior Extremity.

The superficial veins of the upper limb commence in the superficial fascia of the palm and dorsum of the hand and of the digits.

The Veins of the Digits and Hand.—The **special volar digital veins** are two or more fine longitudinal channels which lie in the superficial fascia of the volar aspects of the digits. They communicate, proximally, with a fine venous network which lies in the superficial fascia of the palm, and, at the proximal ends of the interdigital clefts, by means of *intercapitular veins*, which pass dorsally between the heads of the metacarpal bones. They open into the *special dorsal digital veins*.

The **special dorsal digital veins**, two in each digit, anastomose freely together

on the dorsal aspects of the digits. At the proximal ends of the interdigital clefts they communicate, through the intercapitular veins, with the special volar digital veins, and then they unite together to form an indefinite series of *dorsal metacarpal veins* which terminate, a little distal to the middle of the dorsum of the hand, in a **dorsal venous arch.**

The Veins of the Forearm and Arm.—The veins of the forearm emerge from the dorsal venous arch and from the volar venous plexus, and they vary considerably in number and in size. As a rule there are two main longitudinal channels, the *cephalic vein* on the radial side and the *basilic vein* on the ulnar side. In some cases there is an additional median vein on the volar aspect of the forearm.

The **cephalic vein** commences in the radial end of the dorsal venous arch. It receives the metacarpal veins of the thumb, turns round the radial margin of the distal part of the forearm, and runs proximally, parallel with the volar border of the brachio-radialis muscle, to the cubital region. There, frequently much reduced in size, it turns laterally and runs, along the lateral border of the prominence of the biceps, to the interval between the deltoid and pectoralis major, along which it ascends to the delto-pectoral triangle. At the delto-pectoral triangle it turns medially, between the pectoralis minor and the pectoralis major, to the anterior aspect of the costo-coracoid membrane, which separates it from the front of the first part of the axillary artery; then, turning backwards, it pierces the costo-coracoid membrane and ends in the axillary vein. In a few cases instead of piercing the costo-coracoid membrane it crosses the front of the clavicle, deep to the platysma, pierces the deep cervical fascia, and joins the lower part of the external jugular vein.

As it runs proximally, on the volar aspect of the forearm, a number of tributaries join its lateral border. Some of these commence in the dorsal venous arch of the hand and others in the superficial fascia of the dorsal aspect of the forearm.

In the cubital region it is connected with the basilic vein by a large obliquely placed anastomosing channel, the *median cubital vein*, which runs along the medial border of the distal part of the biceps prominence, superficial to the lacertus fibrosus which separates it from the distal part of the brachial artery. In the delto-pectoral triangle it is joined by tributaries which correspond with the acromial and pectoral branches of the thoraco-acromial artery.

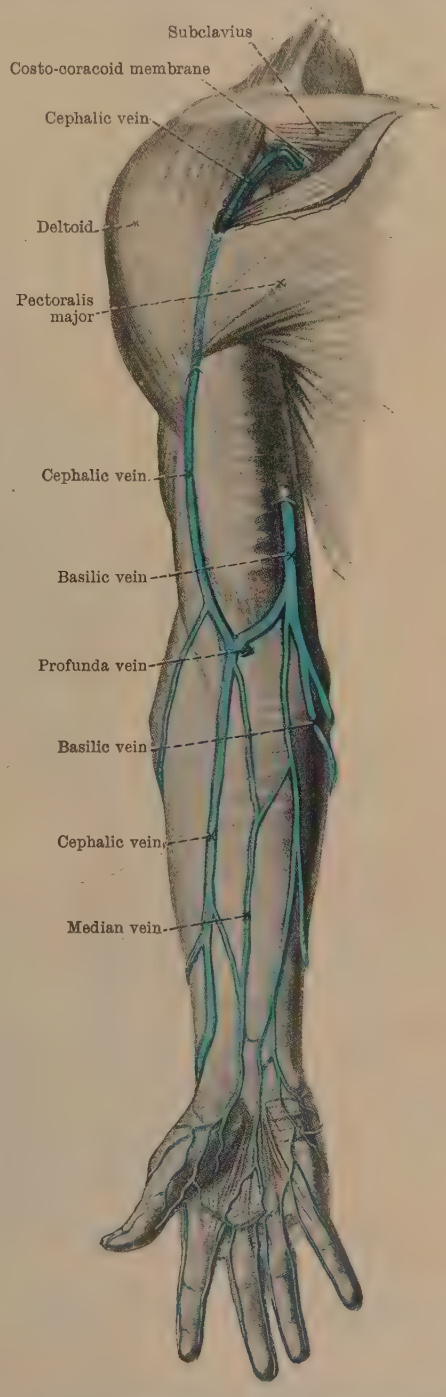

FIG. 766.—SUPERFICIAL VEINS ON THE FLEXOR ASPECT OF THE UPPER EXTREMITY.

The **median cubital vein** not only connects together the cephalic and basilic

veins but it receives also the profunda vein which pierces the deep fascia and connects it with the deep veins of the forearm, and one or more superficial veins of varying size, which pass, proximally, along the volar aspect of the forearm.

In many cases the median cubital vein is relatively very large, and in such cases the more proximal part of the cephalic vein, which lies in the arm, is a comparatively small vessel.

The **basilic vein** commences in the ulnar end of the dorsal venous arch of the hand. It runs along the dorsal aspect of the forearm to the junction of the proximal and middle thirds, where it turns round the ulnar border of the forearm, and runs, anterior to the medial epicondyle of the humerus, to the medial bicipital groove. At the middle of the arm, it pierces the deep fascia. After piercing the fascia, it runs proximally, along the medial border of the brachial artery, to the axilla, and there becomes the axillary vein.

As it runs proximally, in the forearm, it is joined by tributaries from both the volar and dorsal aspects and, in the cubital region, by the median cubital vein which connects it with the cephalic vein.

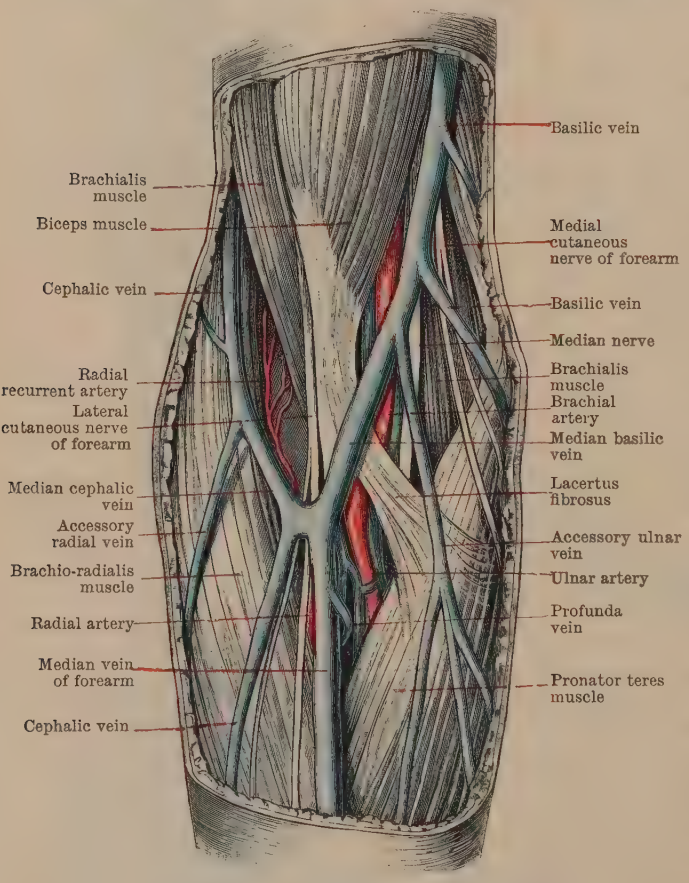

FIG. 767.—SUPERFICIAL VEINS AT THE BEND OF THE ELBOW IN A SPECIMEN IN WHICH THE MEDIAN VEIN WAS LARGE.

The Median Vein of the Forearm.—In a certain number of cases a vein, which commences in the palmar venous plexus, runs along the middle of the volar aspect of the forearm to the cubital region. It is called the median vein of the forearm. At the bend of the elbow it receives the profunda vein and then divides into two branches, the *median cephalic* and the *median basilic* veins (Fig. 767). The median cephalic vein runs along the lateral bicipital sulcus and joins the cephalic vein. The median basilic passes along the medial bicipital sulcus and joins the basilic vein. When the median vein of the forearm is present the median cubital vein is absent.

When venesection is performed in the forearm it is either the median cubital vein or, in its absence, the median basilic vein which is opened.

Abnormalities.—The **superficial veins** of the forearm are extremely variable; any of them may be absent, but most commonly it is the median or the cephalic vein which is wanting. The median cephalic and the cephalic veins may be small or absent, and, on the other hand, the cephalic vein may be larger than usual. Moreover the cephalic vein may end in the external jugular vein, its original termination; or it may be connected with the external jugular vein by an anastomosing channel which sometimes passes over the clavicle and sometimes through that bone.

The basilic vein is sometimes larger and sometimes smaller than usual, and it may pierce the fascia of the arm at a more proximal or at a more distal level than usual.

The **venæ comites** of the arteries of the upper extremity generally terminate at the lower border of the subscapularis, where they join the axillary vein, but they may end above or below the position of their usual termination.

The **subclavian vein** sometimes passes behind instead of in front of the scalenus anterior muscle, and it has been seen passing between the clavicle and the subclavius muscle.

VENA CAVA INFERIOR AND ITS TRIBUTARIES.

The **inferior vena cava** (Fig. 769) is a large venous trunk which receives the whole of the blood from the lower extremities, and the greater part of the blood

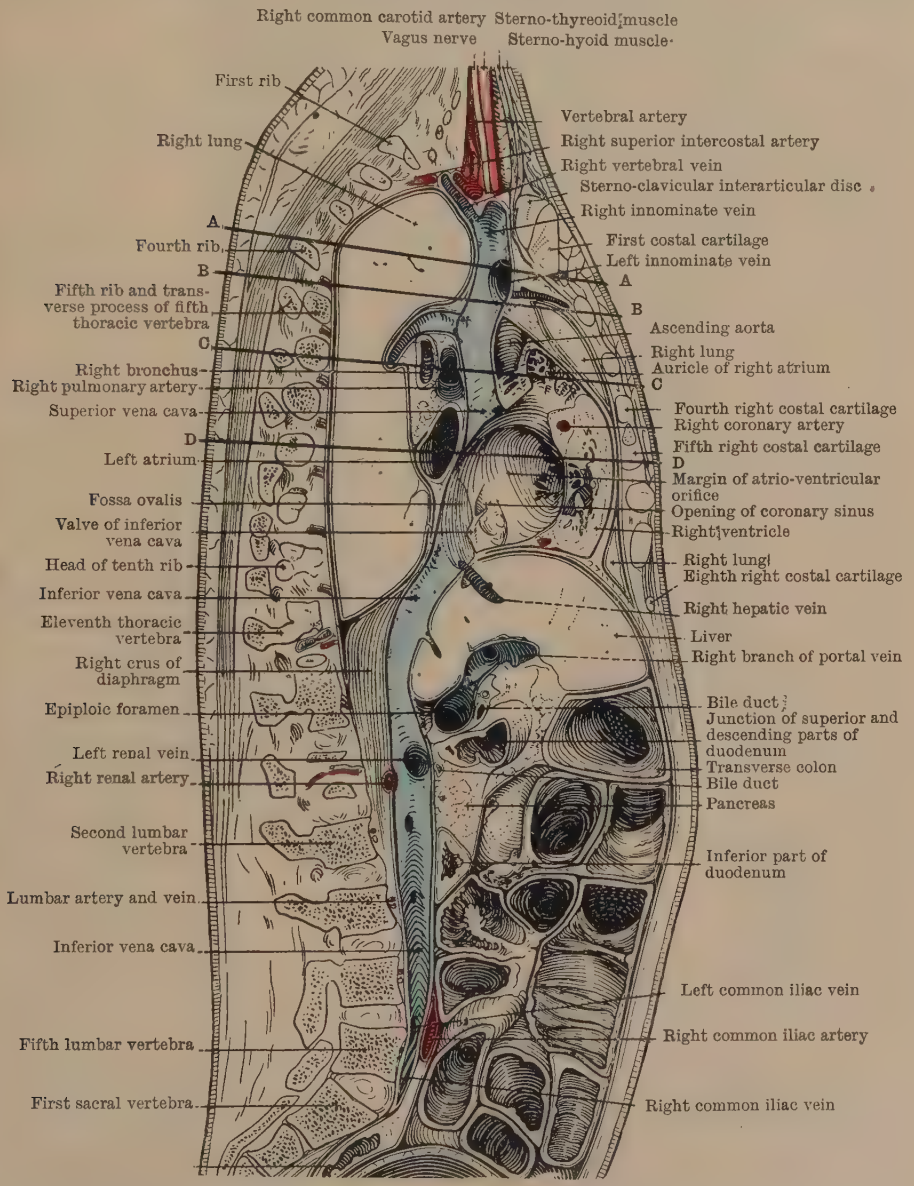

FIG. 768.—A SAGITTAL LATERAL SECTION OF THE BODY OF A YOUNG MALE ALONG THE LINES OF THE SUPERIOR AND THE INFERIOR VENÆ CAVÆ.

from the walls and contents of the abdomen and pelvis. It commences opposite the right side of the body of the fifth lumbar vertebra, behind and to the right of the right common iliac artery. It ascends through the abdomen, anterior and to the right of the vertebral column and the right crus of the diaphragm, and it pierces

the cupola of the diaphragm, between the middle and right sections of the central tendinous leaflet, at the level of the lower part of the eighth thoracic vertebra. It then enters the middle mediastinum, pierces the fibrous pericardium, and terminates in the lower and posterior part of the right atrium. Its intra-thoracic portion is very short, and its intra-pericardial portion, which is still shorter, is covered anteriorly and on its right and left sides by the parietal portion of the serous layer. Attached to the inferior and anterior margin of its atrial orifice is the *valve of the inferior vena cava* (Eustachius). This is a remnant of an important fold of endocardium by which, in the fœtus, the blood from the inferior vena cava is directed, through the foramen ovale, into the left atrium.

Relations.—The inferior vena cava is in relation, *posteriorly*, with the bodies of the lower lumbar vertebræ and the corresponding part of the anterior longitudinal ligament, the anterior portion of the right psoas major muscle, the right lumbar sympathetic trunk, the roots of the right lumbar arteries, the right crus of the diaphragm, the right renal artery, the right suprarenal artery, the right cœliac ganglion, the right inferior phrenic artery, and the medial and upper portion of the right suprarenal gland.

Anterior to it, from below upwards, are the following structures—the right common iliac artery, the lower end of the mesentery and the superior mesenteric artery, the right internal spermatic artery and the third part of the duodenum, the head of the pancreas, the portal vein and the first part of the duodenum, the foramen epiploicum, and the posterior surface of the liver. More superficially are coils of small intestine, the great omentum, and the transverse colon and mesocolon.

To its left side are the aorta and the right crus of the diaphragm.

On its right side, below, is the right ureter, whilst at a higher level the right kidney is separated from the vein by a short interval only.

Tributaries.—In addition to the two common iliac veins, by the union of which it is formed, and through which it receives blood from the pelvis and from the lower extremities, the inferior vena cava receives the following tributaries:—The hepatic veins, the right inferior phrenic vein, the right suprarenal vein, the right and left renal veins, the right internal spermatic vein, and the right and left lumbar veins.

Abnormalities.—The lower part of the inferior vena cava is sometimes absent, in which case the common iliac veins ascend, one on the right and the other on the left of the aorta, to the level of the second lumbar vertebra, where the left common iliac vein receives the left renal vein, and then crosses in front of or behind the aorta to fuse with the corresponding vein of the right side; in such cases, therefore, the inferior vena cava commences at the level of the second lumbar vertebra, and it represents only the upper and last-formed part of the ordinary vessel; the common iliac veins, each of which receives the lumbar veins of its own side, are exceptionally long, and they may or may not be united at the pelvic brim by a small transverse anastomosing channel. Cases of this kind are sometimes described as partial doubling of the inferior vena cava.

Occasionally the inferior vena cava does not terminate in the right atrium, but is continuous with the vena azygos, which is much enlarged, all the inferior caval blood being then carried to the superior vena cava. In such cases the hepatic veins open directly into the right atrium without communicating with the inferior vena cava.

The lower part of the inferior vena cava sometimes lies to the left instead of to the right of the aorta; this condition is associated with a long right common iliac vein, which crosses obliquely from right to left to join the shorter left common iliac vein. After receiving the left renal vein the misplaced inferior vena cava crosses in front of the aorta, reaching the right side at the level of the second or first lumbar vertebra. In other cases, however, the left inferior vena cava continues upwards through the left crus of the diaphragm, usurping the place of a greater or smaller part of the hemiazygos vein; having entered the thorax, it may cross to the opposite side and terminate in the vena azygos, or it may continue upwards on the same side, and after arching over the root of the left lung, descend behind the left atrium to terminate in the right atrium in the situation of the coronary sinus. In this group of cases also the hepatic veins open separately into the right atrium.

The inferior vena cava may lie ventral instead of dorsal to the right internal testicular artery, in which case the lower part of the vessel has been derived from the subcardinal vein instead of from the posterior cardinal vein. (Johnston, *Journ. of Anat. and Phys.* xlvii., 1913.)

The tributaries of the inferior vena cava are also subject to variation. Additional renal, testicular, ovarian, or suprarenal veins may be present. Two or three lumbar veins of one or both sides may unite into a common trunk which terminates in the inferior vena cava, and the hepatic veins may open separately, or after fusing into a common trunk, into the right atrium near the opening of the inferior vena cava.

No explanation of the variations of the inferior vena cava and its tributaries is necessary, beyond the statement that they are due to persistence of portions of the postcardinal, the subcardinal and supracardinal veins which usually disappear, and to the persistence of transverse

anastomoses and tributaries which usually atrophy, or to modifications of those which ordinarily take part in the formation of the inferior vena caval system.

The **hepatic veins** (Fig. 769) convey blood which has passed through the liver from the portal veins and from the hepatic artery, and they open into that portion of the inferior vena cava which lies immediately below the diaphragm, and

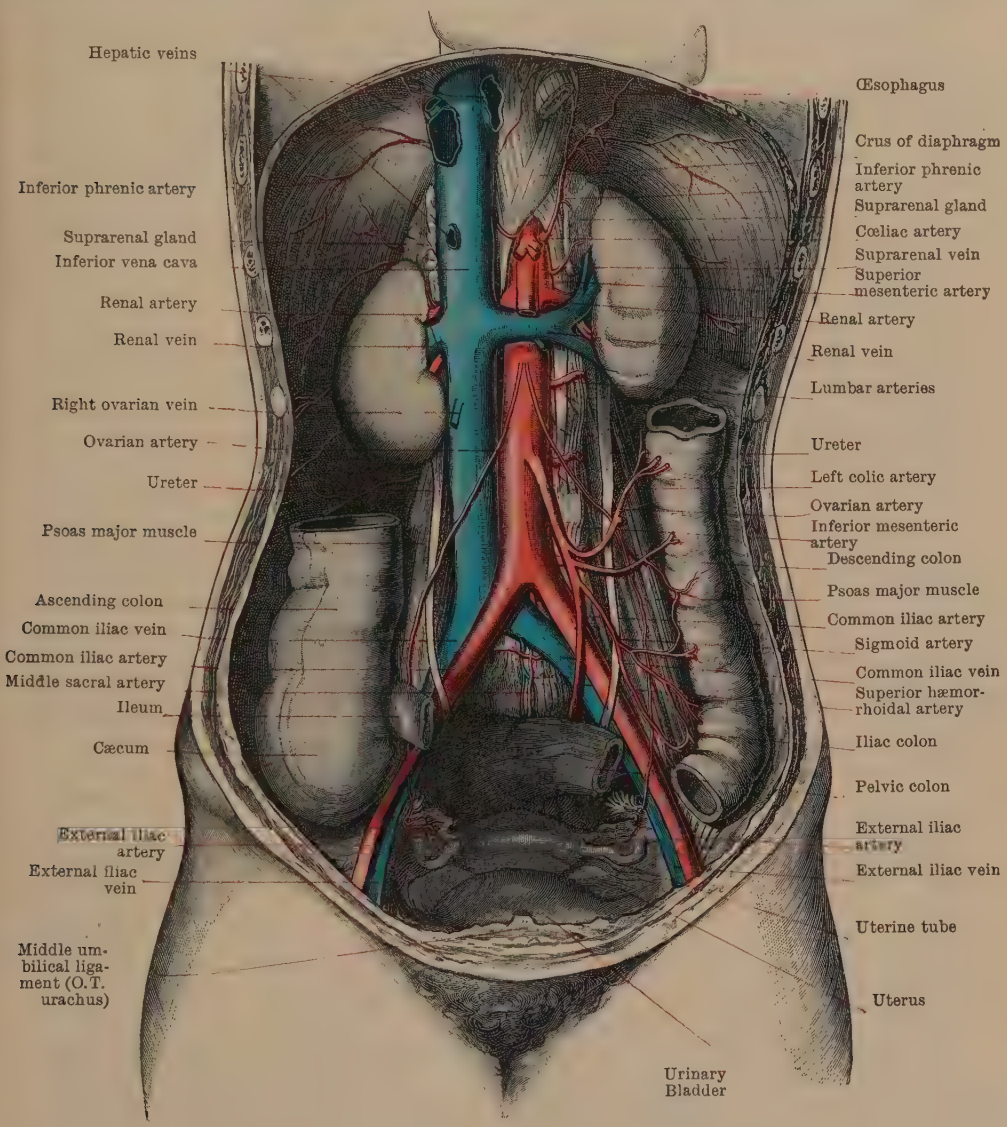

FIG. 769.—THE INFERIOR VENA CAVA AND ITS TRIBUTARIES.

behind the right lobe of the liver. They form two groups, an upper group of two or three large trunks, and a lower group of smaller veins.

The upper group occasionally consists of only two veins, a right and a left; more frequently there are three vessels, a right, a left, and a middle vein, and in the latter case the middle vein issues from the caudate lobe.

The veins of the lower group vary in number from six to twenty; they return blood from the right and caudate lobes.

The hepatic veins commence in the interiors of the lobules of the liver as *central veins*; the central veins issue from the upper and posterior aspects of the lobules, and unite together to form *interlobular veins*; and the interlobular veins

unite with one another, as they converge towards the posterior surface of the liver, to form the larger hepatic veins.

The **inferior phrenic veins** are formed by tributaries which issue from the substance of the diaphragm. The right inferior phrenic vein terminates in the upper part of the inferior vena cava. The left vein passes posterior to the œsophagus, and usually terminates in the left suprarenal vein.

The Suprarenal Veins.—A single **suprarenal vein** issues from the hilum on the anterior surface of each suprarenal gland; the right vein terminates in the inferior vena cava; the left usually ends in the left renal vein, but sometimes it opens directly into the inferior vena cava.

Venæ Renales.—Each **renal vein** is formed by the union of five or six tributaries which issue from the hilum of the kidney, where they lie anterior to or are intermingled with the corresponding arteries.

The **right renal vein** is about 25 mm. (one inch) long; it passes posterior to the descending part of the duodenum, and terminates in the right side of the inferior vena cava.

The **left renal vein** is about 75 mm. long. It crosses anterior to the left psoas major, the left crus of the diaphragm, and the aorta immediately below the superior mesenteric artery. It lies behind the pancreas and the ascending part of the duodenum, and, running above the transverse part of the duodenum, terminates in the left side of the inferior vena cava. The left testicular or ovarian vein, according to the sex, and almost invariably the left suprarenal vein, open into it.

Venæ Lumbales.—There are usually four **lumbar veins** on each side, one with each lumbar artery; the vein with the subcostal artery is not included in this number. By their anterior and posterior branches the lumbar veins drain the lateral and posterior walls of the abdomen. The anterior branches commence in the lateral walls of the abdomen, where they communicate with the superior and inferior epigastric veins. The posterior divisions issue from the muscles of the back, in the lumbar region, and receive tributaries from the spinal plexuses. The main stems pass forwards on the bodies of the vertebræ; on each side they run postero-medial to the psoas major muscle, whilst those of the left side also pass posterior to the aorta. They terminate in the posterior part of the inferior vena cava. Not uncommonly the corresponding veins of opposite sides unite together to form a single trunk which enters the back of the inferior vena cava. All the lumbar veins, of each side, are united together by a longitudinal anastomosing vessel, the **ascending lumbar vein**.

The Ascending Lumbar Vein.—Each ascending lumbar vein passes upwards, between the psoas major and the roots of the transverse processes of the lumbar vertebræ. It commences in the lateral sacral vein of the same side, anastomoses with the ilio-lumbar vein, connects the lumbar veins together, receives tributaries from the anterior external vertebral plexus and anastomoses with the inferior vena cava and the renal vein. The right ascending lumbar vein terminates in the azygos and the left in the hemiazygos vein.

The **testicular veins**, on each side, issue from the testis and epididymis and form a plexus, the *pampiniform plexus*. The plexus is one of the constituents of the spermatic cord, and consists of from eight to ten veins, most of which lie anterior to the ductus deferens; it passes upwards through the scrotum and inguinal canal, and, near the abdominal inguinal ring, terminates in two main trunks which ascend, with the corresponding testicular artery, for some distance, receiving tributaries from the ureter; ultimately the two veins unite together and a single terminal vein is formed. The terminal testicular vein on the right side opens into the inferior vena cava, that on the left side into the left renal vein. The left testicular vein is longer than the right, the left testis being lower than the right, and the termination in the left renal vein being at a higher level than the termination of the right vein in the inferior vena cava. The testicular veins, on each side, lie anterior to the psoas major muscle and the ureter. They are covered by peritoneum, and they are crossed on the right side by the termination of the ileum and the third part of the duodenum, and on the left side by the iliac colon and the lower part of the pancreas. They are provided with

valves, one of which usually lies at the terminations of each vein, but, occasionally, the valve at the orifice of the left testicular vein is absent.

The ovarian veins, on each side, issue from the hilum in the anterior border of the ovary. They pass between the layers of the broad ligament, where they anastomose freely and form the *pampiniform plexus*, which extends, laterally, towards the upper margin of the pelvis minor. From the plexus two veins issue which accompany the corresponding ovarian artery; they pass anterior to the external iliac artery, and then upwards, behind the peritoneum and anterior to the psoas major muscle and ureter. The veins of the right side, like the corresponding testicular veins, also pass behind the termination of the ileum and the third part of the duodenum; whilst the left veins, near the margin of the pelvis minor, pass behind the commencement of the pelvic colon.

The two veins on each side ultimately fuse together to form a single terminal vein which ends, on the right side in the inferior vena cava, and on the left side in the left renal vein.

Venæ Iliacæ Communes.

The **common iliac veins** (Figs. 760 and 769), right and left, are formed by the union of the corresponding external iliac and hypogastric veins. Each commences at the superior aperture of the pelvis minor, immediately posterior to the upper part of the hypogastric artery of its own side, and both vessels pass upwards to the right side of the body of the fifth lumbar vertebra, at the upper part of which, posterior and lateral to the right common iliac artery, they unite together to form the inferior vena cava.

The **right common iliac vein** is much shorter than the left; it passes anterior to the obturator nerve and the ilio-lumbar artery, and at first posterior and then somewhat to the lateral side of the corresponding common iliac artery.

The **left common iliac vein** is much longer than the right, and is also placed more obliquely. It passes upwards and to the right, anterior to the body of the fifth lumbar vertebra, and the middle sacral artery. For some distance it runs along the medial side of the left common iliac artery, and then passes posterior to the right common iliac artery. It also passes posterior to the mesentery of the pelvic colon and the superior hæmorrhoidal vessels.

Abnormalities.—The **left common iliac vein** is short and the right long when the inferior vena cava lies on the left side. The common iliac veins may be absent, the hypogastric veins uniting to form the commencement of the inferior vena cava, into which the external iliac veins open as lateral tributaries.

Tributaries.—Each common iliac vein receives the corresponding external iliac, hypogastric and ilio-lumbar veins. The left common iliac vein receives, in addition, the middle sacral vein.

The **ilio-lumbar veins** receive tributaries from the iliac fossa, from the lower parts of the vertebral muscles, and from the vertebral canal. There is a single vein on each side which accompanies the corresponding artery. It passes posterior to the psoas major muscle and terminates in the corresponding common iliac vein.

The Middle Sacral Vein.—The venæ comites of the middle sacral artery commence by the union of tributaries which issue from the venous plexus in front of the sacrum, through which they communicate with the lateral sacral veins and receive blood from the interior of the sacral canal. They unite, above, into a single **middle sacral vein**, which terminates in the left common iliac vein.

The **hypogastric vein** (Fig. 749) is a short trunk formed by the union of tributaries which correspond to all the branches of the hypogastric artery, with the exception of the umbilical and the ilio-lumbar branches.

It commences at the upper border of the greater sciatic notch, and ascends to the aperture of the pelvis minor; there it unites with the external iliac vein to form the common iliac vein. It lies immediately postero-medial to the hypogastric artery, is crossed laterally by the obturator nerve, and is in relation medially, on the left side with the pelvic colon, and on the right side with the lower part of the ileum.

Tributaries.—The tributaries, which are numerous, are conveniently divisible into extra-pelvic and intra-pelvic groups.

The *extra-pelvic tributaries* are all **parietal**, and include the obturator, internal pudendal, inferior, and superior gluteal veins.

Obturator Vein.—This vein is formed by the union of tributaries which issue from the hip-joint and from the muscles of the proximal and medial part of the thigh. It enters the pelvis minor through the obturator canal, runs backwards, along the lateral wall of the pelvis minor, lying medial to the pelvic fascia, immediately below the corresponding artery, and, passing between the hypogastric artery on the lateral side and the ureter on the medial side, it terminates in the hypogastric vein.

Inferior Gluteal Veins.—The venæ comites of the inferior gluteal artery commence in the subcutaneous tissues on the back of the thigh; they ascend with the artery, and pass into the buttock on the deep aspect of the glutæus maximus, where they receive numerous tributaries from the surrounding muscles. Entering the pelvis, through the greater sciatic foramen, they unite into a single vessel, which terminates in the lower and anterior part of the hypogastric vein below the termination of the obturator vein.

Superior Gluteal Veins.—The venæ comites of the superior gluteal artery are formed by tributaries which issue from the muscles of the buttock. They accompany the artery through the greater sciatic foramen, and terminate in the hypogastric vein; they frequently unite together before reaching their termination.

Internal Pudendal Veins.—The venæ comites of the internal pudendal artery commence by tributaries which emerge from the *pudendal plexus*, which lies below and posterior to the arcuate ligament of the pubis and constitutes the anterior part of the prostatic plexus. They receive blood from the corpus cavernosum penis, or the corpus cavernosum clitoridis, by the deep vein of the penis or clitoris. They follow the course of the internal pudendal artery, and usually join together into a single vessel (the internal pudendal vein) which terminates in the hypogastric vein. They receive as tributaries the veins from the bulb, the perineal and inferior hæmorrhoidal veins, and veins from the muscles of the buttock.

The **inferior hæmorrhoidal veins**, which commence in the substance of the external sphincter of the anus and in the walls of the anal canal, anastomose with the middle and superior hæmorrhoidal veins, and consequently connect the lowest parts of the portal and vena caval systems together.

The *intra-pelvic tributaries* of the internal iliac vein are either (*a*) **parietal** or (*b*) **visceral**; the former comprises the lateral sacral veins, the latter includes the efferent vessels from the plexuses around the several pelvic viscera.

(*a*) **Parietal: Lateral sacral veins** accompany the lateral sacral arteries, and terminate on each side in the postero-medial wall of the corresponding hypogastric vein.

(*b*) **Visceral tributaries** are derived from the rectum and from the plexuses associated with the uterus, vagina, bladder, and prostate. They include the middle hæmorrhoidal, the uterine, the vaginal, and the vesical veins.

The **middle hæmorrhoidal veins** are very irregular; sometimes they cannot be distinguished. When present they are formed by tributaries which commence in the submucous tissue of the rectum, where they communicate with the superior and inferior hæmorrhoidal veins in the hæmorrhoidal plexus; they pass through the muscular coat, and fuse together to form two middle hæmorrhoidal veins, right and left, each of which runs laterally, beneath the peritoneum, on the upper surface of the levator ani, to terminate in the corresponding hypogastric vein. In the male each middle hæmorrhoidal vein receives tributaries from the seminal vesicle and ductus deferens of its own side.

Uterine Plexuses and Veins.—The **uterine plexuses** lie along the borders of the uterus; they receive tributaries, which are entirely devoid of valves, from the uterus; and they communicate above with the ovarian, and below with the vaginal plexuses.

The **uterine veins**, usually two on each side, issue from the lower parts of the uterine plexuses, above their communications with the vaginal plexuses. At first the uterine veins, on each side, lies in the medial part of the base of the broad ligament, above the lateral fornix of the vagina and the ureter; then they pass backwards, accompanying the corresponding artery, in a fold of peritoneum which lies between the back of the broad ligament and the recto-uterine fold; finally they ascend in the floor of the ovarian fossa, and terminate in the corresponding hypogastric vein.

Vaginal Plexuses and Vaginal Veins.—The **vaginal plexuses** lie at the sides of the vagina. They receive tributaries from the walls of the vagina, and communicate with the uterine plexuses above, and with the veins of the bulb below; anteriorly, with the vesical plexus; and posteriorly with the veins which issue from the middle and lower parts

of the hæmorrhoidal plexus. A single **vaginal vein** issues from the upper part of the vaginal plexus on each side; it accompanies the corresponding artery, and terminates in the hypogastric vein.

Superior Vesical Plexus.—The superior vesical plexus of veins lies on the outer surface of the muscular coat of the bladder, at the fundus and the sides. It receives tributaries from the mucous and muscular walls, and its efferent vessels terminate in the prostatico-vesical plexus in the male, and in the inferior vesical plexus in the female.

Prostatico-vesical Plexus.—This plexus is distributed around the prostate and the neck of the bladder, and is enclosed between the proper fibrous capsule of the prostate and its sheath of recto-vesical fascia. Anteriorly it is continuous with the pudendal plexus which receives the dorsal vein of the penis; postero-superiorly it communicates with the superior vesical plexus, and receives tributaries from the seminal vesicles and deferent ducts. One or more efferent vessels pass from it on each side and open into the corresponding hypogastric vein.

The **inferior vesical plexus** of the female, which represents the prostatico-vesical plexus of the male, surrounds the upper part of the urethra and the neck of the bladder. It is continuous with the pudendal plexus which receives the dorsal vein of the clitoris, and its efferent vessels terminate in the hypogastric vein.

Dorsal Veins of the Penis.—There are two dorsal veins of the penis—the superficial and the deep.

The **superficial dorsal vein** receives tributaries from the prepuce, and runs backwards, immediately beneath the skin, to the symphysis, where it divides into two branches which terminate in the superficial external pudendal veins.

The **deep dorsal vein** lies on the dorsum of the penis, deep to the deep fascia. It commences in the sulcus behind the glans, by the union of numerous tributaries from the glans and the anterior parts of the corpora cavernosa penis; and it runs backwards in the mid-dorsal line, in the sulcus between the corpora cavernosa penis from which it receives many additional tributaries. At the root of the penis the vein passes between the two layers of the suspensory ligament, and then between the arcuate ligament and the deep transverse ligament of the perineum, where it lies above the membranous part of the urethra. It terminates by dividing into two branches which join the pudendal plexus.

The **dorsal vein of the clitoris** in the female has a similar course to that of the deep dorsal vein of the penis in the male. It terminates in the pudendal plexus.

THE VEINS OF THE INFERIOR EXTREMITY.

The veins of the inferior extremity, like those of the superior extremity, are arranged in two groups, the **superficial** and the **deep**; and in the lower as in the upper limb the deep veins are associated with the arteries as venæ comites, whilst the trunks of the superficial veins, which lie, at first, in the subcutaneous tissues, ultimately terminate in the deep veins. There is, therefore, a general similarity in the arrangement of the veins of the upper and the lower limbs, but there are differences in the details of the arrangement which are of some importance. Thus, in the superior extremity, there are two deep veins with each artery from the fingers to the root of the limb, where a single trunk, the axillary vein, is formed; but in the inferior extremity each main artery has two venæ comites only as far as the middle of the limb, where a single trunk is frequently formed. That vessel, the **popliteal vein**, is the commencement of the main venous stem of the lower extremity; it is continued proximally, through the thigh, as the **femoral vein**, and along the upper margin of the pelvis minor as the **external iliac vein**, which terminates by uniting with the hypogastric vein to form the common iliac vein.

Further, the superficial veins of the upper limb are more numerous than those of the lower limb, for in the arm there are two main superficial veins, and in the thigh only one.

In the upper limb the blood which passes through the superficial veins is poured into the efferent trunk vein at the root of the limb—that is, into the axillary vein; but in the lower limb the blood from the superficies of the lateral parts of the leg and foot passes into the commencement of the main efferent vein, the popliteal vein, at the middle of the limb—that is, in the region of the knee, whilst the blood from the superficial parts of the medial aspect of the lower limb is poured

into the femoral vein near the root of the limb in the upper part of the femoral trigone.

In addition to the above-mentioned differences in the general arrangement of the veins of the superior and the inferior extremities, it must be noted also that in the superior extremity all the blood of the limb, both that from the shoulder-girdle region as well as that from the free portion of the limb, is returned to the main efferent venous trunk; but in the inferior extremity the greater part of the blood from the region of the pelvic girdle, and a considerable portion from that of the thigh, is returned by the gluteal, obturator, and pudendal veins to the hypogastric vein, which is not the main efferent vein of the inferior extremity.

Abnormalities.—The **great saphenous vein** is not subject to much variation, but the **small saphenous vein** may terminate by joining the great saphenous, or, after piercing the deep fascia in the distal part of the thigh, it may ascend and join the inferior gluteal vein or one of the tributaries of the profunda vein.

The Deep Veins of the Inferior Extremity.

All the arteries of the lower limb, except the popliteal and femoral trunks, are accompanied by two *venæ comites*. They usually lie one on each side of the artery; they are connected with one another by transverse channels which pass across the line of the artery, and they are provided with numerous valves.

The **popliteal vein** (Figs. 751, 755, 756) is formed, at the distal border of the popliteus muscle, by the union of the venæ comites of the anterior and posterior tibial arteries. At its commencement it lies to the medial side of and somewhat superficial to the popliteal artery, and to the lateral side of the tibial nerve. As it runs through the popliteal fossa it inclines towards the lateral side of the artery, and in the middle of the space it is directly posterior to the artery, separating the artery from the tibial nerve, which is still more posterior, whilst at the proximal end of the space it is to the lateral side of the artery, and still between it and the tibial nerve. It then passes through the adductor magnus muscle and becomes the femoral vein.

The popliteal vein, which is provided with two or three bicuspid valves, is closely bound to the artery by a dense fascial sheath. Not uncommonly there are one or more additional satellite veins which anastomose with the popliteal vein, and in those cases the artery is more or less completely surrounded by venous trunks.

Tributaries.—In addition to the venæ comites of the anterior and posterior tibial arteries, it receives tributaries which correspond with the branches of the popliteal artery, and it also receives one of the superficial veins of the leg, viz., the small saphenous vein.

The **femoral vein** is the direct continuation of the popliteal vein. It commences at the junction of the middle and distal thirds of the thigh, at the opening in the adductor magnus muscle. It then ascends, through the adductor canal (Hunter), and through the femoral trigone, and terminates, a little to the medial side of the middle of the inguinal ligament (Poupart), by becoming the external iliac vein.

In the adductor canal it lies at first postero-lateral to the femoral artery, and anterior to the adductors magnus and longus which separate it from the profunda vessels. In the distal part of the femoral trigone it is postero-medial to the artery, and immediately anterior to the profunda vein which separates it from the profunda artery, but in the proximal part of the femoral trigone it is directly on the medial side of the femoral artery. About 37 mm. (one and a half inches) below the inguinal ligament it enters the middle compartment of the femoral sheath, through which it ascends to its termination, lying between the compartment for the femoral artery on the lateral side and the femoral canal on the medial side.

It usually contains two bicuspid valves—one near its termination and the other just proximal to the entrance of its profunda tributary.

Tributaries.—It receives tributaries which correspond with the branches of the femoral artery and the larger of the two superficial veins of the lower extremity, viz., the

great saphenous vein, which enters the femoral vein where that vessel lies in the middle compartment of the femoral sheath, and, not uncommonly, it is joined by the medial and lateral circumflex veins.

The **external iliac vein** (Figs. 752, 753, and 769) is the upward continuation of the femoral vein. It commences, on the medial side of the termination of the external iliac artery, immediately posterior to the inguinal ligament, and ascends, along the aperture of the pelvis minor, to a point opposite the sacro-iliac joint, and at the level of the lumbo-sacral articulation, where it ends, immedi-

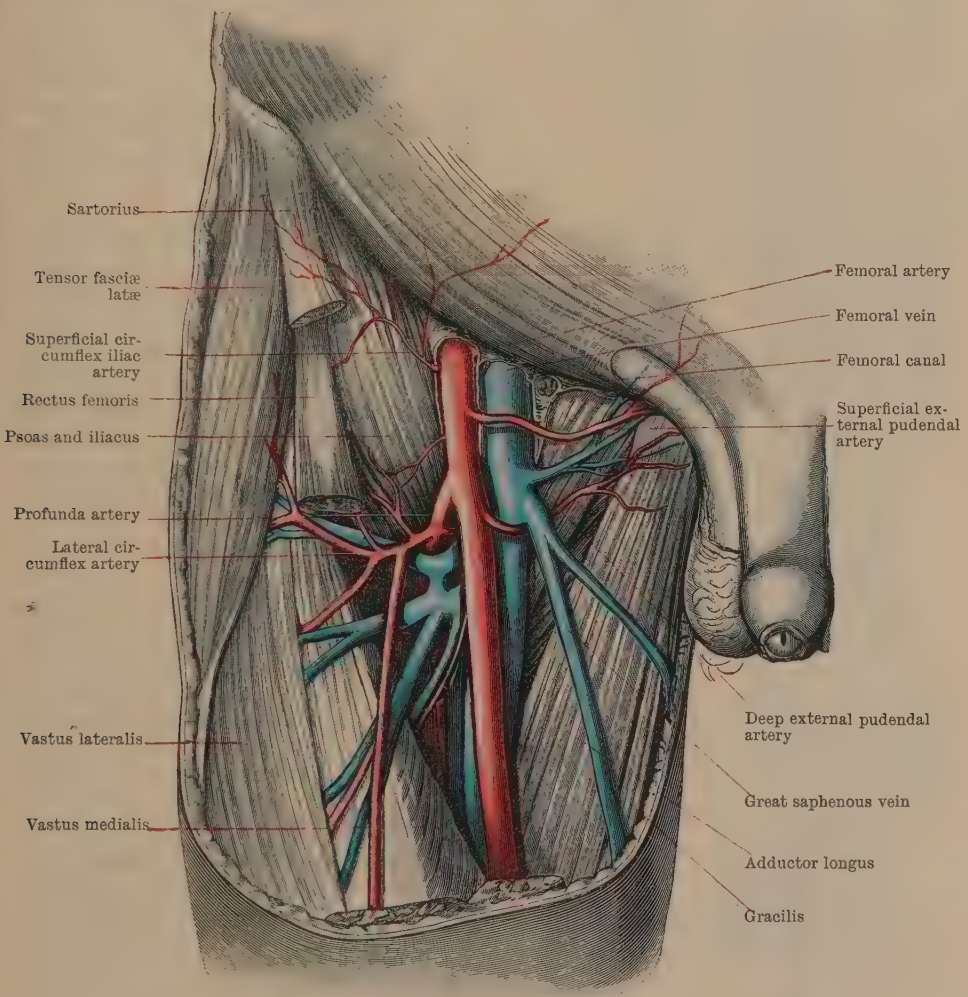

FIG. 770.—THE FEMORAL VESSELS IN THE FEMORAL TRIGONE.

ately behind the hypogastric artery, by joining the hypogastric vein to form the common iliac vein. It lies, at first, on the medial side of the external iliac artery, but on a somewhat posterior plane, and then directly posterior to the artery, whilst just before its termination it crosses the lateral side of the hypogastric artery, and separates that vessel from the medial border of the psoas major muscle. In its whole course the vein lies anterior to the obturator nerve. It is usually provided with one bicuspid valve; sometimes there are two, but both are usually incompetent. Its tributaries correspond to the branches of the external iliac artery; that is, the deep circumflex iliac and inferior epigastric veins open into it, close to its commencement, whilst, in addition, it frequently receives the pubic vein.

The **pubic vein** forms a communication between the obturator vein and the external iliac vein. It varies in size, and may form the main termination of the obturator vein, from which it arises. Commencing in the obturator canal, it ascends, along the pubic branch of the inferior epigastric artery, to reach the external iliac vein.

FIG. 771.—THE GREAT SAPHENOUS VEIN AND ITS TRIBUTARIES.

THE SUPERFICIAL VEINS OF THE INFERIOR EXTREMITY.

The superficial veins of the lower limb terminate in two trunks, one of which, the **small saphenous vein**, passes from the foot to the popliteal space; whilst the other, the **great saphenous vein**, extends from the foot to the groin.

The superficial veins of the sole of the foot form a fine plexus, immediately under cover of the skin, from which anterior, medial, and lateral efferents pass. The anterior efferents terminate in a transverse arch which lies in the furrow at the roots of the toes, and the medial and lateral efferents pass round the sides of the foot to the great or small saphenous veins. The transverse arch receives also small plantar digital veins from the toes, and it communicates by **intercapitular veins** with the veins on the dorsum of the foot.

The superficial veins on the dorsal aspect of each toe unite to form two **dorsal special digital veins**, which run along the borders of the dorsal surface. The special dorsal digital veins of the adjacent borders of the interdigital clefts unite, at the apices of the clefts, to form four dorsal metatarsal veins which terminate in the dorsal venous arch. The dorsal digital vein from the medial side of the great toe ends in the great, and that from the lateral side of the little toe in the small saphenous vein.

The **dorsal venous arch** lies in the subcutaneous tissue, between the skin and the dorsal digital branches of the superficial peroneal nerve, opposite the anterior parts of the bodies of the metatarsal bones. It ends, medially, by uniting with the medial dorsal digital vein of the great toe to form the great saphenous vein, and laterally by joining the lateral dorsal digital vein of the little toe to form the small saphenous vein. The dorsal venous arch receives the dorsal metatarsal veins; interdigital efferents from the plantar transverse arch; and numerous tributaries from the dorsum of the foot, which anastomose freely together forming a wide-meshed dorsal venous plexus, open into it posteriorly.

The **great saphenous vein** is formed by the union of the medial extremity of

the dorsal venous arch with the medial dorsal digital vein of the great toe. It passes anterior to the medial malleolus, crosses the medial surface of the distal third of the body of the tibia, and ascends, immediately posterior to the medial margin of the tibia, to the knee, where it lies just posterior to the medial condyle of the femur; continuing proximally, with an inclination forwards and laterally, it gains the proximal part of the femoral trigone, where it perforates the fascia cribrosa and the femoral sheath to reach its termination in the femoral vein. In the foot and leg it is accompanied by the saphenous nerve, and for a short distance distal to the knee by the superficial or saphenous branch of the arteria genu suprema. In the thigh, branches of the medial cutaneous nerve (O.T. internal) lie in close relation with it. It contains from eight to twenty bicuspid valves.

FIG. 772.—THE SMALL SAPHENOUS VEIN AND ITS TRIBUTARIES.

Tributaries. — It communicates freely, through the deep fascia, with the deep intermuscular veins. In the foot, it receives tributaries from the medial part of the sole and from the dorsal venous plexus. In the leg it is joined by tributaries from the dorsum of the foot, the medial and posterior parts of the heel, the front of the leg and the back of the calf, and it anastomoses freely with the small saphenous vein. In the thigh it receives numerous tributaries, and amongst them are two **superficial femoral veins**. Of these, the *lateral* ascends from the lateral side of the knee and terminates in the great saphenous vein at the distal part of the femoral trigone; the other, the *medial*, ascends from the posterior aspect of the thigh, along its medial side, and terminates in the great saphenous vein near the fossa ovalis. In many cases the medial superficial femoral vein communicates distally with the small saphenous vein, and when that condition exists the medial superficial femoral vein is called the *accessory saphenous vein*. The last tributaries to enter the great saphenous vein are the **superficial circumflex iliac, superficial epigastric**, and **superficial external pudendal veins**. They accompany the corresponding arteries, and terminate in the great saphenous vein immediately before it perforates the fascia cribrosa.

The superficial circumflex iliac vein receives blood from the lower and lateral part of the abdominal wall and the proximal and lateral parts of the thigh. The superficial epigastric vein drains the lower and medial part of the abdominal wall, and the superficial external pudendal vein receives blood from the dorsum of the penis and the scrotum in the male, and from the labium majus in the female.

The **small saphenous vein** is formed by the union of the lateral extremity of the dorsal venous arch with the lateral dorsal digital vein of the little toe. At first it passes posteriorly, along the lateral side of the foot and distal to the lateral malleolus, lying on the peroneal retinacula (O.T. ext. ann. lig.), in company with the nervus suralis; then it passes posterior to the lateral malleolus, and along the lateral border of the tendo calcaneus, still in company with the nervus suralis, to the middle of the calf, proximal to which it is continued in the superficial fascia, accompanied by the superficial sural artery, to the distal part of the popliteal fossa,

where it pierces the deep fascia, and terminates in the popliteal vein. It communicates, round the medial side of the leg, with the great saphenous vein, and through the deep fascia with the deep veins, and it contains from six to twelve bicuspid valves.

Tributaries.—It receives tributaries from the lateral side of the foot, the lateral side and back of the heel, the back of the leg, and, occasionally, a descending tributary from the back of the thigh. Just before it pierces the popliteal fascia it frequently gives off a small branch which ascends round the medial side of the thigh and unites with the medial superficial femoral vein to form the accessory saphenous vein. In that way a communication is established between the great and small saphenous veins, which may become enlarged, and constitute the main continuation of the small saphenous vein.

Abnormalities.—The **venæ comites** are generally described as terminating in the lower extremity, at the distal part of the popliteal fossa, but they may ascend as far as the femoral trigone; as a matter of fact, one or more small additional veins usually accompany the popliteal and femoral arteries, although as a rule there is only one large popliteal and one large femoral vein.

In a few cases the popliteal vein does not pierce the distal part of the adductor magnus, but ascends behind that muscle and becomes continuous with the profunda vein, the femoral artery being unaccompanied by any large vein during its passage through the adductor canal.

THE PORTAL SYSTEM.

The veins which form the **portal system** are the portal, the superior and inferior mesenteric and the splenic veins and their tributaries. They convey blood to the liver—(1) from almost the whole of the abdominal and pelvic parts of the alimentary canal, (2) from the pancreas, and (3) from the spleen. The tributaries of origin correspond closely with the terminal branches of the splenic, and the superior and inferior mesenteric arteries, after which they are named and which they accompany for a considerable distance. The larger or terminal veins, however, leave their associated arteries; the **inferior mesenteric vein** joins the **splenic vein**, and the latter unites with the **superior mesenteric vein** to form the **portal vein**, which passes to the liver. All the larger vessels of this system are devoid of valves, but valves are present in the tributaries.

Vena Portæ.—The **portal vein** is a wide venous channel, about 75 mm. (three inches) long, which conveys blood from the stomach, from the whole of the intestine, except the terminal portion of the rectum, and from the spleen and pancreas to the liver. Unlike other veins, it ends like an artery, by breaking up into branches which ultimately terminate in capillaries in the substance of the liver; from the capillaries, which also receive the blood conveyed to the liver by the hepatic artery, the hepatic veins arise; and, as the hepatic veins open into the inferior vena cava, the portal blood ultimately reaches the general systemic circulation.

The portal vein commences by the union of the superior mesenteric and the splenic veins, posterior and to the left of the neck of the pancreas, and either anterior to the left border of the inferior vena cava, at the level of the body of the second lumbar vertebra, or in front of the upturned extremity of the processus uncinatus of the head of the pancreas. It ascends, anterior to the inferior vena cava and posterior to the neck of the pancreas and the first part of the duodenum, to the lower border of the epiploic foramen (Winslow), where it passes forwards, in the right gastro-pancreatic fold of peritoneum, and enters the lower border of the gastro-hepatic ligament. Continuing its upward course, it lies posterior to the bile-duct and hepatic artery, and anterior to the epiploic foramen (Winslow); it ultimately reaches the right end of the porta hepatis, where it ends by dividing into a short and wide right and a longer and narrower left branch. Just before its termination it enlarges, forming the *sinus of the portal vein.*

The **right branch** generally receives the **cystic vein** and then enters the right lobe of the liver, in which it breaks up into numerous branches which terminate in the portal capillaries around the periphery and in the substance of the liver lobules.

The **left branch** runs from right to left, along the porta hepatis, giving off branches to the caudate and quadrate lobes; it crosses the umbilical fossa, and

ends in the same manner as the right branch, but in the substance of the left lobe of the liver.

As it crosses the umbilical fossa, the left branch of the portal vein is joined, anteriorly, by the **round ligament** of the liver and some small veins, and, posteriorly, by the **ligamentum venosum.** The round ligament is a fibrous cord which passes from the umbilicus to the left branch of the portal vein. It represents the remains of the left umbilical vein of the fœtus. The small veins which accompany

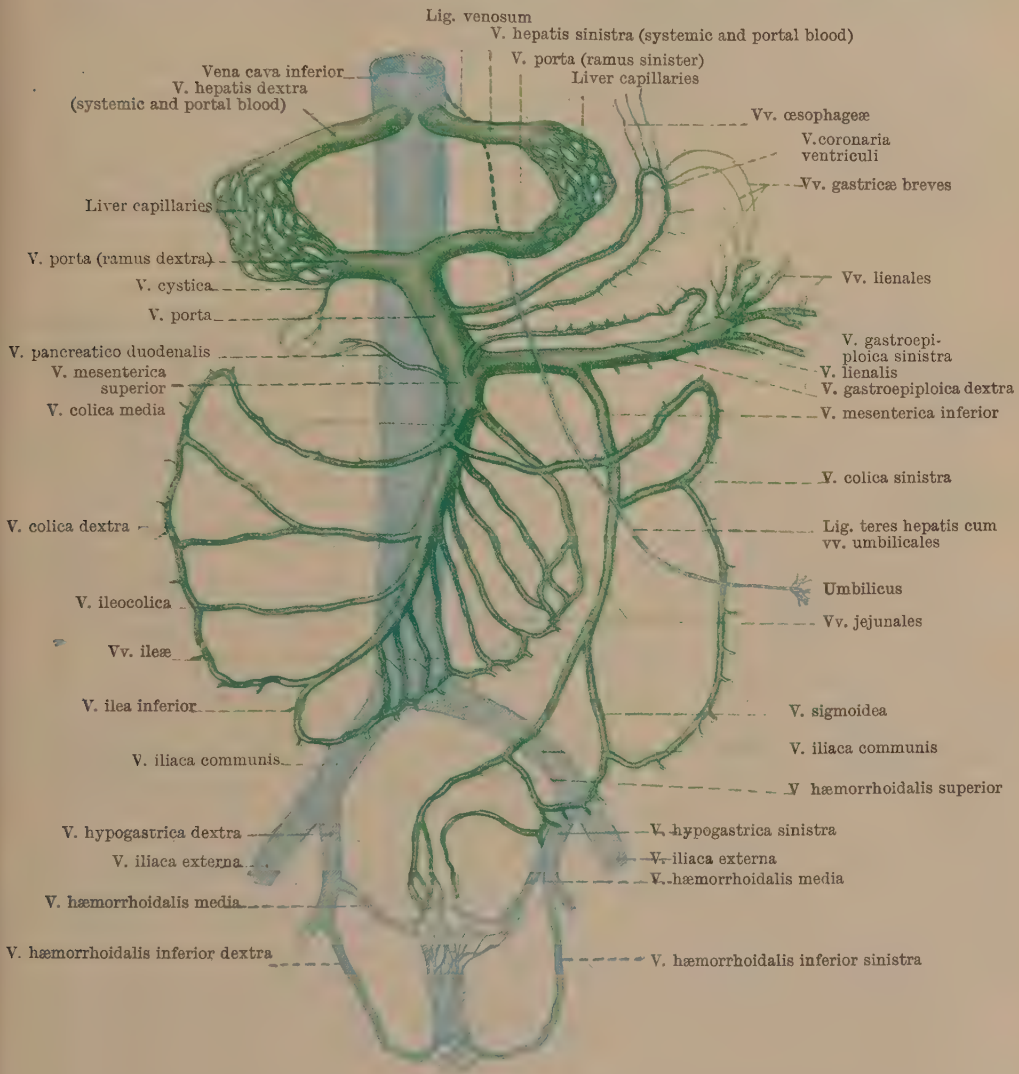

FIG. 773.—SCHEMA OF THE PORTAL SYSTEM OF VEINS AND ITS CONNEXIONS WITH THE SYSTEMIC SYSTEM.—It must be remembered that systemic blood carried by the hepatic artery also enters the liver capillaries, therefore the hepatic veins contain both portal and systemic blood.

it connect the left branch of the portal vein with the superficial veins round the umbilicus. The ligament venosum connects the left branch of the portal vein with the upper part of the inferior vena cava. It is the remains of a fœtal blood-vessel, the **ductus venosus**, through which blood, carried from the placenta by the left umbilical vein, passed to the inferior vena cava without going through the liver.

The portal vein is accompanied by numerous lymph vessels, and it is surrounded, in the lesser omentum, by filaments of the hepatic plexus of nerves.

Tributaries.—Soon after its formation the portal vein receives the coronary and right gastric veins, and the cystic vein opens into its right branch.

Vena Coronaria Ventriculi.—The **coronary vein** commences in the lesser omentum by the union of tributaries from both surfaces of the stomach. It runs to the left between the layers of the lesser omentum, and along the lesser curvature of the stomach, with the left gastric artery, to the œsophagus, where it receives œsophageal tributaries. It then turns posteriorly, in the left gastro-pancreatic fold, and reaches the posterior wall of the abdomen, where it again changes its direction to run from left to right, behind the omental bursa, to the right gastro-pancreatic fold, at the root of which it opens into the portal vein.

The **right gastric vein** is a small vessel which is formed by the union of tributaries from the upper parts of both surfaces of the stomach. It runs from left to right along the right portion of the lesser curvature, between the layers of the lesser omentum, and terminates in the portal vein, after that vessel has entered the lesser omentum.

Vena Cystica.—The **cystic vein** is formed by the union of tributaries which accompany the branches of the cystic artery on the anterior and posterior surfaces of the gall-bladder; it ascends along the cystic duct and, as a rule, terminates in the right branch of the portal vein. Some small veins pass directly from the gall-bladder into the substance of the liver.

The Mesenteric and Splenic Veins.

The **superior mesenteric vein** commences in the right iliac fossa, in connexion with the lower part of the ileum. It ascends, along the right side of the superior mesenteric artery, in the root of the mesentery, forming a curve with the convexity to the left.

As it ascends it passes anterior to the right ureter, the lower part of the inferior vena cava, the third part of the duodenum, and the uncinate process of the head of the pancreas; and, after passing behind the root of the transverse mesocolon, it terminates, behind the neck of the pancreas, by uniting with the splenic vein to form the portal vein.

Its **tributaries** correspond with the branches of the superior mesenteric artery. It is formed by the union of the ileo-cæcal and appendicular veins. Anteriorly and towards the left side it receives intestinal tributaries (**venæ intestinales**) from between the layers of the mesentery; the right colic and ileo-colic veins enter its right side; the middle colic vein joins it anterior to the lower border of the head of the pancreas, and close to its termination it receives the right gastro-epiploic and the pancreatico-duodenal veins.

The **right gastro-epiploic vein** runs from left to right along the lower border of the stomach, between the two anterior layers of the greater omentum. It receives tributaries from both surfaces of the stomach, and near the pylorus turns posteriorly, in the right gastro-pancreatic fold of peritoneum, passes in front of the neck of the pancreas, and ends in the superior mesenteric vein.

The **pancreatico-duodenal** vein receives tributaries from the head of the pancreas and the adjacent parts of the duodenum; it ascends along the superior pancreatico-duodenal artery, and terminates in the upper part of the superior mesenteric vein or in the portal vein.

The **splenic vein** is formed by the union of five or six tributaries which issue from the hilum on the gastric surface of the spleen. It passes posteriorly and medially, in the lieno-renal ligament, to the kidney, then, turning to the right, it runs behind the upper border of the pancreas and below the splenic artery; it crosses the front of the abdominal aorta, immediately below the origin of the cœliac artery, and terminates, behind the neck of the pancreas, by joining the superior mesenteric vein to form the portal vein.

Tributaries.—It receives the vasa brevia or short gastric veins, the left gastro-epiploic vein, the pancreatic veins, and the inferior mesenteric vein. Occasionally the coronary vein terminates in it.

The **short gastric veins** are a series of small venous channels which gather blood from the region of the left portion of the greater curvature of the stomach; they pass backwards towards the spleen, in the gastro-splenic ligament, and terminate either in the trunk of the splenic vein or in one of its main tributaries.

The **left gastro-epiploic vein** runs from right to left along the lower border of the stomach between the layers of the greater omentum. At the left extremity of the lower part of the greater curvature of the stomach it enters the gastro-splenic ligament, through which it passes towards the hilum of the spleen, and it terminates in the commencement of the splenic vein. It receives tributaries from both surfaces of the stomach.

The **pancreatic veins** issue from the substance of the pancreas, and terminate directly in the splenic vein.

The **inferior mesenteric vein** commences, as the **superior hæmorrhoidal vein**, in the venous plexus which lies between the muscular and mucous coats of the rectum. The **superior hæmorrhoidal vein** drains the greater part of the blood from the hæmorrhoidal plexus, through which it communicates with the middle and inferior hæmorrhoidal veins. It ascends, in company with the superior hæmorrhoidal artery and between the layers of the pelvic mesocolon,

to the aperture of the pelvis minor, where it passes in front of the left common iliac artery and becomes the inferior mesenteric vein.

The inferior mesenteric vein runs upwards, on the left of the aorta, behind the peritoneum and in front of the left psoas major muscle and the left internal spermatic artery. Near its termination it crosses in front of the left renal vein, and, passing behind the body of the pancreas, ends in the splenic vein. Occasionally it terminates in the angle of union of the superior mesenteric and splenic veins.

Tributaries.—In addition to the superior hæmorrhoidal vein, of which it is the direct continuation, the inferior mesenteric vein receives **sigmoid tributaries** from the iliac and pelvic colon, and the **left colic vein** from the descending colon and left colic flexure.

THE LYMPH VASCULAR SYSTEM.

The vessels of the lymph vascular system, **vasa lymphatica**, contain a colourless fluid, rich in white corpuscles, which is called **lymph**.

In many respects the lymph vessels resemble blood-vessels, especially veins, and, like the veins, many of the lymph vessels, but not all, contain numerous valves, which control the direction of the circulation. Unlike the veins, however, the lymph vessels communicate directly or indirectly with the great serous cavities of the body; and also unlike the veins, the continuity of the lymph vessels is interrupted by interposed nodular aggregations of lymphoid tissue which are known as **lymph glands**.

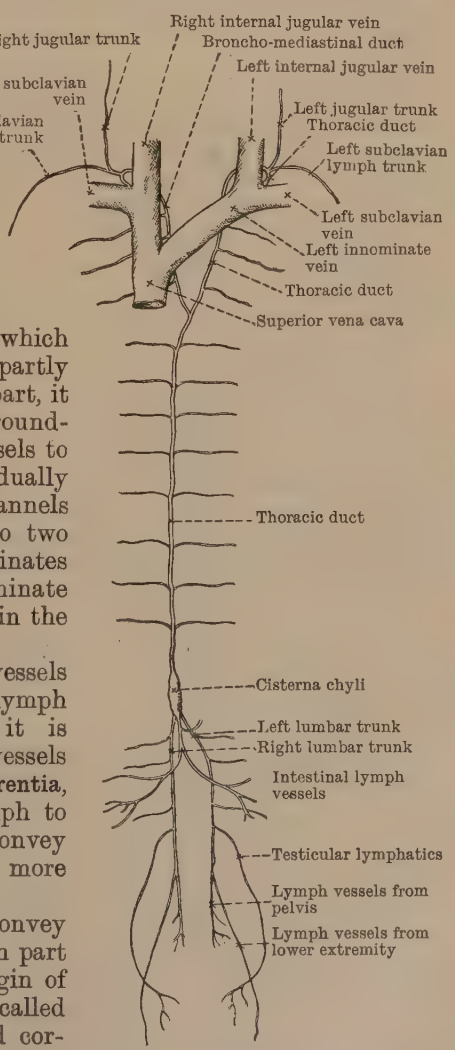

Fig. 774.—Diagram of Main Lymph Vessels.

The corpusculated fluid called lymph, which fills the interiors of the lymph vessels, is partly collected from the serous cavities, and, in part, it passes into the lymph vessels from the surrounding tissues. It is carried by the lymph vessels to the veins; for the smaller lymph vessels gradually unite together to form larger and larger channels until, ultimately, all the lymph passes into two main trunks—the **thoracic duct**, which terminates in the commencement of the left innominate vein, and the **right lymph duct**, which ends in the beginning of the right innominate vein.

Obviously, therefore, all the lymph vessels are afferent inasmuch as they carry the lymph towards the great central vessels, but it is customary to speak of some of the lymph vessels as **vasa afferentia** and others as **vasa efferentia**, the former being vessels which carry lymph to lymph glands, and the latter, those which convey the lymph from more peripheral towards more central glands.

The lymph vessels merely collect and convey lymph; the lymph glands probably serve in part as filters and in part as the sources of origin of some of the lymph corpuscles, which are called **lymphocytes** and which become white blood corpuscles when they enter the blood stream.

In its course from the tissues to the blood-vessels the greater part, if not the whole, of the lymph passes through one and generally through more than one lymph gland.

All parts of the body which possess blood-vessels, except the central nervous

system, the eye and the internal ear, are plentifully provided with lymph vessels, which are divided, according to their positions, into superficial and deep vessels.

The *superficial lymph vessels* lie in the skin and subcutaneous tissues; they frequently accompany the superficial veins and, in the limbs, they join the deep vessels in definitely localised situations.

The *deep lymph vessels* drain the lymph from all parts of the body which lie internal to the deep fascia; they tend to accompany the blood-vessels of the various parts and organs.

The lymph glands also are divided into superficial and deep groups. The former lie in the superficial fascia and are comparatively few in number. They are associated more particularly with the superficial lymph vessels of the limbs. The deep lymph glands of the limbs are also comparatively few in number, but those of the head, neck, and trunk are very numerous.

Vasa Lymphatica.—The smaller lymphatics are channels of various shapes but of greater calibre than the blood capillaries. They anastomose freely together, forming lymphatic plexuses.

Their walls are formed by a single layer of endothelial cells of irregular shape and sinuous outline, which are in close contact, externally, with the tissue elements amidst which they lie. In some cases lymph vessels, or plexuses of lymph vessels, surround the blood-vessels forming *perivascular lymph channels.* It has been generally believed that such perivascular channels are numerous in the central nervous system, but the researches of Bruce tend to show that, whilst the lymphocytes travel along the walls of the blood-vessels of the central nervous system, they pass along cleft-like spaces in the adventitial sheaths, and not in distinct perivascular channels.

As the lymph vessels attain a larger size their walls are strengthened by the deposition of a layer of elastic fibres on the outer surface of the endothelial coat. The fibres run longitudinally, and in some cases fuse together to form a fenestrated elastic membrane.

The walls of all the largest lymph vessels, like those of the blood-vessels, are formed by three tunics, external, middle, and internal. The **tunica intima** consists of a layer of endothelium covered externally by elastic fibres or fenestrated elastic membrane. The **tunica media** is formed of transverse and oblique unstriped muscle fibres, intermingled with elastic fibres. The **tunica externa** consists of longitudinal connective tissue elements, with which are intermingled oblique and longitudinal unstriped muscle fibres; the latter feature being peculiarly characteristic, for it is not met with in the blood vascular system, except in the walls of the large veins.

Bicuspid valves, formed by semilunar folds of the tunica intima are extremely numerous in the lymph vascular system. They are either absent or they are few and incompletely developed in the small vessels and the lymph plexuses, but they are very prevalent in the larger vessels; consequently when the latter are injected they assume a modulated outline. Valves are present also at the entrances of the great lymph channels into the venous system.

Lymphoglandulæ.—**Lymph glands** are globular, ovoid, flattened, or irregular bodies, and each gland presents a localised depressed area which is known as the *hilum.* The lymph glands vary considerably in size, some being no larger than a pin's-head, whilst others are as large as a bean. In colour they are usually grayish pink, but the tint varies with the position, vascularity, and state of activity of the gland. The lymph glands of the lung are generally blackened by the deposition of carbonaceous material in their substance, and those of the liver and spleen frequently have a brownish hue. The lymph glands of the mesentery are creamy or white whilst the chyle is rapidly passing through them, but when the absorption of food-material from the intestine ceases they become a rosy pink.

The lymph glands are embedded in the connective tissues, some lying superficially in the subcutaneous tissues, but the majority more deeply and usually at the sides of the great blood-vessels. As a rule, they are arranged in groups of from two to fifteen, but a few of those which lie in the subcutaneous tissues are solitary.

They form centres to which afferent lymphatic vessels converge, and from which efferent vessels pass onwards to other glands or to the larger lymph channels.

The student should, therefore, acquaint himself with the various groups of glands, with their afferents and efferents, and with the exact position and relations of the large lymphatic trunks; he will then be in a position to understand the course which minute organisms or particles, which have gained access to the lymph spaces, may take as they are carried in the lymph stream; and he will realise that such structures may either be entangled in the glands through which the lymph passes, or, having escaped all obstructions, that they will finally enter the veins at the root of the neck. At the same time, if he bears in mind the existence of the numerous anastomoses between the lymph vessels, he will have no difficulty in appreciating that variations from any regular course may not infrequently occur, and his clinical experience at a later period will show that such variations are by no means uncommon.

Structure of Lymph Glands.—Lymph glands consist of (1) a skeleton or framework, (2) lymph sinuses, and (3) lymph follicles and cords; and each gland is separable into cortex and medulla. The cortex lies immediately internal to the capsule, except at the hilum, where it is absent. The medulla forms the internal part of the gland, and reaches the surface at the hilum.

(1) The **skeleton** or framework consists of a **capsule** and of primary, secondary, and tertiary **trabeculæ**.

The *capsule* is formed of white fibrous tissue, interspersed with elastic fibres, and in some cases with unstriped muscular fibres.

The *primary trabeculæ* spring from the deep surface of the capsule and radiate through the cortex into the medulla. In the cortex they are flattened lamellæ, but as they reach the medulla they break up into flattened, rounded, and angular bands which unite freely together; their structure is the same as that of the capsule, and from their surfaces the secondary trabeculæ are given off. The *secondary trabeculæ* spring from the surfaces of the primary trabeculæ, cross the lymph sinuses and enter the follicles of the cortex and the cords of the medulla, where they terminate by dividing into tertiary trabeculæ. As they cross the lymph sinuses they unite together freely, forming a fine mesh-work through which the lymph passes in its course from the afferent to the efferent vessels. The secondary trabeculæ consist of fine strands of fibrous tissue devoid of nuclei. The *tertiary trabeculæ* are finer and more delicate than the secondary trabeculæ, from the terminations of which they spring, but they have a similar structure. They unite together, forming a fine network in the lymph cords and follicles, and the spaces of the network are filled with lymph corpuscles. The surfaces of the trabeculæ which bound the lymph sinuses are covered with flat cells which according to some observers are endothelial plates, similar to those which line all tubes of the vascular system, but it is also asserted that the flat cells are continuous with the fibrils of the reticulum and are, therefore, merely flattened connective tissue cells.

(2) The **lymph sinuses** lie internal to the capsule and around the primary trabeculæ which form their boundaries on one side, whilst on the other they are limited by the lymph cords and follicles. They are traversed by the secondary trabeculæ, and their channels are thus converted into a kind of sponge-work through which the lymph stream flows. In the cortical parts of the glands they form more or less cylindrical channels, but in the medulla they become moniliform. Afferent vessels enter the sinuses of the cortex, and the efferent vessels emerge from the medulla at the hilum.

The **lymph follicles** lie in the cortical portions of the lymph glands, where they form the inner boundaries of the lymph sinuses. They consist of dense masses of lymphoid cells, embedded in a stroma formed by the tertiary trabeculæ, and they are continuous internally with the lymph cords of the medullary substance.

The **lymph cords** are continuous with the lymph follicles, and have the same structure, but they lie in the medullary portions of the glands; they are cord-like and not nodular in shape, and they form the peripheral boundaries of the lymph sinuses of the medulla.

The Blood-Vessels of the Lymph Glands.—Blood-vessels are distributed to the capsule and through the capsule to the primary trabeculæ of the glands; but the main blood-vessels to each gland enter the hilum and ramify in the lymph cords and follicles, amidst the tertiary trabeculæ which are connected with the walls of the vessels.

Hæmal Lymph Glands.—In various parts of the body, but more particularly in the retro-peritoneal region, and especially along the line of the abdominal aorta, a number of bodies may be found which have all the ordinary structural characters of lymph glands, but they differ from lymph glands inasmuch as some of their sinuses contain blood. These structures are called hæmal lymph glands. The sinuses of the hæmal lymph glands which contain lymph are in continuity with lymphatics, whilst the blood-filled sinuses open into blood-vessels. It is stated that communications exist between the blood and the lymph containing sinuses of the hæmal lymph glands, but the evidence on this point is not quite satisfactory.

Hæmal Glands.—The term "hæmal gland" is applied to nodules possessing the structure of ordinary lymph glands, but which contain only blood in their sinuses;

they probably belong, however, as their development shows, to the lymph vascular and not to the blood vascular system.

THE TERMINAL LYMPH VESSELS.

The terminal lymph vessels are the **thoracic duct** and the **right lymph duct.**

The **thoracic duct** is by far the larger and the longer of the two terminal lymph vessels. It commences, in the epigastric region of the abdomen, as an

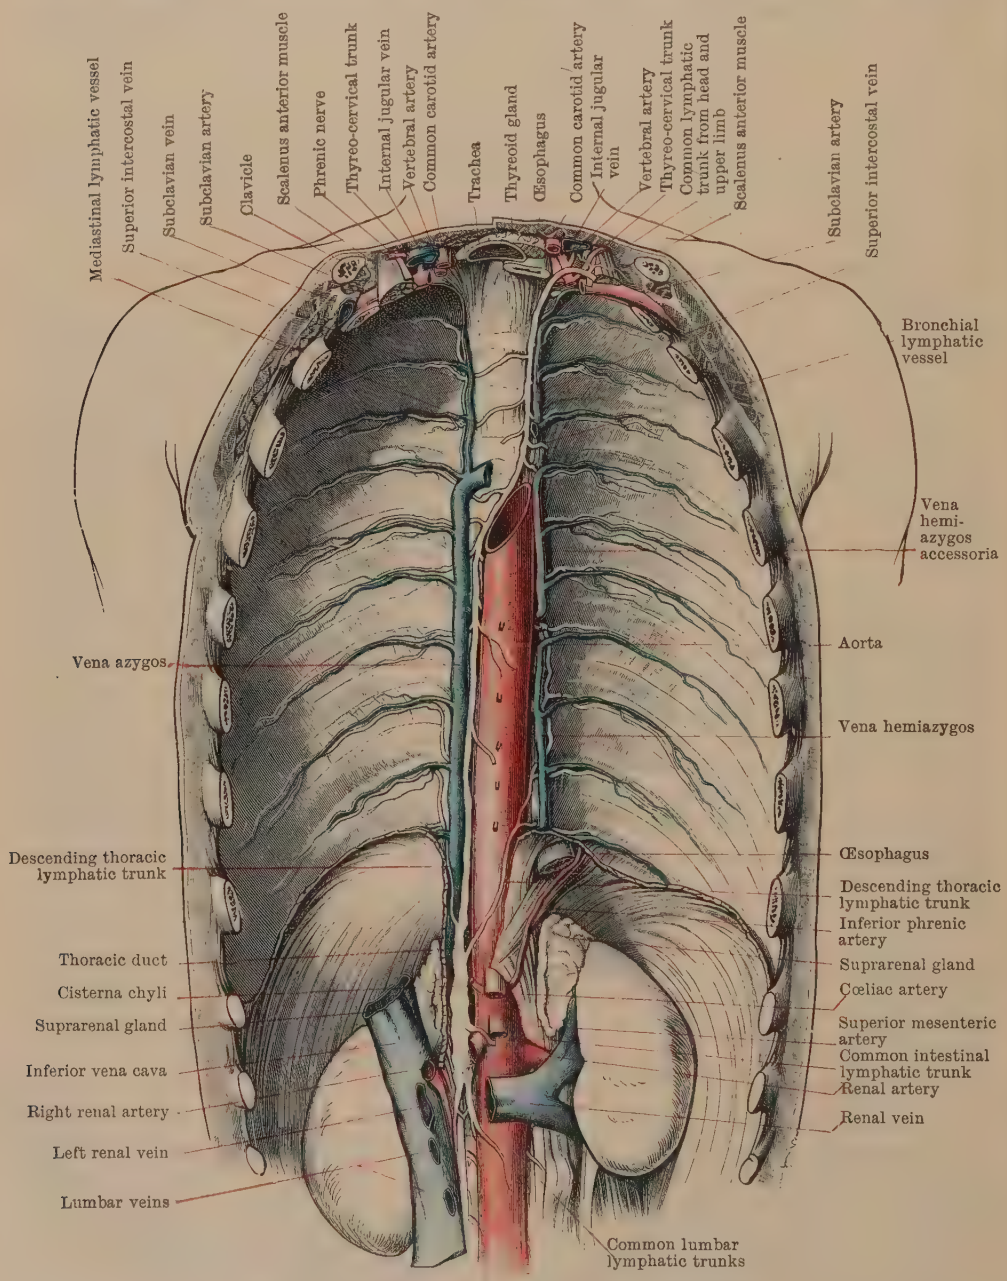

FIG. 775.—THE THORACIC DUCT AND ITS TRIBUTARIES.

elongated ovoid dilation—the **cisterna chyli**—which measures 6 to 8 mm. ($\frac{1}{4}$ to $\frac{1}{3}$ in.) in its broadest diameter, and from 50 to 75 mm. (2 to 3 in.) in length. The cisterna chyli lies between the aorta and the lower part of the vena azygos,

posterior to the right crus of the diaphragm, and opposite the first and second lumbar vertebræ. Passing upwards from the cisterna, the thoracic duct traverses the aortic opening of the diaphragm and enters the posterior mediastinum, through which it ascends, lying anterior to the vertebral column and to the right of the median plane, to the level of the fifth thoracic vertebra; it then crosses somewhat abruptly from the right to the left of the median plane, and ascends through the superior mediastinum to the root of the neck, where it turns laterally, between the vertebral and common carotid arteries, and it terminates, at the medial border of the left scalenus anterior, by joining the left innominate vein at its commencement.

Length and Diameter.—The total length of the duct averages about 45 cm. (18 inches). It is dilated at both its origin and termination. As a rule it is narrowest opposite the fifth thoracic vertebra, but its calibre is very variable, and sometimes the thoracic portion is broken up into a series of anastomosing channels. The widest portion of the tube is usually the cisterna, but occasionally that dilatation is entirely absent. The duct is provided with several valves, formed by semilunar folds of the tunica intima, arranged in pairs, and the most perfect of them is situated at or near the orifice of communication with the left innominate vein.

Relations.—*In the abdomen* the cisterna chyli lies anterior to the upper two lumbar vertebræ and the corresponding lumbar arteries, between the aorta on the left and the vena azygos and the right crus of the diaphragm on the right. *In the posterior mediastinum* the thoracic duct is separated from the vertebral column and the anterior longitudinal ligament by the right aortic intercostal arteries and the transverse parts of the hemiazygos and accessory hemiazygos veins; it is covered, in front, in the lower part of its extent by the right pleural sac, and in the upper part by the œsophagus; to its right is the vena azygos, and to its left the descending aorta. *In the superior mediastinum* it passes forwards from the vertebral column, and it is separated from the left longus colli muscle by a mass of fatty tissue; the œsophagus lies in front of it in that region, but the left margin of the duct projects beyond the œsophagus, and is in relation anteriorly, and from below upwards, with the termination of the arch of the aorta, the left subclavian artery and the pleura. As the duct enters the root of the neck it passes behind the left common carotid artery, whilst to its right and somewhat anterior is the œsophagus, and the left pleura is still in association with its left border.

At the root of the neck it arches laterally above the apex of the pleural sac and the first part of the left subclavian artery. It passes anterior to the vertebral artery and vein, the roots of the inferior thyreoid, transverse cervical, and transverse scapular arteries, the medial border of the scalenus anterior and the left phrenic nerve, and posterior to the left carotid sheath and its contents.

Tributaries. — The cisterna chyli commonly receives five tributaries. (1) **Truncus Intestinalis.**—The **intestinal trunk**, which is formed by the efferents of mesenteric and upper pre-aortic glands, and which conveys lymph from the lower and anterior part of the liver, the stomach, the small intestine, the spleen, and the pancreas. (2) Two **trunci lumbales**, one on each side; they are formed by the efferents of the lumbar glands. They carry lymph from the lower extremities, from the deep portions of the abdominal and pelvic walls, the large intestine and the pelvic viscera, and from the kidneys, suprarenal glands, and genital glands. (3) Two **descending lymphatic trunks**, one on each side, each of which is formed by the efferent vessels from the corresponding lower intercostal glands; these descend to the cisterna through the aortic opening of the diaphragm. Occasionally they unite to form a single trunk, and in others they, or the tributaries from which they are usually formed, open directly into the thoracic duct (Figs. 774, 775).

In its course through the posterior mediastinum the thoracic duct receives efferents from the upper and posterior part of the liver, and from the posterior mediastinal and œsophageal glands; the latter carry lymph from the œsophagus, the pericardium, and the left side of the thoracic wall.

In the superior mediastinum the vessels which open into it are derived from the upper left intercostal glands; it receives lymph also from the heart and left lung by efferents from the left peritracheo-bronchial glands and the intertracheo-bronchial glands, but the efferents of those glands may unite with the internal

mammary lymphatic to form a common trunk which may open either into the thoracic duct or into the innominate vein. In the superior mediastinum, therefore, it may receive lymph from the upper and median part of the abdominal wall, the liver, the diaphragm, the wall of the thorax, and the mammary gland of the left side, the thymus, the pericardium, the left lung, and the left part of the heart.

At the root of the neck, just before its termination, it receives the efferents from the glands of the left superior extremity, which frequently unite to form a subclavian trunk, and the left jugular trunk, which conveys the lymph from the left side of the head and neck; but either of those vessels or both of them may end separately in the innominate vein.

The **right lymph duct** (Fig. 775) is not always present. It is a short trunk, from 12 to 17 mm. (half to three-quarters of an inch) in length, which lies at the right side of the root of the neck along the medial border of the right scalenus anterior, and it is formed by the confluence of (1) the **right jugular trunk**, (2) the **right subclavian trunk**, and (3) the **right broncho-mediastinal trunk**, which carries lymph from the bronchial, the posterior, and the anterior mediastinal and the sternal glands. It thus receives lymph from the right side of the head and neck, the right upper limb and the right side of the trunk, including the upper part of the thoracic wall, the right lung and pleura, the right half of the heart and pericardium, the right side of the diaphragm, and the upper surface of the liver. As a rule, the right lymph duct is not present as a definite stem, and the right jugular trunk carrying the lymph from the head and neck, the right subclavian trunk bearing lymph from the right upper extremity, and the right broncho-mediastinal trunk, end separately in the upper part of the right innominate vein, but any two of the three main trunks of the right side may unite together. The right broncho-mediastinal trunk frequently communicates, below, with the thoracic duct.

LYMPH GLANDS OF HEAD AND NECK.

THE LYMPH GLANDS OF THE HEAD.

All the lymph glands of the head are extracranial.

The **occipital lymph glands**, two or three in number, lie, in or deep to the deep fascia, upon the upper part of the trapezius muscle, or, if the trapezius is small, upon the upper part of the semispinalis capitis or on the splenius muscle. They receive *afferent* vessels from the occipital region of the scalp and from the superficial parts of the upper and back portion of the neck. Their *efferents* terminate in the deep cervical glands. Some of the lymph vessels of the occipital region pass directly to the deep cervical glands (Fig. 776).

The **posterior auricular lymph glands** (O.T. **mastoid**) lie on the upper part of the sterno-mastoid muscle and on the mastoid portion of the temporal bone, and they are bound down by a sheathing of deep cervical fascia. They receive *afferent* vessels from the posterior part of the parietal region of the scalp, and from the medial surface of the auricle. Their *efferents* join the superficial and the deep cervical glands (Fig. 776).

The **anterior auricular lymph glands** (O.T. **parotid**) lie both superficial and deep to the parotid fascia on the lateral surface of the parotid gland. They receive *afferents* from the frontal and the temporal regions of the scalp, from the eyebrow, the upper and lower eyelids, the upper part of the cheek, the root of the nose, and the lateral surface of the auricle. Their *efferents* pass to the superficial and the upper deep cervical glands, and to the parotid lymph glands (Fig. 776).

The **parotid lymph glands** (O.T. **deep parotid glands**) lie embedded in the deeper parts of the parotid gland. They receive *afferents* from the external acoustic meatus, the tympanum, the soft palate, the posterior part of the nose, and the deeper portions of the cheek. Their *efferents* open into the upper deep cervical glands.

The Superficial Facial Lymph Glands.—Several lymph glands, or groups of

lymph glands, have been found in the region of the face but, apparently, they are irregular, both in occurrence and in position. Those which appear to be most frequently found are: **Infra-orbital**, which lie along the angle between the nose and the cheek, and below the margin of the orbit. Their *afferents* are derived from the surrounding parts; and their *efferents* pass to the anterior auricular and the submaxillary lymph glands. **Buccinator lymph glands** have been found on the superficial surface of the anterior part of the buccinator, both anterior and posterior to the anterior facial vein. Those posterior to the vein usually lie close to the point where the parotid duct turns, medially, round the anterior border of

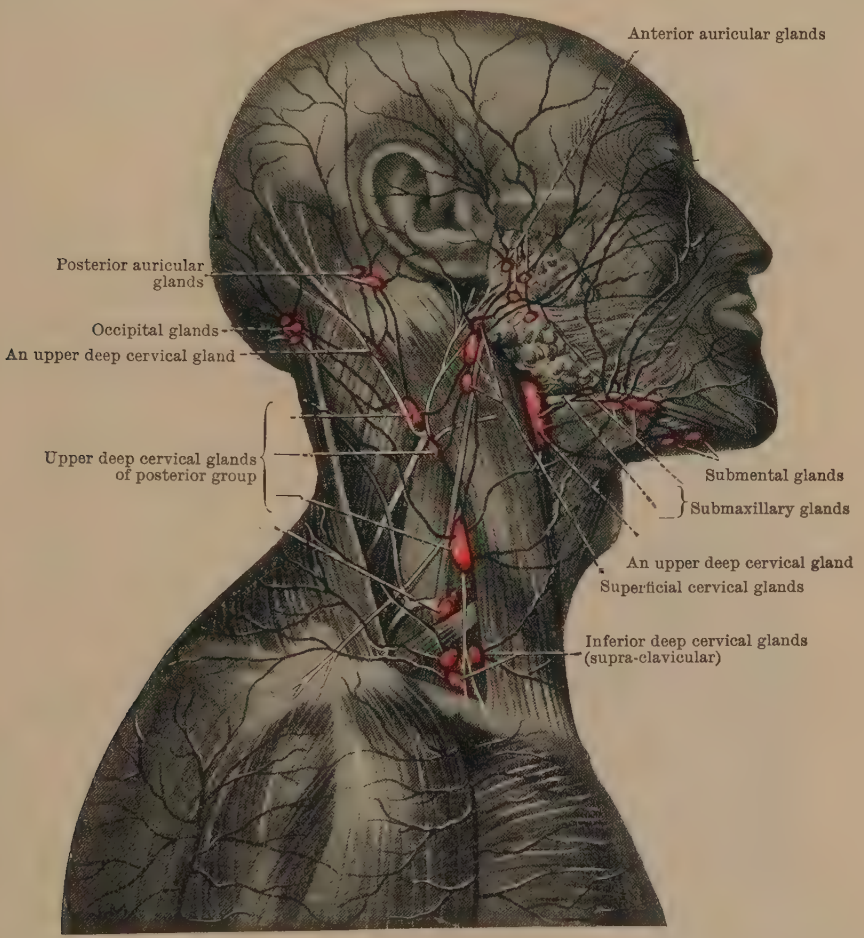

FIG. 776.—LYMPH GLANDS OF THE HEAD AND NECK AS SEEN WHEN THE STERNO-MASTOID IS IN ITS USUAL POSITION. The occipital and the posterior and anterior auricular glands are inserted in accordance with descriptions. The other glands were present in one or other of the two bodies from which the drawing was made. Compare Fig. 778.

the masseter. They receive lymph from the eyelids and cheeks, and transmit it to the anterior auricular glands. **Supra-mandibular lymph glands** lie superficial to the mandible at the anterior border of the masseter, between the anterior facial vein and the external maxillary artery. They receive lymph from the region of the lower lip, and transmit it to the anterior auricular and superficial cervical glands.

The **deep facial lymph glands** are very variable both in number and size; they lie in association with the internal maxillary artery on the external pterygoid muscle, or on the adjacent part of the wall of the pharynx. Their *afferent* vessels are derived from the orbit, the temporal fossa, the infra-temporal fossa, the palate, the nose, and the cerebral meninges. Their *efferent* vessels open into the upper deep cervical glands.

The **lingual lymph glands** lie between the genio-glossi muscles and, on the lateral surfaces of the hyo-glossi and genio-glossi muscles, deep to the mylo-hyoid muscles; they are simply small lymph nodules interposed in the course of the lymphatics which are passing from the tongue and the floor of the mouth to the deep cervical glands.

THE LYMPH GLANDS OF THE NECK.

The **superficial cervical lymph glands** lie on or are embedded in the deep fascia along the course of the external jugular vein, superficial to the sterno-mastoid (Fig. 776). They receive *afferent* vessels from the superficial tissues of the neck, the posterior and anterior auricular, and the submaxillary lymphatic glands. Their *efferent* vessels terminate in the upper deep cervical glands and the supra-clavicular glands. The uppermost superficial cervical glands are sometimes described as infra-auricular glands.

The **submaxillary lymph glands** vary in number from three to six. They lie under cover of the deep fascia of the neck, in the angle between the lower border of the mandible and the submaxillary gland, and the largest of the series is usually situated near the point where the external maxillary artery turns round the lower border of the mandible (Fig. 776). Occasionally some smaller gland nodules are found on the deep surface of the submaxillary gland, but these are comparatively rare. The *afferent* vessels of the submaxillary lymph glands carry lymph from the side of the nose, the upper lip, the lateral part of the lower lip, the anterior third of the border of the tongue, the gums, the submaxillary and sublingual glands, and the adjacent parts of the floor of the mouth. The *efferents* descend, over the superficial surface of the submaxillary gland, and terminate in the upper deep cervical glands, more particularly in those in the immediate neighbourhood of the termination of the common carotid artery.

Paramandibular Lymph Gland.—This term is applied to one or more lymph glands which lie inside the capsule of the submaxillary gland, in close relation with the gland or embedded in its substance. They receive lymph from the gland and the adjacent parts of the mouth and transmit it to the submaxillary and deep cervical glands.

The **submental lymph glands** lie below the chin, superficial to the mylo-hyoid muscles and between the anterior bellies of the two digastric muscles. There are usually two on each side, a medial or superior close to the median plane, and a lateral or inferior on the anterior border of the anterior belly of the digastric. They are apt to become enlarged in diseased conditions of the middle part of the lower lip, the adjacent part of the gums, the anterior part of the floor of the mouth, the tip of the tongue, and the skin beneath the chin, for their afferent vessels drain those parts. The *efferents* from this group of glands pass partly to the submaxillary lymph glands, and partly to a deep cervical gland situated on the superficial surface of the internal jugular vein at the level of the cricoid cartilage (Figs. 777, 778).

The **retro-pharyngeal lymph glands** lie posterior to the upper part of the pharynx, embedded in the fascia covering the superior constrictor muscle. They are separable into two groups, lateral and median.

The *lateral retro-pharyngeal glands*, 1-3, appear to be constant both in children and adults. Each lateral gland, or group of glands, lies at the level of the atlas, anterior to the upper part of the longus capitis, and posterior to the internal carotid artery.

The *median retro-pharyngeal glands*, commonly present in children and frequently absent in adults, lie at the same level as the lateral glands, but in the median plane. They are irregular in number and size.

The retro-pharyngeal lymph glands receive lymph from the adjacent muscles and bones, from the nasal part of the pharynx, from the auditory tube and tympanum, and from the posterior parts of the nasal cavities. Their *efferents* pass to the medial and the lateral deep cervical glands.

The Anterior Cervical Lymph Glands.—The lymph glands of the anterior part of the neck are separable into two groups, superficial and deep.

The **superficial anterior cervical lymph glands** are very irregular in number and size. When they are present they lie in association with the anterior jugular veins. The exact origin of their afferents and the terminations of their efferents are unknown, but it is probable that they receive lymph from the superficial tissues of the anterior parts of the neck, and transmit it to the lower deep cervical glands.

The **deep anterior cervical lymph glands** are—

(*a*) *Infra-hyoid glands*, which lie anterior to the hyo-thyreoid membrane.

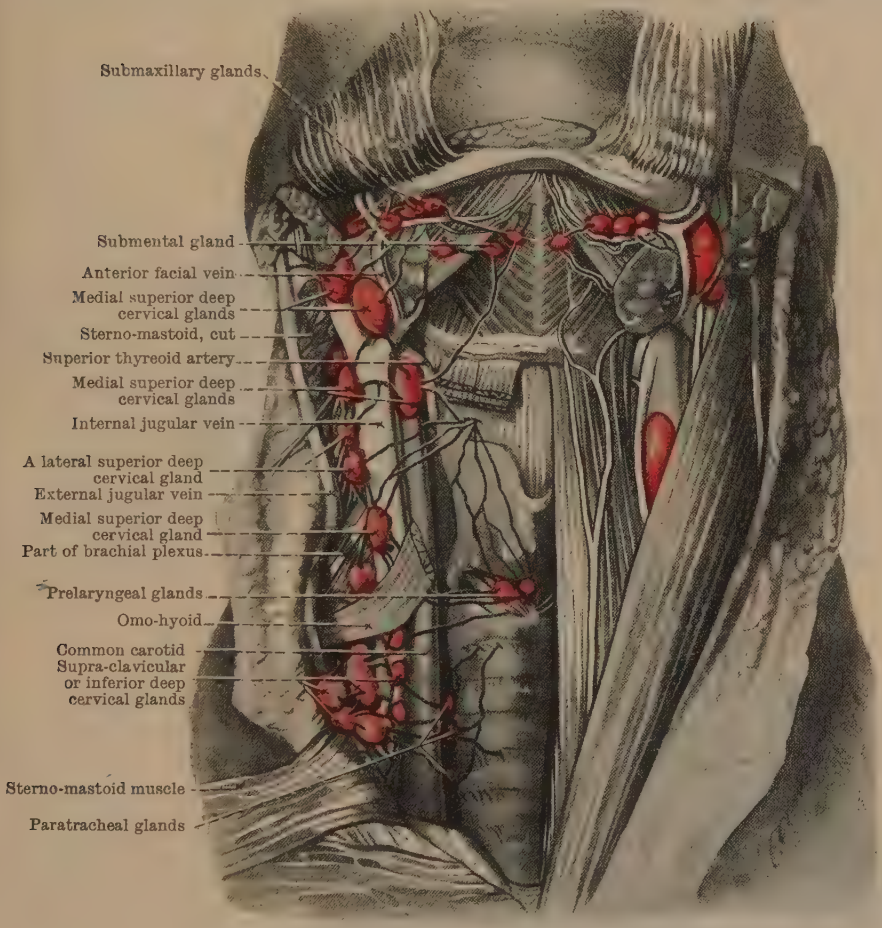

FIG. 777.—LYMPH GLANDS OF THE NECK SEEN FROM THE FRONT.
Infra-hyoid glands and pretracheal glands were not present.

They receive lymph from the region of the epiglottis and transmit it to the deep cervical glands. They are not constantly present.

(*b*) The *prelaryngeal gland*, which lies either anterior to the cricoid cartilage or to the crico-thyreoid ligament. Its occurrence is very constant. It receives lymph from the anterior part of the larynx and from the isthmus and the adjacent parts of the right and left lobes of the thyreoid gland. Its efferents terminate in the deep cervical and the pretracheal glands.

(*c*) The *pretracheal lymph glands* are numerous small nodules which lie along the inferior thyreoid veins. They receive lymph from the trachea, the lower part of the larynx, and from the lobes and the isthmus of the thyreoid gland; and they transmit it to the lower deep cervical glands.

(*d*) The *paratracheal lymph glands* lie along the sulcus between the larynx and the trachea, anteriorly, and the pharynx and œsophagus, posteriorly, in association

with the branches of the superior and inferior thyreoid arteries and the recurrent nerves. They receive lymph from the adjacent parts and transmit it to the deep cervical glands (Fig. 777).

Deep Cervical Lymph Glands.—The **deep cervical lymph glands** lie in the anterior and posterior triangles of the neck and under cover of the sterno-mastoid muscle. They form a more or less continuous sheet of gland nodules and intercommunicating lymph vessels; but the glands are divided into two main groups, the (*a*) superior, and (*b*) inferior, and each group is separable into (1) medial, and (2) lateral components.

(*a*) **The Superior Deep Cervical Lymph Glands.**—(1) The *medial group* of upper

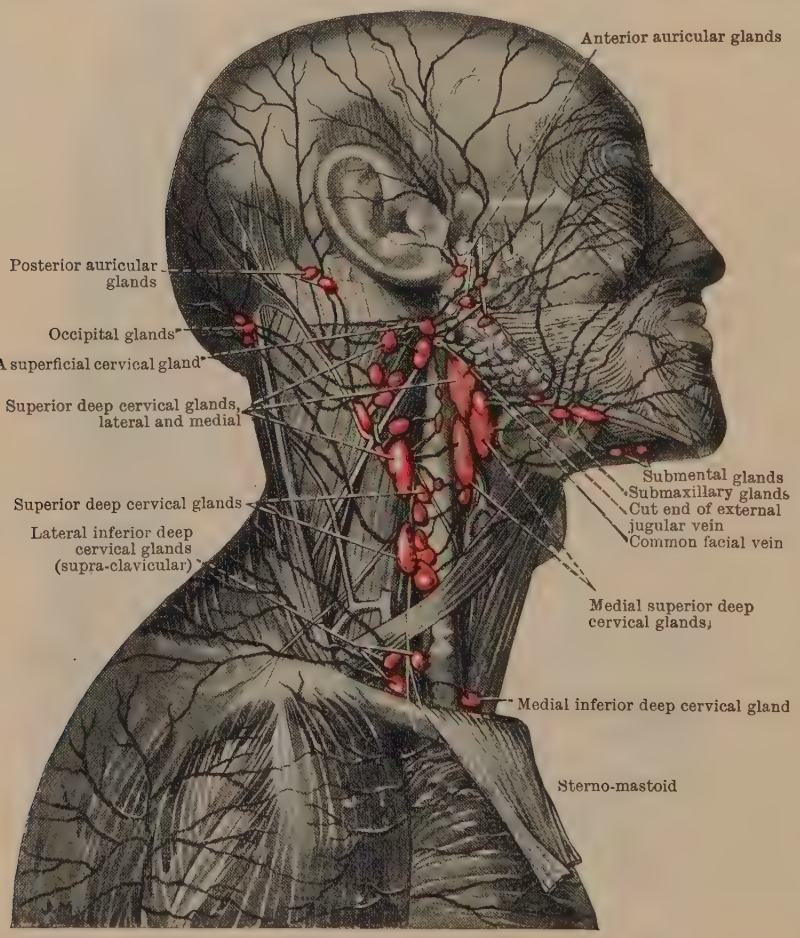

FIG. 778.—LYMPH GLANDS OF THE HEAD AND NECK AS SEEN AFTER THE REMOVAL OF THE STERNO-MASTOID MUSCLE. The anterior and posterior auricular and the occipital glands are inserted in accordance with descriptions. The other glands were present in one or other or in both the bodies from which the figure was made. Compare Fig. 776.

deep cervical lymph glands lies on the superficial surface of the internal jugular vein and in the carotid triangle of the neck. One of the largest, which is closely associated with the tongue, lips, gums, cheeks, and the outer part of the nose, is frequently situated in the region of the union of the common facial vein with the internal jugular vein. The lowest gland of the group lies on the lateral surface of the internal jugular vein immediately above the omo-hyoid muscle; it receives a communication from the submental glands. The highest members of the group may be under cover of the postero-medial surface of the parotid gland, in association with the posterior belly of the digastric muscle. (2) The members of the *lateral group* of superior deep cervical lymph glands lie under cover of the posterior

part of the upper portion of the sterno-mastoid, and in the upper part of the posterior triangle of the neck. They are embedded in the fat-laden fascia which covers the roots of the cervical plexus and the upper part of the brachial plexus, and the levator scapulæ and the scalene muscles, and several of them are in close relation with the accessory nerve (Fig. 778).

The superior deep cervical glands are connected by *afferent* vessels with the various groups of glands which lie in the regions of the pharynx, the face, and the upper part of the neck. They receive lymph, therefore, from the nose, the mouth, the tongue, the upper parts of the pharynx and larynx, the tonsil, the upper part of the thyreoid gland, the submaxillary, sublingual, and parotid salivary glands, and from the interior of the cranium. Their *efferents* pass either to the inferior deep cervical glands or to the jugular lymph trunk. In some cases the medial and lateral members of the superior group are connected with the corresponding members of the lower group only, but in other cases the medial or lateral members of the superior group may be connected with both the medial and the lateral members of the inferior glands.

The **inferior deep cervical lymph glands** (Figs. 776, 778), which are also termed the supra-clavicular glands, are situated below the level of the omo-hyoid muscle. (1) The members of the *medial group* lie in relation with the lower part of the internal jugular vein, opposite the interval between the sternal and the clavicular heads of the sterno-mastoid. They receive *afferents* from the members of the upper medial group and from the pretracheal and the paratracheal glands and from the upper part of the thorax. Their *efferents* unite with some of the efferents of the upper medial group and pass with them to the jugular lymph trunk.

(2) The members of the *lateral group* of inferior deep cervical glands lie in the subclavian triangle, in the fatty tissue superficial to the lower part of the brachial plexus and the third part of the subclavian artery. They receive lymph from the lower parts of the neck, from the upper part of the thorax, and from the upper lateral glands. They receive lymph also from the deep parts of the mammary gland, and they are in communication with the axillary glands. Their *efferents* join the jugular lymphatic trunk.

THE LYMPH VESSELS OF THE HEAD AND NECK.

The lymph vessels of the head and neck may be separated into two groups, intracranial and extracranial.

Intracranial Lymph Vessels and Lymph Spaces.—The cerebro-spinal fluid which fills the ventricles of the brain, the central canal of the spinal medulla, and the subarachnoid and subdural spaces, differs in chemical constitution from true lymph; nevertheless it plays the part of lymph, to some extent, and there can be little doubt that some of it eventually passes into lymph vessels; therefore it may be considered as a modified form of lymph. The fluid is secreted by the chorioid plexuses of the cerebral ventricles, and it passes through the medial and lateral foramina of the fourth ventricle into the cerebello-medullary subarachnoid cistern. Part of the fluid transudes through the arachnoideal granulations into the superior sagittal and other cerebral blood sinuses; and part, probably, passes by osmosis into the subdural space and thence into the meningeal lymphatics, by which it is conveyed to the exterior of the cranium.

Cerebral Lymph Channels.—It appears probable that the so-called peri-vascular and peri-cellular lymph spaces which have so frequently been described in the central nervous system are merely artifacts produced by unsatisfactory methods of preparation. Nevertheless, the fluid which pervades the cerebral substance must have some exit, and it is not unlikely that it passes, with the lymphocytes, through cleft-like intercommunicating spaces in the adventitial coats of the blood vessels, similar to those demonstrated by Bruce in the case of the spinal medulla, and so reaches the pia-mater and subarachnoid space; that is, it runs along the walls of the arteries, enters the meningeal lymphatics, and passes through them to the exterior of the cranium where it enters the extracranial lymph vessels. The above statements are based upon Bruce's researches and the fact that the lymph vessels of the nose, the ear, and the deep lymph vessels of the neck have been injected from the subdural space.

The Superficial Lymph Vessels of the Head.—(1) The superficial lymphatics from the *frontal* and *anterior temporal regions* of the head accompany the branches of the superficial temporal artery and terminate in anterior auricular glands, from which efferents pass to the parotid, the superficial cervical, and to the medial glands of the superior deep cervical group.

(2) The lymphatics of the *posterior temporal* and *parietal region* run to the posterior auricular glands. It is stated that they sometimes communicate directly with the lateral glands of the superior deep cervical group.

(3) The lymphatics from the *occipital part of the scalp* pass along the branches of the occipital

artery and terminate in the occipital glands, which transmit the lymph to the lateral superior deep cervical glands.

The Superficial Lymph Vessels of the Neck.—The majority of the lymph vessels from the skin and the subcutaneous tissues of the upper part of the neck pass to the inferior deep cervical glands, but some end in the occipital glands and others in the superior deep cervical glands.

The superficial lymph channels of the lower part of the neck terminate in the axillary glands.

The Lymph Vessels of the Eyelids and the Conjunctiva.—The lymph vessels which drain the region of the eyelids and the conjunctiva form two groups, a medial and a lateral. (*a*) The *medial vessels* pass from the superficial and deeper parts of the medial portions of the superior and inferior eyelids and, following the course of the angular and the external maxillary arteries, they pass to the submaxillary lymph glands. The more superficial vessels lie anterior, and the deeper vessels posterior to the orbicularis oculi. Both groups may be connected with the infra-orbital and anterior buccinator glands. (*b*) The lymph vessels from the *lateral parts of the eyelids* pass posteriorly, along the line of the transverse facial artery. They end in the anterior auricular and the parotid lymph glands. In some cases they become connected also with the buccinator and superficial cervical glands.

Lymph Vessels of the Eyeball.—It is doubtful if any true lymph vessels exist in the eyeball. Lymph spaces have been described in association with the coats of the eyeball, and lymph

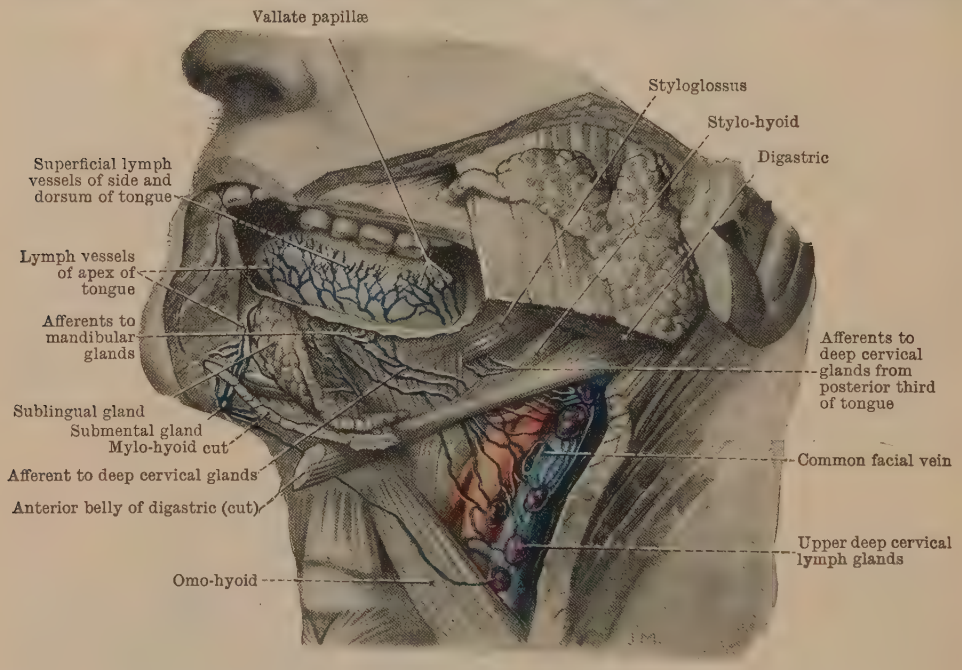

FIG. 779.—LYMPH VESSELS OF THE TONGUE.

vessels are stated to exist in the chorioid coat, but their existence is uncertain. The sinus venosus scleræ (Schlemm), formerly looked upon as a lymph channel, is probably a venous canal. If lymph vessels are absent then the fluids in the tissues and spaces of the eye must pass into the capillaries of the veins, unless channels exist in the adventitia of the vessels similar to those described by Bruce in the spinal medulla.

The Lymph Vessels of the Ear.—The **lymph vessels** from the upper and lateral parts **of the auricle** end in the anterior auricular glands. Those from the lower part of the auricle go to the upper superficial cervical glands. The lymph channels from the medial surface of the auricle end in the posterior auricular glands, but in a few cases they establish direct communication with the superior deep cervical glands.

The **lymph vessels of the external acoustic meatus** end in the anterior and posterior auricular glands.

The **lymph vessels of the middle ear** pass in two directions. Those from the more laterally situated parts of the walls of the cavity join the vessels of the external acoustic meatus and terminate in the posterior auricular glands. The lymph vessels which drain the more medial parts of the middle ear and the auditory tube terminate in the lateral retro-pharyngeal glands.

It is doubtful if any lymph vessels exist in the **internal ear.** It is possible that the perilymph drains into the subarachnoid space of the posterior fossa of the skull along the line of the ductus endolymphaticus and that the endolymph reaches the subarachnoid space along the fibres of the acoustic nerve.

The Lymph Vessels of the Nose.—The lymph vessels from the external part of the nose form two groups, superior and inferior. The *superior group* accompanies the vessels from the lateral parts of the eyelids and ends in the anterior auricular glands. The *inferior group*

accompanies the angular and the external maxillary arteries, and the majority of the vessels end in the submaxillary glands, but in some cases one or more vessels of this group pass to the upper superficial cervical glands.

The Lymph Vessels of the Nasal Muco-periosteum.—The vessels from the anterior part of the nasal muco-periosteum accompany the vessels of the lower portion of the external part of the nose and end in the submaxillary glands. Those from the posterior part of the muco-periosteum end partly in the medial superior deep cervical glands, and partly in the lateral retro-pharyngeal glands.

There is little definite knowledge regarding the lymph vessels of the accessory sinuses of the nose, but it is probable that they follow the lines of the blood-vessels which supply the muco-periosteum of the cavities.

The Lymph Vessels of the Lips.—The vessels from the skin of the medial part of the lower lip pass to the submental glands and, occasionally, direct to the superior deep cervical glands. The vessels from the deeper parts of the lower lip unite with those from the upper lip and end in the submaxillary glands, but some of the superficial vessels of the upper lip may end in the superficial cervical glands.

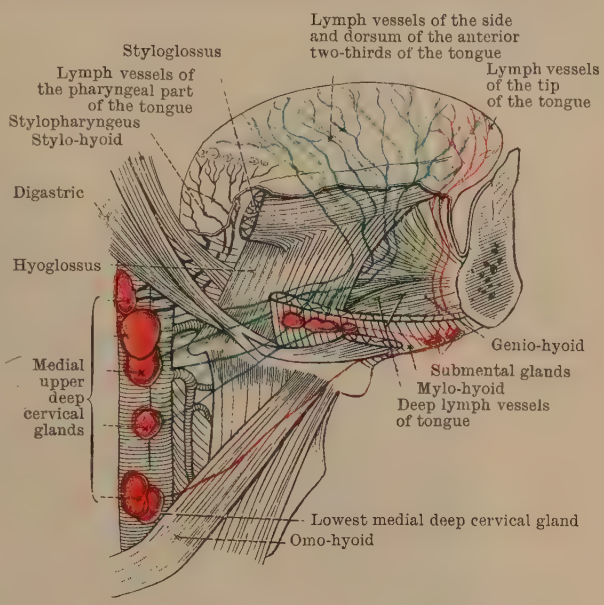

FIG. 780.—DIAGRAM OF SIDE-VIEW ORIGINS AND TERMINATIONS OF THE LYMPH VESSELS OF THE TONGUE. (After Poirier, modified.)

The Lymph Vessels of the Cheeks.—The majority of the superficial and deep lymph vessels of the cheeks pass to the submaxillary glands, but in some cases they communicate directly with the superficial or with the superior deep cervical glands. They may communicate also with the buccinator glands.

The Lymph Vessels of the Gums.—The vessels from the outer part of the anterior portion of the mandibular gum pass to the submental glands. Those from the posterior part, together with the vessels from the outer part of the gum of the maxilla, terminate in the submaxillary glands. The vessels of the gum of the maxilla may also communicate with the buccinator glands.

The vessels from the inner part of the gum of the mandible end in the submaxillary glands; those of the inner part of the gum of the maxilla, together with the vessels of the hard and the soft palate, end in the medial superior deep cervical glands.

FIG. 781. — DIAGRAM OF LYMPH VESSELS OF ANTERIOR TWO-THIRDS OF TONGUE, SEEN FROM BELOW. (After Poirier, modified.)

The Lymph Vessels of the Teeth.—It is known that lymph vessels exist in connexion with the teeth of the mandible as well as with the mandible itself, but their terminations are not definitely established. It is probable that they end in the submaxillary or the superior deep cervical glands.

The lymph vessels of the teeth of the maxilla pass partly into the infra-orbital canal and so to the face, where they join the vessels from the lateral parts of the eyelids, and terminate in the anterior auricular and submaxillary glands. The remaining vessels of the maxillary teeth end in the submaxillary glands.

The Lymph Vessels of the Tongue.—The lymph vessels of the tongue form three groups—(1) anterior, (2) middle, (3) posterior. The anterior and middle groups communicate freely with one another and with their fellows of the opposite side, but the posterior group have little or no

communication with the middle group. (1) The anterior lymph vessels drain the tip and the lower surface of the anterior free portion of the tongue. The main trunks pierce the mylohyoid muscle and end in the submental glands. (2) The middle group of lymph vessels of the tongue drain the anterior two-thirds, exclusive of the tip, and they terminate partly in the submaxillary glands and partly in the medial superior deep cervical glands. Small lingual glands are intercalated in the course of some of these vessels. (3) The posterior lymph vessels drain the portion of the tongue which lies in the anterior wall of the pharynx posterior to the papillæ vallatæ; they pass to the medial superior deep cervical glands. (4) The lymph vessels from the deeper central portions of the tongue go, mainly, to the upper deep cervical glands.

The Lymph Vessels of the Salivary Glands.—The lymph vessels of the parotid gland terminate in the parotid and superior deep cervical lymph glands. The lymph vessels of the submaxillary gland terminate, according to Most, not in the submaxillary lymph glands but in the medial superior deep cervical glands. Practically nothing is known of the lymph vessels of the sublingual gland.

The Lymph Vessels of the Pharynx.—From the upper part of the pharynx, and from the posterior wall and lateral borders of the middle and lower parts, the lymph stream flows to the median line posteriorly. There the larger vessels pierce the walls of the pharynx, then they turn laterally and end in the lateral retro-pharyngeal glands.

From the lower and anterior part of the pharynx, that is, from the region of the piriform recesses and the adjacent part of the larynx, the lymph vessels pass along the course of the laryngeal branch of the superior thyreoid artery, pierce the hyo-thyreoid membrane and terminate in the medial superior deep cervical glands; they may be connected also with the infra-hyoid, and with the prelaryngeal glands.

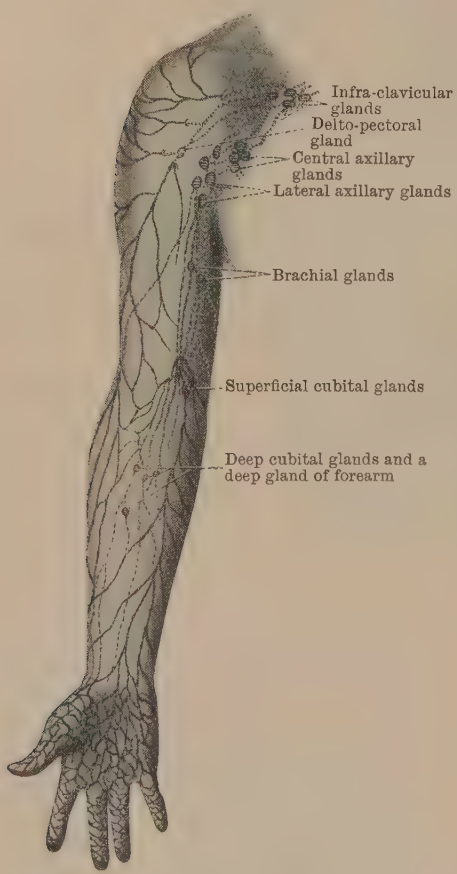

FIG. 782.—SCHEMA OF THE LYMPH VESSELS AND GLANDS OF THE UPPER EXTREMITY.

The lymph vessels of the palatine tonsil and the adjacent parts of the glosso-palatine and pharyngo-palatine arches pierce the lateral wall of the pharynx and end in a gland, or group of glands, which lies on the lateral surface of the internal jugular vein, immediately below the posterior belly of the digastric at the level of the angle of the mandible.

The Lymph Vessels of the Thyreoid Gland.—The lymph vessels of the thyreoid gland form a plexus common to both lobes and the isthmus, therefore the lymph can pass from the lobe of one side to the terminal glands of the opposite side. The terminal vessels end in the prelaryngeal, the pretracheal, the paratracheal, the superior and inferior deep cervical, and the upper mediastinal glands.

The Lymph Vessels of the Larynx.—The lymph plexus of the larynx is separable into upper and lower portions; they are connected together on the posterior wall of the cavity, but are separated, laterally and anteriorly, by the plicæ vocales which contain extremely few lymph vessels. The efferent stems of the upper part pass mainly along the laryngeal branch of the superior thyreoid artery, and they end in the superior deep cervical glands, but are frequently connected also with the infra-hyoid glands. The efferent vessels from the lower part of the larynx form two subordinate groups. Those from the anterior region pierce the median crico-thyreoid ligament and end in the prelaryngeal, the pretracheal, and the deep cervical glands. The efferents from the posterior region pierce the crico-tracheal membrane and end in the paratracheal glands (Fig. 777).

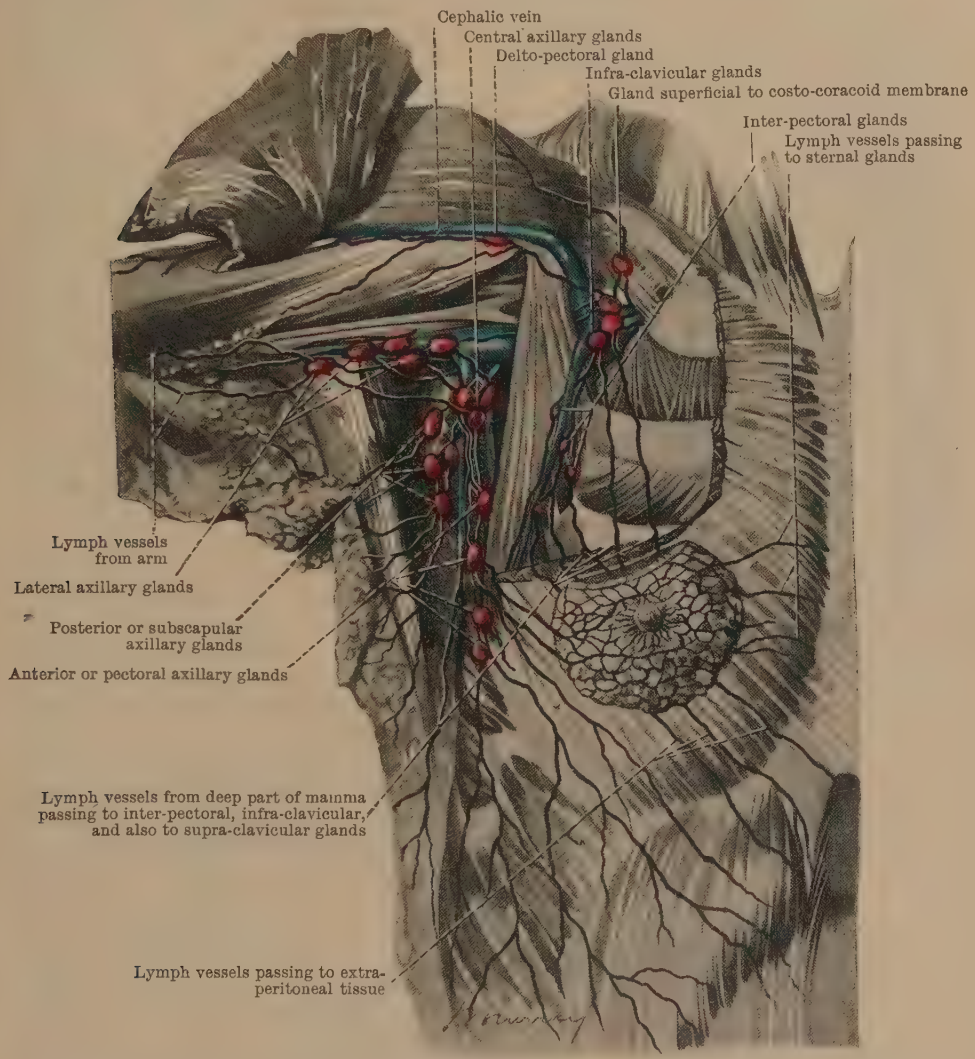
The Lymph Vessels of the Cervical Part of the Trachea and Œsophagus.—The terminal vessels of the cervical part of the trachea and the adjacent portion of the œsophagus and the paratracheal and the inferior deep cervical glands. From the upper part of the trachea some vessels pass to the prelaryngeal glands also.

LYMPH GLANDS OF THE SUPERIOR EXTREMITY.

The lymph glands of the superior extremity form two groups—(1) superficial, (2) deep.

(1) The **superficial cubital lymph glands,** one or two in number, lie on the medial side of the basilic vein, a short distance proximal to the medial epicondyle of the humerus. They receive lymph from both aspects and from the ulnar border of the forearm, and their *efferents* pass to the deep glands of the arm.

(2) **Deep Cubital Lymph Glands.**—Occasionally small glands are found in association with the arteries of the forearm, but in most cases the lymph from the deeper parts of the hand and forearm, below the region of the elbow, passes to the deep cubital glands or to the brachial or axillary glands.



Cephalic vein
Central axillary glands
Delto-pectoral gland
Infra-clavicular glands
Gland superficial to costo-coracoid membrane
Inter-pectoral glands
Lymph vessels passing to sternal glands
Lymph vessels from arm
Lateral axillary glands
Posterior or subscapular axillary glands
Anterior or pectoral axillary glands
Lymph vessels from deep part of mamma passing to inter-pectoral, infra-clavicular, and also to supra-clavicular glands
Lymph vessels passing to extra-peritoneal tissue

Fig. 783.—Dissection of Axilla and Anterior Part of Thoracic Wall, showing Lymph Glands and Vessels. (Semi-diagrammatic.)

The **deep cubital lymph glands** lie anterior to the elbow in the neighbourhood of the terminal part of the brachial artery. They receive many of the deep lymph vessels of the forearm and their *efferents* pass to the brachial and axillary glands.

Brachial lymph glands, irregular in number and size, are found along the course of the brachial artery. Their *afferents* are derived from the forearm, from the deep cubital and superficial cubital glands, from adjacent parts, and from the elbow-joint. Their *efferents* end in lateral group of axillary glands.

In addition to the glands which lie along the course of the brachial artery other deep glands are occasionally met with in the arm. (1) One in the sulcus

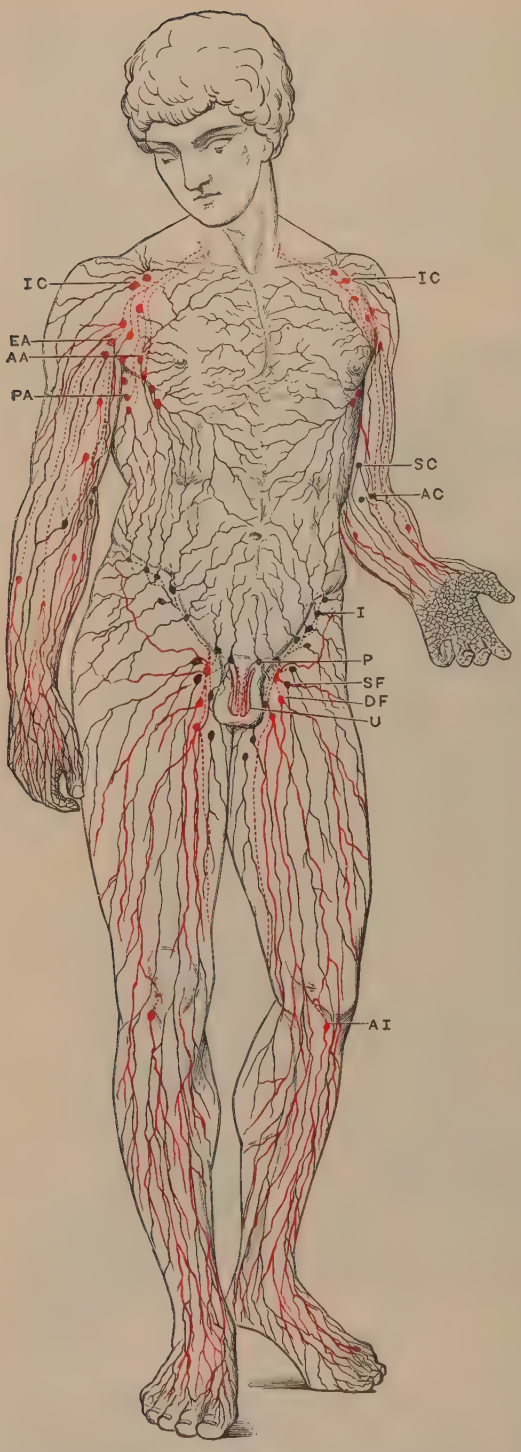


FIG. 784.—SUPERFICIAL LYMPH VESSELS OF THE TRUNK, AND THE LYMPH GLANDS AND VESSELS—SUPERFICIAL AND DEEP—OF THE LIMBS (diagrammatic). All superficial lymph vessels are printed black; the deep lymph vessels throughout are coloured red. Afferent vessels are represented by continuous lines; efferent and interglandular vessels by dotted lines.

between the brachioradialis and the brachialis; (2) another in the radial sulcus. When they are present both of these glands receive lymph from the ligaments of the elbow-joint as well as from other adjacent soft parts.

Axillary Lymph Glands.[1]—The axillary lymph glands lie in the region of the axilla, where they form several groups, some of which are practically constant, whilst others are very variable.

(*a*) The **lateral or brachial group of axillary lymph glands**, 1-7, lies in relation with the lateral boundary of the axillary space along the line of the great axillary vessels. The glands receive the lymph from the greater part of the upper extremity. Their *efferents* anastomose with the lymph vessels of the central glands; some terminate in the inferior deep cervical glands and others pass to the subclavian lymph trunk (Fig. 774).

(*b*) The **posterior or subscapular lymph glands** lie in relation with the posterior wall of the axilla, along the line of the subscapular vessels. Their *afferents* are the vessels of the lateral and posterior walls of the body, above the level of the umbilicus, and lymph vessels from the lower and posterior part of the neck. Their *efferents* join the lateral, the central, and the infra-clavicular axillary glands (Fig. 783).

(*c*) The **anterior or pectoral group of axillary lymph glands**, 2-4, lies along the line of the lateral thoracic artery, in the angle between the lower border of the pectoralis major and the serratus anterior. The glands extend from the third to the sixth intercostal space, sometimes in a single and sometimes in a double row. Occasionally one or two outlying members of this group, called the *paramammary glands*, are found on the superficial surface of the pectoralis major. The *afferents* of the

[1] The B.N.A. axillary lymph glands are the lateral glands of the axilla, but, as the other groups mentioned also lie in the axillary region, the general term "axillary" is used here to include all the groups.

anterior glands are derived from the anterior wall of the body above the umbilicus from the lateral two-thirds of the mamma. Their *efferents* pass to the central, lateral, and infra-clavicular axillary glands (Fig. 783).

(*d*) The **central axillary lymph glands**, 2-6, lie in the central part of the axilla, and frequently along the line of the intercosto-brachial nerve. They receive afferents from the anterior, the subscapular, and the lateral glands. Their *efferents* pass to the infra-clavicular glands (Fig. 783).

(*e*) The **subpectoral group of axillary lymph glands**, 3-14, is formed by several small glands which lie posterior to the pectoralis minor and anterior or medial to the axillary artery. They receive lymph from the glands situated at a lower level and from the lateral wall of the thorax. Their *efferents* pass to the infra-clavicular glands.

(*f*) The **infra-clavicular group of axillary lymph glands**, 1-11, lies in the region between the upper border of the pectoralis minor and the clavicle, along the medial side of the axillary artery. The glands receive efferents from the arm, from the other groups of axillary glands, and directly from the mamma and the pectoral muscles, along the line of the pectoral branches of the thoraco-acromial artery, and from the inter-pectoral glands. Their *efferents* pass to the inferior deep cervical glands and to the subclavian lymph trunk (Fig. 774).

(*g*) A **delto-pectoral lymph gland** is occasionally found in the groove between the deltoid and the pectoralis major muscles. It receives *afferents* from the superficial parts of the arm and the shoulder, and gives *efferents* to the subclavian trunk and to the infra-clavicular glands.

(*h*) Small **inter-pectoral lymph glands** are sometimes found between the great and small pectoral muscles. They are connected with the lymph vessels which pass from the posterior part of the mamma to the infra-clavicular glands (Fig. 783).

THE LYMPH VESSELS OF THE SUPERIOR EXTREMITY.

The lymph vessels of the superior extremity, like the glands, form two groups—(1) superficial, and (2) deep.

(1) The **superficial lymph vessels** lie in the skin and the subcutaneous tissues. They commence in cutaneous plexuses, which are finest and most dense on the volar aspects of the fingers and hand. The efferents from the volar digital plexus of each finger pass to the dorsum of the digit. There they unite to form dorsal digital vessels, 2-4, which run to the dorsum of the hand, where they unite together to form new vessels.

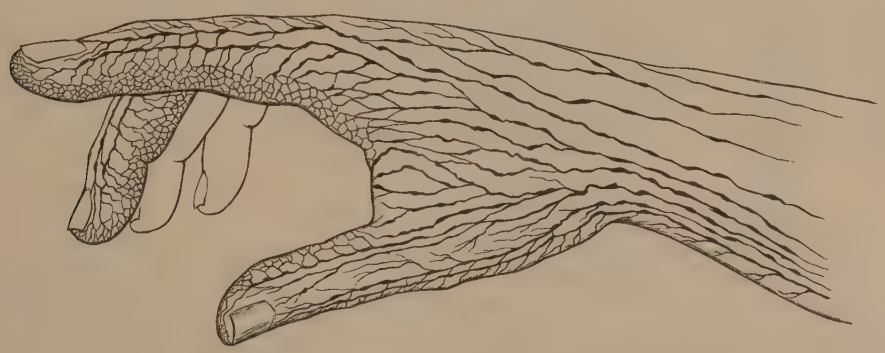

Fig. 785.—Superficial Lymphatics of the Digits and of the Dorsal Aspect of the Hand.

The efferents from the volar plexus of the hand run proximally, distally, and to the lateral and medial margins of the hand. The lateral efferents, as they turn round the lateral border of the hand, join the efferents of the thumb. The medial efferents turn round the medial border of the hand, and join the efferents of the little finger. The afferents which run proximally are few and variable; when they are present they lie along the line of the superficial median vein of the forearm. The efferents which run distally pass to the interdigital clefts where they turn dorsally and join the vessels on the dorsum of the hand (Figs. 784, 785).

As the superficial lymphatics pass towards the elbow they tend to form two main streams—(1) a lateral stream which accompanies the cephalic vein, and (2) a medial stream which accompanies the basilic vein. The lymph vessels which commence on the dorsum of the hand and forearm converge to one or other of the two main groups of vessels. In the region of

the elbow the vessels of the two streams anastomose together and some pass through the fascia and join the deep cubital glands.

As they pass from the forearm to the arm, the majority of the lymph vessels converge towards the medial side. Some join the superficial cubital glands, but others pass those glands and accompany their efferents, along the basilic vein, to the axilla, where they join the lateral group of axillary glands. There is, however, a varying number of lymph vessels, from the lateral stream of the forearm, which accompany the cephalic vein in the arm. Some of these terminate in the delto-pectoral gland, if it is present, but, whether it is present or not, some pass directly to the infra-clavicular glands.

The superficial lymph vessels of the arm terminate, for the most part, in the lateral group of axillary glands.

The **deep lymph vessels** of the upper extremity accompany the deeper blood-vessels. Some of the lymph vessels of the hand and forearm end in the deep glands, which are occasionally present in the forearm, but the majority either end in the deep cubital glands, or they pass directly to the lateral group of axillary glands.

The Lymph Vessels of the Mamma.—As the mamma is a modified skin gland, and as it is embedded in the superficial fascia, the lymph vessels which issue from it pass first into the superficial fascia and thence into the deep fascia. Having traversed the deep fascia, more or less obliquely, they either end in lymph glands or enter and traverse other layers of the body wall.

The main outflow of lymph from the substance of the mamma is towards the areola, where a subcutaneous plexus of lymph vessels is formed. From that plexus two or more main vessels of large size pass laterally (Fig. 783), pierce the deep fascia and join the anterior group of axillary glands. There are, however, other groups of vessels by which lymph may pass from the mamma. Some vessels issue from the medial border of the gland and run along the lines of the neighbouring anterior perforating branches of the internal mammary artery to the anterior ends of the intercostal spaces; there they pass through the deeper parts of the thoracic wall and end in the sternal lymph glands. Clinical evidence (Sampson Handley) has shown that some vessels, from the lower and medial part of the gland, pass to the angle between the seventh rib and the xiphoid process, where they pierce the fibrous layers of the abdominal wall and join the lymph vessels in the extra-peritoneal fascia of the upper part of the abdomen. It is through those vessels that cancer cells not uncommonly travel from the mamma to the abdomen (Fig. 783).

Lymph vessels pass also from the deep part of the mammary gland, through the deep fascia and the pectoralis major, and then ascend, along the line of the pectoral branches of the thoraco-acromial artery, to the infra-clavicular region, where they terminate either in the inter-pectoral or the infra-clavicular glands, or in both groups. It is possible that some of those vessels, after piercing the costo-coracoid membrane, may pass directly to the inferior deep cervical glands (Fig. 778).

It is stated, further, that some of the lymph vessels which issue from the mamma pierce the whole thickness of the thoracic wall and join the lymph vessels which lie in the endo-thoracic fascia, which intervenes between the ribs and the intercostal muscles externally and the pleural membrane internally. Finally it should be noted that the lymph vessels of opposite sides anastomose across the front of the sternum.

THE LYMPH GLANDS OF THE THORAX.

The lymph glands of the thorax form 5 named groups, with subdivisions.

(1) The **sternal lymph glands** form two groups each of which lies at the corresponding margin of the sternum along the line of the internal mammary artery. The glands are variable in number (4-18) and in size. They receive *afferents* from the upper part of the muscles of the abdominal wall, from the diaphragm, from the anterior part of the wall of the thorax, and from the medial portions of the mammæ. Their *efferents* communicate with the upper anterior mediastinal glands and with the inferior deep cervical glands, and they terminate on the right side in the right lymphatic or the right broncho-mediastinal duct and on the left in the thoracic duct. Occasionally, also, they end directly in the internal jugular or the subclavian vein.

(2) The **intercostal lymph glands** are lateral and medial. The *lateral glands* lie in the posterior parts of the intercostal spaces, the *medial* are placed in front of the heads of the ribs. Their *afferents* are derived from the boundaries and contents of the spaces. The *efferents* of the glands of the upper spaces pass

either to the posterior mediastinal glands or to the thoracic duct. Those of the lower spaces, on each side, form a descending trunk which passes through the aortic opening of the diaphragm and ends in the cisterna chyli.

(3) The **anterior mediastinal lymph glands** form two groups, a lower and an upper. The *lower group* consists of 3 or 4 glands, and is situated, posterior to the sternum, in the lower part of the anterior mediastinum. It receives *afferents* from immediately adjacent parts and from the liver and the diaphragm. Its *efferents* communicate with the upper anterior mediastinal glands, and they end, for the main part, in the broncho-mediastinal trunk.

The *upper group* consists of from 8 to 19 glands which lie posterior to the manubrium sterni and anterior to the thymus and the great vessels of the superior mediastinum. Their *afferents* are derived from the lower group of anterior mediastinal glands, from the pericardium, the heart, the thymus, the thyreoid gland, and from the sternal glands. Their *efferents* pass mainly to the broncho-mediastinal trunk, but they communicate with the medial inferior deep cervical glands and possibly also with the thoracic duct.

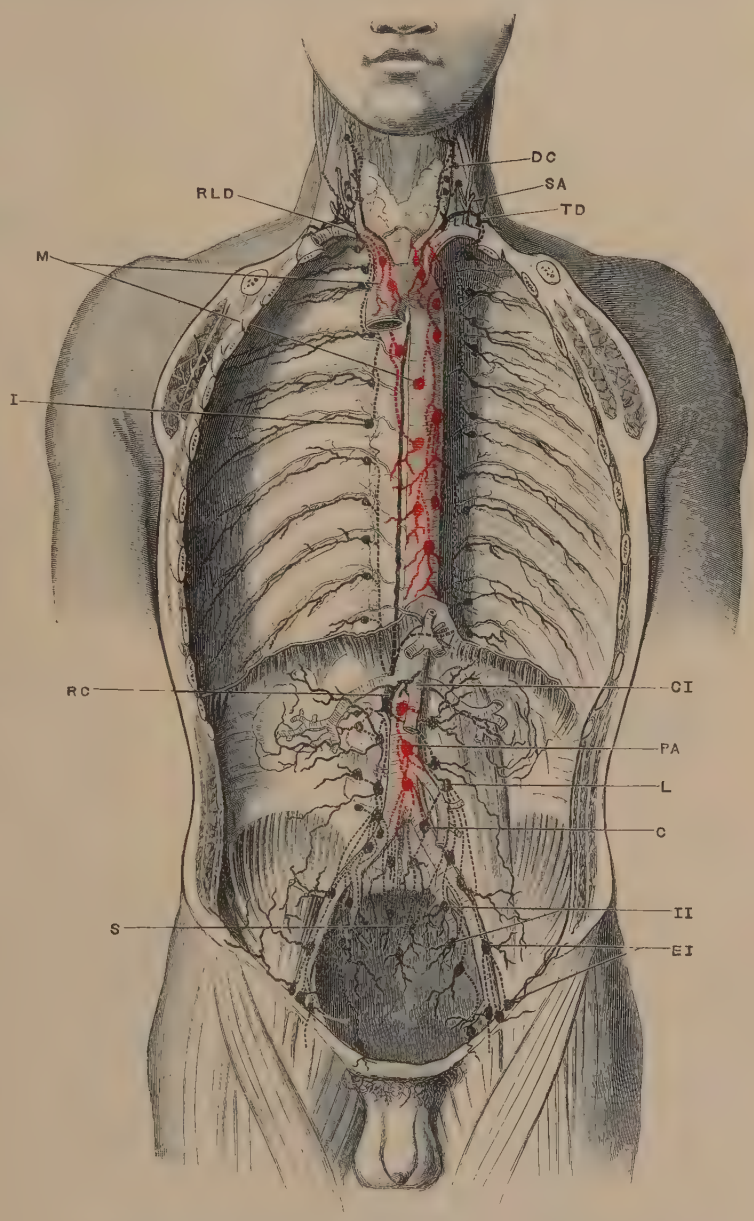

FIG. 786.—DEEP LYMPHATIC GLANDS AND VESSELS OF THE THORAX AND ABDOMEN (diagrammatic).

Afferent vessels are represented by continuous lines, and efferent and interglandular vessels by dotted lines.

C.	Common iliac glands.	M.	Mediastinal glands and vessels.
C.I.	Common intestinal trunk.	P.A.	Pre-aortic glands and vessels.
D.C.	Deep cervical glands.	R.C.	Cisterna chyli.
E.I.	External iliac glands.	R.L.D.	Right lymphatic duct.
I.	Intercostal glands and vessels.	S.	Sacral glands.
I.I.	Hypogastric glands.	S.A.	Scalenus anterior muscle.
L.	Lumbar glands.	T.D.	Thoracic duct.

(4) The **posterior mediastinal lymph glands**, 8-12, lie along the descending part of the thoracic aorta and the thoracic part of the œsophagus. They receive *afferents* from the diaphragm, the pericardium, the œsophagus, and other immediately adjacent tissues. Some of their *efferents* join the thoracic duct, others the broncho-mediastinal trunk, and some pass to the bronchial glands.

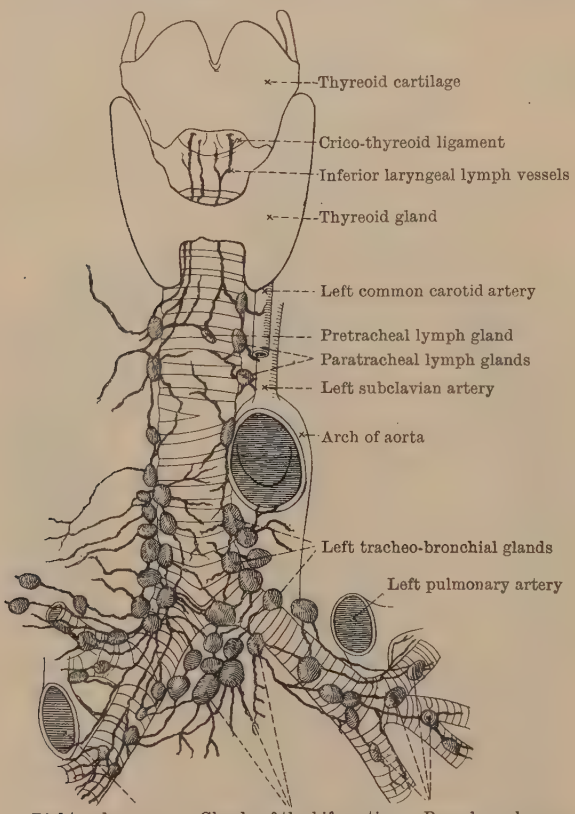

FIG. 787.—THE GLANDS IN RELATION TO THE TRACHEA AND THE MAIN BRONCHI.

(5) **Bronchial Lymph Glands.**—Under the term are included all the lymph glands which are closely associated with the walls of the intra-thoracic part of the trachea and with the main bronchi and their intra-pulmonary branches. The glands are extremely numerous, and they are conveniently classified, by Bartels, into four groups—(1) tracheo-bronchial right and left; (2) the glands of the bifurcation, also called inter-tracheo-bronchial; (3) broncho-pulmonary; (4) pulmonary. At birth and for some years afterwards they are pink in colour, but later they become blackened by the deposit of carbonaceous particles derived from the atmosphere.

(1) The **tracheo-bronchial lymph glands** are those which are situated in the lateral angle between the trachea and the bronchus, on each side. On the right side they vary in number from 5 to 9, on the left from 3 to 6. Those on the left are in close relation with the left recurrent nerve. Their *afferents* are derived from the other groups of bronchial glands and from the adjacent parts of the trachea and bronchi. They are connected with the anterior and posterior mediastinal glands. Their *efferents* pass to the broncho-mediastinal trunk and also to the inferior deep cervical glands. They are associated, also, by interglandular vessels, with the paratracheal glands.

(2) The **lymph glands of the bifurcation** (intertracheo-bronchial) lie below the trachea, in the angle between the two main bronchi. They are situated between the roots of the great vessels anteriorly and the œsophagus and the aorta posteriorly. Their *afferents* are derived from the broncho-pulmonary glands and from adjacent parts; their *efferents* terminate in the tracheo-bronchial glands. They are connected with the posterior mediastinal glands.

(3) **The Broncho-Pulmonary Lymph Glands.**—Each group of broncho-pulmonary glands, right and left, lies in the hilum of the corresponding lung, in the angles between the branches of the bronchial tube. The glands vary considerably in number, and they receive *afferents*, either directly or through the pulmonary glands, from the lung substance. They also receive afferents from the pleura; and their *efferents* pass to the tracheo-bronchial glands and to the glands of the bifurcation.

(4) The **pulmonary lymph glands** lie in the lung substance and usually in the angles between two bronchial tubes. Their *afferents* are derived from the lung substance, and their *efferents* pass to the broncho-pulmonary glands.

THE LYMPH VESSELS OF THE THORAX.

The lymph vessels of the thorax form two main groups—(*a*) the vessels of the thoracic wall, and (*b*) the vessels of the contents of the thorax.

(*a*) The **Lymph Vessels of the Thoracic Wall** are the intercostal lymph vessels and the lymph vessels of the diaphragm.

(1) The **Intercostal Lymph Vessels** receive lymph from the ribs and from the content of the intercostal spaces, and they terminate in the intercostal and sternal glands. Communications are said to exist between the intercostal vessels and the glands of the axilla.

(2) The **Lymph Vessels of the Diaphragm.**—The lymph vessels from the anterior part of the diaphragm pass to the lower sternal and anterior mediastinal glands, and those from the posterior part to the posterior mediastinal glands.

(*b*) The **Lymph Vessels of the Contents of the Thorax** are :—

(1) The **Lymph Vessels of the Heart**, which follow the courses of the coronary arteries, and pass to the anterior mediastinal glands.

(2) The **Lymph Vessels of the Pericardium**, which terminate in adjacent glands.

(3) The **Lymph Vessels of the Thymus**, some of which pass to the anterior mediastinal glands, some to the tracheo-bronchial glands, others to the medial inferior deep cervical glands.

(4) The **Lymph Vessels of the Thoracic Part of the Œsophagus**, which are separable into upper and lower groups. The upper pass to the bronchial, the posterior mediastinal, and the lower deep cervical glands. The lower group end in the glands situated at the cardiac end of the stomach. The two groups anastomose together.

(5) The **Lymph Vessels of the Pleura.**—The vessels from the apical parts of the parietal portion of the pleura pass to the adjacent lymph trunks or their tributaries. The vessels from the posterior part of the parietal pleura join the intercostal glands, and those from the anterior part end in the sternal glands.

The **Lymph Vessels of the Lungs and the Visceral Pleura** pass to the broncho-pulmonary glands.

THE LYMPH GLANDS OF THE INFERIOR EXTREMITY.

The lymph glands of the inferior extremity, like those of the superior, are separable into a superficial and a deep group.

The **superficial lymph glands** lie, almost entirely, in the subinguinal region, though occasionally one or more may be situated above the level of the inguinal ligament, and therefore in the inguinal region. On this account they are separated in the B.N.A. into inguinal and subinguinal groups. Both groups lie in the superficial fascia.

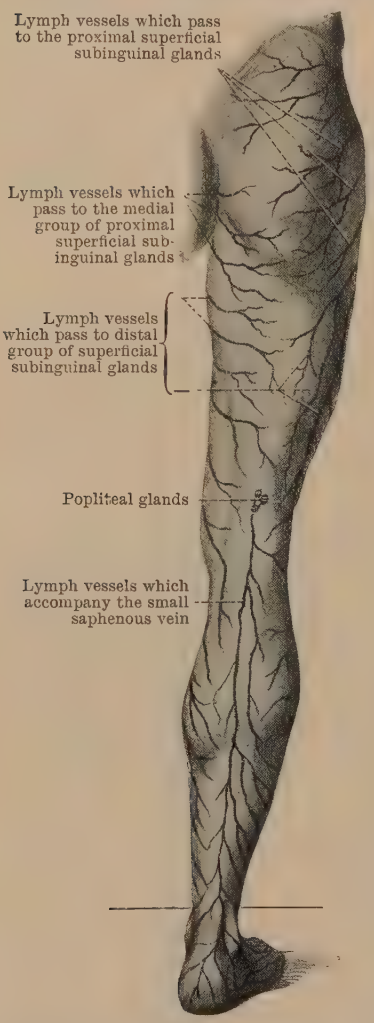
The **inguinal lymph glands**, when they exist, are merely scattered members of the subinguinal group which lie above the level of the inguinal ligament. They receive *afferents* from the lower and anterior part of the abdominal wall. Their *efferents* terminate either in the superficial or the deep subinguinal glands.

The **superficial subinguinal glands** (Figs. 784, 788) form two groups, a proximal and a distal, each of which is separable into medial and lateral parts; but the various members of the groups are intimately connected together by communicating vessels.

The *proximal group* lies along the line of the inguinal ligament. It may extend from the anterior superior spine of the ilium to the pubic tubercle. Its lateral members receive *afferents* from the lower and lateral part of the abdominal wall, from the buttock, and the proximal and lateral part of the thigh.

Fig. 788.—Diagram of the Lymph Vessels and Lymph Glands of the Lower Extremity.

The more medial members of the proximal group receive afferents from the anal canal, the perineum, the scrotum, the penis, and the pubic region in the male, and from the corresponding parts, including the lower part of the vagina, in the female.



Lymph vessels which pass to the proximal superficial subinguinal glands
Lymph vessels which pass to the medial group of proximal superficial subinguinal glands
Lymph vessels which pass to distal group of superficial subinguinal glands
Popliteal glands
Lymph vessels which accompany the small saphenous vein

FIG. 789.—DIAGRAM OF THE LYMPH VESSELS OF THE POSTERIOR PART OF THE LOWER EXTREMITY.

The *distal group* of superficial subinguinal glands lies along the line of the proximal part of the great saphenous vein—some on its lateral and some on its medial side. They receive *afferents* bearing lymph from the superficies of the greater part of the inferior extremity, with the exception of the lateral part of the foot, the heel, and a part of the posterior aspect of the leg.

The *efferents* of both proximal and distal groups of subinguinal glands pass to the deep subinguinal glands.

The **deep lymph glands** of the inferior extremity are the popliteal and the deep subinguinal glands. Occasionally a deep gland is met with in the leg in relation with the proximal third of the anterior tibial artery.

The **popliteal lymph glands** (Fig. 789) lie in the popliteal fossa. One is usually situated, comparatively superficially, at the point where the small saphenous vein pierces the deep fascia and enters the fossa. It receives *afferents*, which accompany the small saphenous vein, from the lateral part of the foot, the heel, and the posterior part of the calf. Its *efferents* pass to the deeper glands.

The deeper glands lie in the fat around the popliteal vessels and are sometimes separated into inter-condylar and supra-condylar groups. Their *afferents* are derived from the more superficial gland and from the deeper tissues of the leg and foot. Their *efferents* pass to the deep subinguinal glands.

The **deep subinguinal glands** (Figs. 784, 788, 794) lie in the femoral trigone. They are small glands, three to seven in number, which are difficult to demonstrate. Some of them lie in the femoral canal, the most proximal being situated in or close to the femoral ring. Their *afferents* are the efferents of the other glands of the lower extremity, and, in addition, vessels from the deeper parts of the penis or the clitoris. Their *efferents* pass to the external iliac glands.

THE LYMPH VESSELS OF THE INFERIOR EXTREMITY.

The arrangement of the **superficial lymph vessels** of the toes and the foot is very similar to that met with in the fingers and the hand. From lymph plexuses on the plantar aspect vessels pass to the dorsum of the foot and toes, where they unite into a number of vessels, the majority of which accompany the great saphenous vein and terminate in the distal group of superficial subinguinal glands. Some of the lymph from the lateral part of the plantar surface and from the lateral border of the foot, and the lymph from the heel enter vessels which accompany the small saphenous vein; they end either in the more superficial gland of the popliteal fossa or in the deeper glands of that region (Fig. 789).

With the exception of the lymph vessels from the lateral and posterior part of the leg, which accompany the small saphenous vein to the popliteal glands, all the superficial lymph vessels of the leg, thigh, and buttock pass to the superficial subinguinal glands; those from the leg and thigh mainly to the glands of the distal group; those of the buttock chiefly to the lateral glands of the proximal group.

The **deep lymph vessels** of the inferior extremity accompany the deep blood-vessels. Many of the vessels from the leg and foot end in the popliteal glands, but some pass directly to the deep subinguinal glands. The deep vessels of the more proximal parts of the inferior extremity end in the deep subinguinal glands and in the hypogastric glands.

THE LYMPH GLANDS OF THE ANTERIOR ABDOMINAL WALL.

Some lymph glands are regularly, and others are occasionally present in the anterior wall of the abdomen. Those fairly regularly present are :—

The **inferior epigastric lymph glands**, 3-6, which lie along the course of the inferior epigastric artery. Their *afferents* are from the deep part of the umbilicus and their *efferents* pass to the inferior external iliac glands.

The **Pubic Gland or Glands.**—One or more small glands which lie anterior to the suspensory ligament of the penis or clitoris. Their *afferents* are vessels from the superficial parts of the penis or clitoris, and their *efferents* end in the proximal superficial subinguinal glands.

The occasional glands are :—

(1) A **superior epigastric gland** which sometimes lies in the superficial fascia of the median part of the epigastric region. Its *afferents* are from the adjacent parts and its *efferents* pass to the sternal glands. It is probably very rare.

(2) **Circumflex iliac glands**, 2-4, which lie along the course of the deep circumflex iliac artery.

(3) An **umbilical gland** which lies in the extra-peritoneal tissue below the umbilicus. When it is present it receives vessels from the umbilicus and its *efferents* go to the external iliac glands.

(4) **Supra-umbilical glands**, 1-2, small glands which lie in the extra-peritoneal tissue above the umbilicus. Its *afferents* are from the region of the umbilicus. The *efferents* probably pass to the inferior anterior mediastinal glands.

THE LYMPH VESSELS OF THE ANTERIOR WALL OF THE ABDOMEN.

The superficial lymph vessels of the upper part of the anterior wall of the abdomen go, for the most part, to the anterior or pectoral group of axillary glands ; but some pierce the wall of the lower part of the thorax and end in the sternal glands.

The superficial lymph vessels of the lower part of the anterior wall of the abdomen terminate either in the inguinal glands or in the proximal group of superficial subinguinal glands.

The deep lymph vessels of the upper part of the anterior abdominal wall accompany the superior epigastric vessels and terminate in the sternal glands ; but some may be connected with the supra-umbilical glands if they are present.

The deep lymph vessels of the lower part of the anterior wall of the abdomen accompany the inferior epigastric vessels, and end in the inferior external iliac glands or the inferior epigastric glands.

THE LYMPH VESSELS OF THE EXTERNAL GENITALS.

The **lymph vessels of the scrotum** in the male and of the **labia majora** in the female pass to the proximal superficial subinguinal glands, and mostly to the medial group.

The **superficial lymph vessels of the penis** go to the medial glands of the proximal subinguinal group.

The **deep lymph vessels of the penis**, including those of the penile portion of the urethra, end either in the medial glands of the proximal subinguinal group or in the deep subinguinal glands.

The termination of the **lymph vessels of the clitoris** is similar to that of the lymph vessels of the penis.

LYMPH GLANDS OF THE PELVIS AND ABDOMEN.

The lymph glands of the pelvis are separable into visceral and parietal groups.

The Visceral Glands of the Pelvis.

Vesical Lymph Glands.—The **lymph glands of the urinary bladder** form an anterior and two lateral groups.

(*a*) The anterior lymph glands of the bladder are variable in number. They lie in the retro-pubic fat and receive *afferents* from the anterior and antero-lateral parts of the bladder wall. Their *efferents* go to the external iliac glands.

(*b*) The lateral lymph glands of the bladder lie along the course of the umbilical artery on each side. Their *afferents* are derived from the upper and lateral parts of the bladder and their *efferents* end in the external iliac glands.

The **ano-rectal lymph glands** (2-8) lie in the lower part of the pelvis minor, in relation with the ampullary part of the rectum, between its muscular wall and

its external fibrous coat. Their *afferents* are derived from the muscular and mucous coats of the rectum and from the upper part of the anal canal, and their *efferents* pass to the superior hæmorrhoidal glands.

The **para-uterine lymph glands** (1-6), lie at the sides of the neck of the uterus in the bases of the broad ligaments. They receive afferents from the neck of the uterus and the efferents pass to the hypogastric glands.

The **superior hæmorrhoidal lymph glands** lie along the course of the superior hæmorrhoidal artery in the pelvic meso-colon. They receive *afferents* from the walls of the rectum, and from the ano-rectal glands. Their *efferents* go to the inferior mesenteric glands.

The Parietal Lymph Glands of the Pelvis.

The **sacral lymph glands**, variable in number, lie along the anterior aspect of the sacrum, between the anterior sacral foramina. Their *afferents* are from the

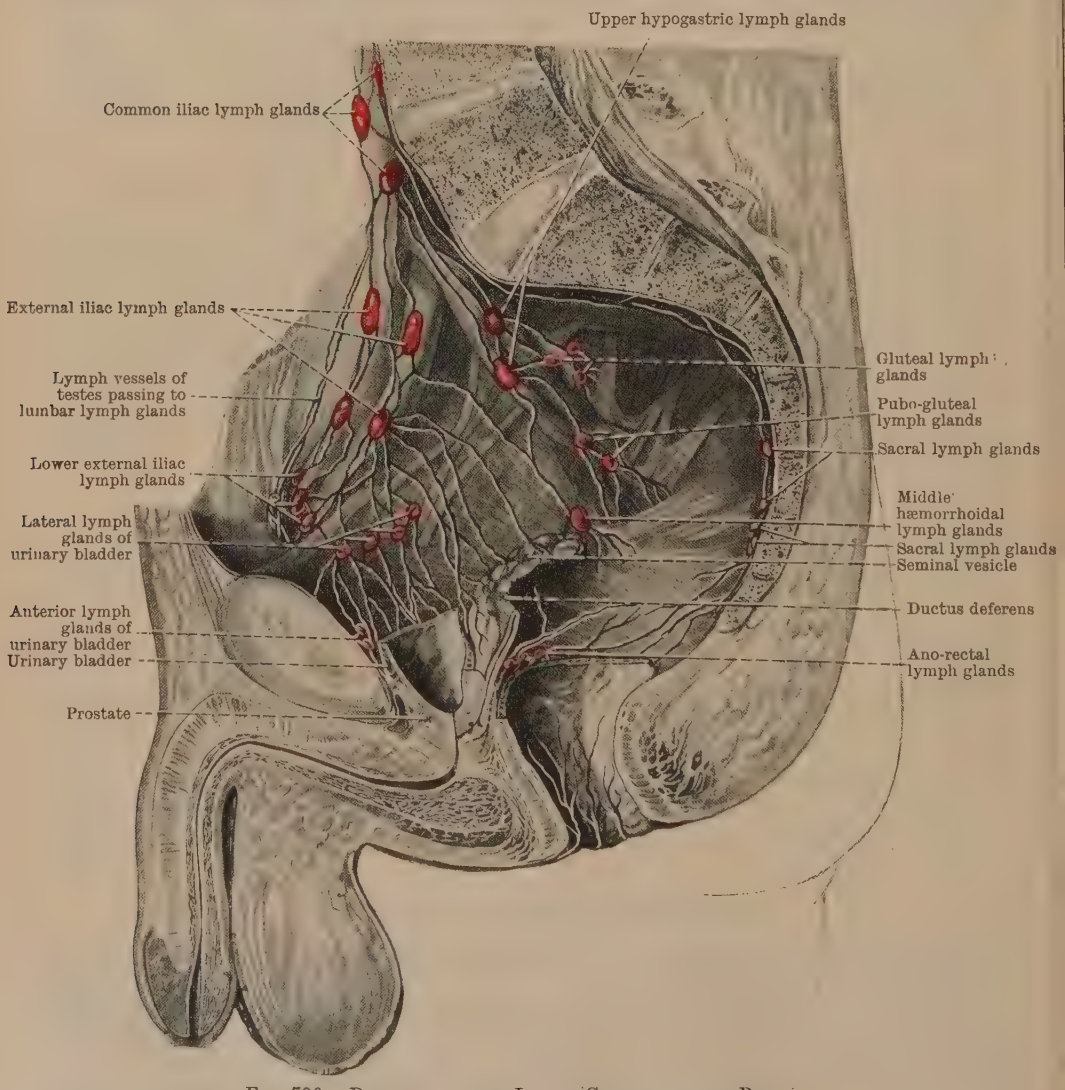


FIG. 790.—DIAGRAM OF THE LYMPH GLANDS OF THE PELVIS.

rectum, the prostate, and the adjacent parts of the wall of the pelvis. Their *efferents* end in the sub-aortic, the aortic, and the hypogastric glands.

The **subaortic lymph glands** (1-3) lie on the anterior aspect of the fifth

lumbar vertebra. Their *afferents* are from the sacral glands, the hypogastric glands, and the external iliac glands. Their *efferents* go to the aortic glands (Fig. 794).

The **Hypogastric Lymph Glands** form right and left groups, which are associated with the corresponding hypogastric vessels. As a rule they lie near the origins of the main branches of the hypogastric artery, or in the angles between the branches, and they, therefore, are separable into a number of groups.

The **Gluteal Lymph Glands** lie in relation to the superior gluteal artery and receive *afferents* from the gluteal region. Their *efferents* pass to the common iliac glands.

The **Pubo-gluteal Lymph Glands** (1-2) lie in relation to the origins of the inferior gluteal and internal pudendal arteries. They receive *afferents* from the thigh and perineum and their *efferents* end in the common iliac glands.

The **Middle Hæmorrhoidal Gland** lies more medially than the other glands of the group, close to the lateral wall of the rectum at the point where the middle hæmorrhoidal artery breaks up into its terminal branches. It receives *afferents* from the rectum and gives *efferents* to the other hypogastric and to the external iliac glands.

The **Inter-iliac Glands** lie in the angle between the external iliac and the hypogastric arteries, and cannot be clearly disassociated from the medial external iliac glands. They receive *afferents* from the lower parts of the pelvic portions of the genito-urinary organs. Their *efferents* pass to the common iliac glands.

The **Obturator Gland** lies at the inner end of the obturator canal, above the obturator vessels. It receives *afferents* from the upper and medial parts of the thigh and its *efferents* join the inter-iliac and common iliac glands.

The **Iliac Lymph Glands** are separable into a lower group, associated with the external iliac artery, **lymphoglandulæ iliacæ externæ**, and an upper group, the **lymphoglandulæ iliacæ communes.**

The External Iliac Glands.—According to Poirier and Cuneo, the external iliac lymph glands form three chains, lateral, intermediate, and medial, which lie, respectively, at the lateral side, anterior to, and at the medial side of the external iliac vessels. The three lowest members of the group, that is the lowest member of each chain, lie in close relation to the abdominal aperture of the femoral ring, and are frequently spoken of as supra-femoral glands. They receive *afferents* from the superficial subinguinal and the deep subinguinal glands, from the urethra and the deeper parts of the penis, and from the portions of the abdominal wall supplied by the deep circumflex iliac and inferior epigastric arteries. Their *efferents* end in the upper glands of the external iliac group.

The higher members of the external iliac lymph glands receive *afferents* from the membranous part of the urethra, the prostate, the bladder, the vagina, and the neck of the uterus. They are connected by anastomoses with the hypogastric glands, particularly the middle hæmorrhoidal gland, and their *efferents* pass to the common iliac glands.

The Common Iliac Lymph Glands.—The glands of the common iliac group are sometimes separated into a lateral and intermediate and a medial series. The lateral and intermediate groups are quite distinct, the former lying along the lateral margin of the artery and the latter posterior to it, but the medial group is not clearly defined from the sub-aortic group already mentioned. Indeed the sub-aortic group may be looked upon as constituted by the medial common iliac glands of opposite sides.

The common iliac glands receive *afferents* from the external iliac and the hypogastric glands, and consequently from practically the whole of the pelvic contents, except the ovaries of the female.

THE LYMPH VESSELS OF THE PELVIC VISCERA.

The Lymph Vessels of the Urethra of the Male.—It has been pointed out that the lymph vessels of the greater part of the penile portion of the urethra are said to pass to the deep subinguinal glands. The lymph vessels of the bulbar and membranous parts of the urethra have not yet been satisfactorily demonstrated, but it is stated that they pass to the hypogastric glands, to the medial supra-femoral gland of the external iliac group, and to the

higher glands of the external iliac group. The lymph vessels of the prostatic part of the urethra unite with the other lymph vessels of the prostate.

The Lymph Vessels of the Prostate pass to the anterior and lateral vesical glands, to the external iliac glands, to the hypogastric glands, and to the sacral and hæmorrhoidal glands. They anastomose with the lymph vessels of the bladder and the deferent duct.

The Lymph Vessels of the Urethra of the Female have terminations corresponding with those of the vessels of the membranous and prostatic portions of the urethra of the male.

The Lymph Vessels of the Seminal Vesicle, on each side, pass to the medial glands of the external iliac group.

The Lymph Vessels of the Ductus Deferens, on each side, anastomose with those of the seminal vesicle, and they pass to the hypogastric and external iliac glands.

The Lymph Vessels of the Urinary Bladder.—Many of the lymph vessels from the antero-lateral aspect of the urinary bladder pass to the corresponding anterior and lateral vesical lymph glands and, through them, become connected with the external iliac and hypogastric glands, but some apparently pass directly to the hypogastric lymph glands.

The lymph vessels from the superior, and many from the posterior part of the bladder, on each side, end in the external iliac and hypogastric glands, but some from the posterior part pass directly to the sub-aortic glands.

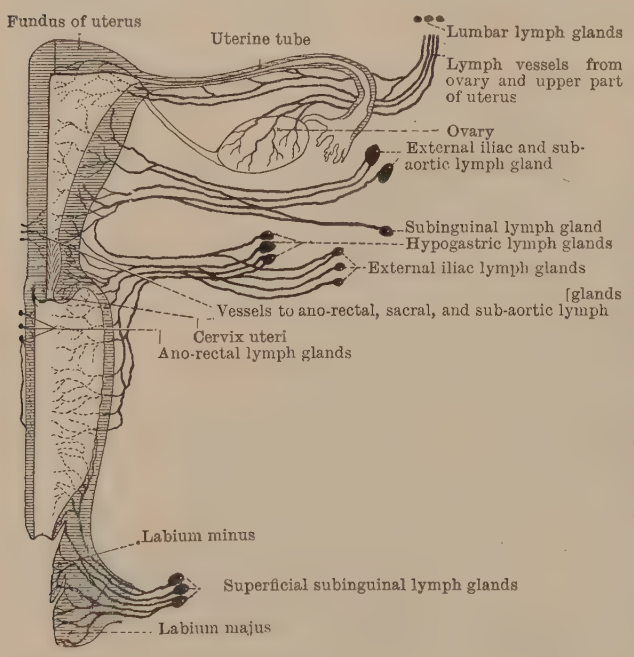

FIG. 791.—DIAGRAM OF LYMPH VESSELS OF FEMALE GENITAL ORGANS.

The Lymph Vessels of the Ureter.—Little is known of the lymph vessels of the ureter except that those of its lower extremity anastomose with the lymph vessels of the urinary bladder. It is suggested that the vessels pass to the nearest lymph glands.

The Lymph Vessels of the Vagina.—The lymph vessels of the lower part of the vagina anastomose with the lymph vessels of the labia minora and so transmit lymph to the superficial subinguinal glands. The lymph vessels of the upper parts of the vagina pass to the hypogastric glands and also, with the lymph vessels of the cervix uteri, to the external iliac glands. Some of the lymph vessels from the posterior wall of the vagina terminate in the ano-rectal glands.

The Lymph Vessels of the Uterus.—The Lymph Vessels of the Lower Part of the Uterus. The majority of the lymph vessels from the lower part of the uterus, including the cervix, unite with the lymph vessels of the upper part of the vagina and pass to the hypogastric glands including the inter-iliac group (p. 1025). Some pass to the external iliac glands, and others from the lower and posterior part become associated with the ano-rectal, the sacral, and the sub-aortic glands.

The Lymph Vessels of the Body of the Uterus run in several directions. The most important outflow is along the upper part of the broad ligament, below the uterine tube, to the region of the ovary where there is an anastomosis with the ovarian lymph vessels. Afterwards the lymph vessels of this stream cross the brim of the pelvis minor and ascend to the lumbar lymph glands. The accessory outflows are to the external iliac glands; to the sub-aortic glands; and, along the round ligament, to the superior group of subinguinal glands.

The Lymph Vessels of the Uterine Tube accompany the vessels of the main outflow from the body of the uterus, and those from the ovary, and pass to the lumbar lymph glands.

The Lymph Vessels of the Ovaries.—The lymph vessels of each ovary accompany the ovarian artery and some of the uterine lymph vessels, along the upper part of the broad ligament, to the brim of the pelvis minor and then upwards to the lumbar lymph glands.

The Lymph Vessels of the Testis and Epididymis.—The testis and the epididymis are not normally pelvic organs in the adult, but their lymph vessels may be considered here, inasmuch as the testes correspond, morphologically, with the ovaries. The lymph vessels of each testis and its epididymis accompany the testicular arteries and ascend to the lumbar region where they terminate in the lumbar lymph glands.

The Lymph Vessels of the Rectum.—The lymph vessels of the rectum and the upper part of the anal canal pass for the most part along the middle and superior hæmorrhoidal vessels. Those which accompany the branches of the middle hæmorrhoidal artery, on each side, pass to the corresponding middle hæmorrhoidal gland of the hypogastric group; whilst the lymph

vessels of the rectum which accompany the branches of the superior hæmorrhoidal artery become associated with the ano-rectal, the sacral, and the inferior mesenteric lymph glands. The lymph vessels of the lower part of the anal canal go to the medial proximal subinguinal glands.

THE LYMPH GLANDS OF THE ABDOMEN.

The lymph glands of the abdomen are separated into visceral and parietal groups. The visceral groups are those more directly associated with the lymph vessels which issue from the walls of the abdominal part of the alimentary canal, although they may lie posterior to the peritoneum in relation to the posterior wall of the abdomen. The parietal glands lie in relation with the abdominal part of the aorta and the inferior vena cava and the adjacent parts of the posterior abdominal wall.

Visceral Lymph Glands of the Abdomen.

Lymphoglandulæ Gastricæ.—The **gastric lymph glands** are arranged in two main groups, the *lymphoglandulæ superiores* which lie in association with the arteries of the smaller curvature, and the *lymphoglandulæ inferiores* associated with the greater curvature. Jamieson and Dobson have separated the superior gastric glands into several subdivisions.

Lymphoglandulæ Gastricæ Superiores.—(*a*) The **Anterior Left Gastric Glands** (lower coronary glands, J. and D.). The anterior left gastric glands lie between the layers of the lesser omentum along the course of the left gastric artery. They receive *afferents* from the greater part of the lesser curvature of the stomach and the adjacent parts of its anterior and posterior walls, and they send *efferents* to the posterior left gastric glands.

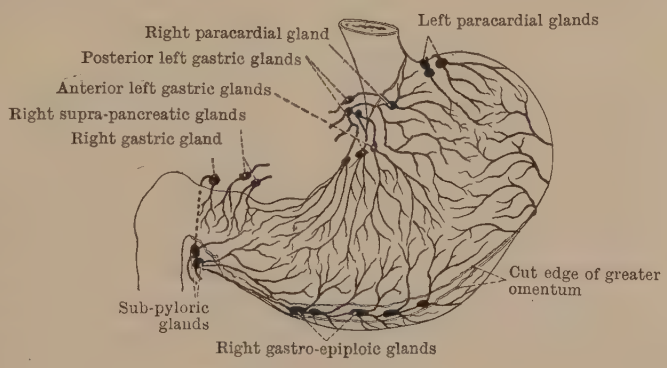

Fig. 792.—Lymph Vessels and Glands of the Stomach. (After Jamieson and Dobson, modified.)

(*b*) The **Right Paracardial Glands** are essentially members of the anterior left gastric group which lie to the right of the cardiac orifice of the stomach. Their *afferents* are derived from the cardiac part of the stomach and their *efferents* go to the posterior left gastric glands.

(*c*) The **Left Paracardial Glands** lie to the left of the œsophageal orifice. They receive *afferents* from the adjacent parts of the cardiac portion of the stomach, and their *efferents* end in the posterior left gastric glands.

(*d*) The **Posterior Paracardial Glands** lie on the posterior aspect of the stomach, between the layers of the gastro-phrenic ligament. Their *afferents* are from the neighbouring parts of the cardia and their *efferents* go to the posterior left gastric glands.

(*e*) The **Posterior Left Gastric Glands** (upper coronary, J. and D.) lie around the left gastric artery as it passes forwards through the left gastro-pancreatic fold of peritoneum. They receive *afferents* from the previously mentioned groups of gastric glands and *direct afferents* from the cardiac portion of the stomach. Their efferents pass to the middle supra-pancreatic glands of Jamieson and Dobson (cœliac glands, B.N.A.).

(*f*) The **Right Gastric Gland** (pyloric of J. and D.) is a small gland, occasionally present, which lies immediately above the pylorus or the first part of the duodenum, in association with the right gastric artery. It receives *afferents* from the pylorus, and its *efferents* end in the sub-pyloric glands.

(*g*) The **Right Gastro-epiploic Glands** lie along the lower part of the greater curvature of the stomach, in association with the right gastro-epiploic artery. Their *afferents* are from the adjacent parts of the anterior and posterior surfaces of the stomach and their *efferents* pass to the sub-pyloric glands.

(*h*) The **Left Supra-pancreatic Glands** of Jamieson and Dobson (lympho-glandulæ pancreaticolienales, B.N.A.) lie along the course of the splenic artery and in the gastro-splenic ligament: they receive *afferents* from the left part of the stomach and from the spleen. Their *efferents* pass to the middle supra-pancreatic glands.

(*i*) The **Right Supra-pancreatic Glands** (J. and D.) lie in relation with the stem of the hepatic artery as it passes through the right gastro-pancreatic fold. They receive *afferents* directly from the pyloric part of the stomach and the liver, and give off *efferents* to the middle supra-pancreatic glands.

(*j*) The **Sub-pyloric Glands** (J. and D.). The sub-pyloric lymph glands lie at the right border of the omental bursa, in the angle between the superior and descending parts of the duodenum, between the head of the pancreas posteriorly and the peritoneum of the posterior wall of the great sac anteriorly. Their *afferents* are from the right gastro-epiploic glands, the right gastric gland, and from the pyloric portion of the stomach. The *efferents* pass to the middle supra-pancreatic glands.

(*k*) The **Biliary Lymph Glands** (J. and D.) lie along the line of the bile duct. They receive *afferents* from the gall-bladder and liver. One of the lower glands of the group, which lies posterior to the head of the pancreas, close to the lower end of the bile-duct, is associated, by direct afferents, with the upper part of the pylorus. Their *efferents* pass to the right and middle supra-pancreatic glands.

The highest member of the series is associated with the cystic artery and the gall-bladder and is called the *cystic gland.*

Lymphoglandulæ Hepaticæ (B.N.A.).—The **Hepatic Lymph Glands** of the Basle nomenclature are a few small glands which lie in the region of the porta hepatis, between the layers of the lesser omentum; they receive *afferents* from the liver and give *efferents* to the right supra-pancreatic glands (J. and D.).

Lymphoglandulæ Mesentericæ (B.N.A.).—The **Mesenteric Lymph Glands** lie between the layers of the mesentery, where they form three main groups: (*a*) a series of juxta-intestinal glands which lie close to the walls of the small gut; (*b*) an intermediate series of larger glands which lie in relation with the trunks of the rami intestinales of the superior mesenteric artery; and (*c*) a terminal group of large glands which lie round the upper part of the stem of the superior mesenteric artery. They receive lymph from all parts of the small intestine, from the cæcum, the vermiform process, the ascending colon, the transverse colon, and the part of the descending colon. Their *efferents* unite to form a common intestinal trunk, which enters the cisterna chyli.

The Lymph Glands of the Cæcum and the Vermiform Process and the Terminal part of the Ileum.—The lymph glands particularly associated with the terminal part of the ileum, the cæcum and its vermiform process, according to Jamieson and Dobson, are (1) the ileal, (2) the anterior ileo-colic, (3) the posterior ileo-colic, and (4) the appendicular. All these glands give off vessels which pass to the larger ileo-colic glands which lie along the ileo-colic branch of the superior mesenteric artery.

The **Ileal Glands** lie in the lower part of the mesentery. They receive *afferents* from the lower part of the ileum and give *efferents* to the main ileo-colic glands.

An **Appendicular Lymph Gland** is sometimes met with in the mesentery of the vermiform process. When it is present it may be associated with the vessels which pass from any part of the vermiform process. Its *efferents* pass to the main ileo-colic glands.

The **Anterior Ileo-colic Glands**, 1-4, lie in the anterior ileo-colic fold of peritoneum. Their *afferents* are derived from the anterior part of the cæcum and the root of the vermiform process, and *efferents* pass to the main ileo-colic glands.

The **Posterior Ileo-colic Glands**, more numerous than the anterior, lie in the angle between the ileum and the cæcum, and in the angle between the ileum and the ascending colon. Their *afferents* are from the posterior part of the cæcum

and the root of the vermiform process. Their *efferents* pass to the main ileo-colic glands.

The **Lymph Glands of the Colon**, according to Jamieson and Dobson, may be considered as forming four groups, epicolic, paracolic, intermediate, and main.

The **Epicolic Glands** are small nodules which lie in the appendices epiploicæ and in relation with the wall of the gut. The **paracolic glands** lie along the medial borders of the ascending, descending, and iliac parts of the colon; along the upper border of the transverse colon, and on the mesenteric border of the pelvic colon. The intermediate glands lie along the branches of the colic arteries and the main groups are situated around the stems from which the colic arteries arise. The lymph gathered by the lymph plexuses in the walls of the gut passes through one or more of the groups of glands, and that which issues from the main group, in association with the ileo-colic and middle colic arteries, enters the main mesenteric glands which surround the upper part of the superior mesenteric artery. It is then carried by the efferents of those glands to the common intestinal lymphatic trunk. The lymph from the descending, the iliac, and the pelvic parts of the colon passes to the intermediate groups of inferior mesenteric glands and thence, for the main part, to the lumbar glands, but some of the efferents from the upper intermediate inferior mesenteric glands pass to the main group of superior mesenteric glands.

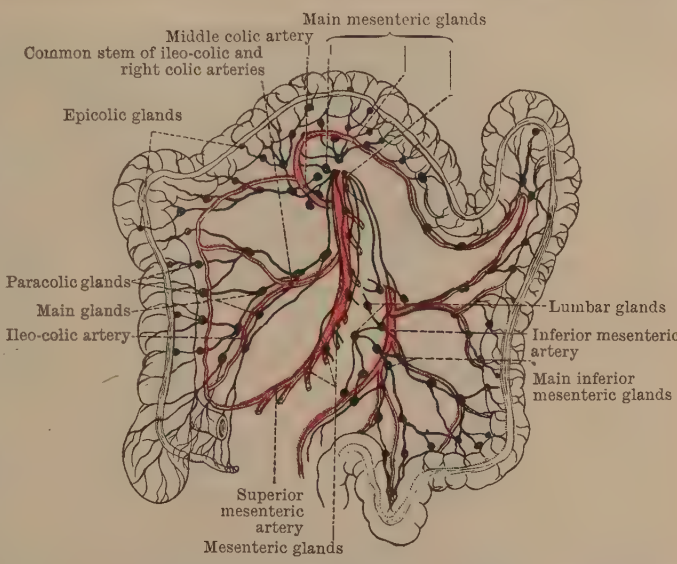

FIG. 793.—DIAGRAM OF THE LYMPH GLANDS AND LYMPH VESSELS OF THE LARGE INTESTINE. (After Jamieson and Dobson.)

The lymph glands associated with the middle colic artery and its branches are the **lymphoglandulæ mesocolicæ** of the Basle nomenclature.

The **Main Glands of the Inferior Mesenteric Group** receive lymph from the intermediate left colic glands and transmit it to the lumbar glands through which it passes, by the lumbar lymph trunks, to the cisterna chyli; but some of the lymph from the upper intermediate left colic glands passes to the main mesenteric glands, and so to the common intestinal lymph trunk.

The **Middle Supra-pancreatic Lymph Glands** of Jamieson and Dobson correspond fairly closely with the **lymphoglandulæ cœliacæ** of the Basle terminology. They lie at the upper border of the pancreas around the cœliac artery. Their *afferents* are from the right and left supra-pancreatic glands, from the posterior left gastric glands, and from the sub-pyloric glands. They are connected by intermediate channels with the superior mesenteric glands, and they give *efferents* to the common intestinal lymph trunk and also to the common lumbar trunks.

Lymphoglandulæ Lumbales (B.N.A.).—The **Lumbar Lymph Glands** lie behind the peritoneum of the posterior wall of the abdomen, in association with the aorta, the inferior vena cava, the psoas and quadratus lumborum muscles, and the crura of the diaphragm. Those which are situated on the anterior aspect of the aorta are frequently spoken of as **pre-aortic glands** and those situated more laterally as **para-aortic glands.**

The **afferents** of the lumbar lymph glands are (1) the efferents of the common iliac glands, (2) efferents from the sub-aortic glands, (3) efferents from the sacral glands, (4) some efferents from the hypogastric glands, (5) efferents from the

main inferior mesenteric glands, (6) the lymph vessels from the testes and epididymides and their coverings in the male, and from the ovaries, the uterine tubes, and the upper part of the uterus in the female, (7) lymph vessels from the

kidneys, (8) lymph vessels from the suprarenal glands, (9) lymph vessels from the muscles of the back and of the posterior wall of the abdomen.

The *efferents* of the lumbar glands form two common lumbar lymph trunks, which pass to the cisterna chyli.

THE LYMPH VESSELS OF THE ABDOMINAL VISCERA AND THE SUPERIOR AND POSTERIOR WALLS OF THE ABDOMEN.

The Lymph Vessels of the Abdominal Part of the Alimentary Canal.—The lymph vessels in the walls of the alimentary canal form four plexuses: (1) a mucous plexus, in the mucous membrane, (2) a submucous plexus, in the submucous tissue, (3) a muscular plexus, between the two muscle coats, (4) a subserous plexus which lies in the areolar tissue between the peritoneal covering and the outer muscular coat. The four plexuses communicate freely with each other. The lymph is eventually collected from the subserous plexus and carried to the various groups of lymph glands. The vessels which carry away the lymph from the subserous plexuses of the various parts of the alimentary canal are spoken of in the following account as the lymph vessels of those parts.

The Lymph Vessels of the Stomach.—The lymph vessels of the stomach communicate

freely with the lymph vessels of the œsophagus on the one hand and those of the duodenum on the other.

From the point of view of lymph outflow the area of each surface of the stomach may be divided into four parts. First a small right portion of the region of the pyloric canal, and, second, the remaining larger portion which is subdivided into three parts by two lines: (1) A line from the apex of the fundus to the pyloric canal along the junction of the upper and right two thirds with the left and lower third, (2) a line, parallel with the œsophagus, dividing the left and lower part into left and right portions (J. and D.). It must be understood, however, that the lymph vessels of the various areas communicate freely with one another (Fig. 792).

The Lymph Vessels of the Region of the Pyloric Canal pass (*a*) partly to the anterior left gastric glands, (*b*) partly to the right supra-pancreatic lymph glands, and (*c*) partly to the lower biliary group of lymph glands. If the right gastric gland is present some of the vessels of the upper pyloric region go to it, and in some cases vessels from the pyloric region pass directly to the posterior left gastric lymph glands.

The Lymph Vessels from the Right Upper Area of the larger portion of the stomach pass (*a*) to the anterior left gastric lymph glands, (*b*) to the posterior left gastric lymph glands, (*c*) to the paracardial lymph glands.

The Lymph Vessels from the Left Section of the Left and Lower Portion of the stomach pass along the gastro-splenic ligament to the splenic glands, which are occasionally present near the hilum of the spleen, and partly to the left supra-pancreatic lymph glands.

The Lymph Vessels from the Right Part of the Lower and Left Area follow the course of the right gastro-epiploic artery and terminate in the sub-pyloric glands.

The Lymph Vessels of the Duodenum are apparently few and difficult to inject; they communicate with those of the stomach above and the jejunum below, and the collecting vessels which pass from the subserous plexus end in the biliary, the sub-pyloric, and the mesenteric lymph glands.

The Lymph Vessels of the Jejunum and Ileum, with the exception of those from the terminal part of the ileum, pass to the mesenteric lymph glands. The lymph vessels from the terminal part of the ileum go to the ileo-colic lymph glands.

The Lymph Vessels of the Cæcum, the Vermiform Process, and the Ascending Colon pass to the ileo-colic lymph glands, either directly or after having traversed glands which lie nearer to the walls of the various parts of the gut.

The Lymph Vessels of the Right Colic Flexure and the Transverse Colon pass to the meso-colic and the superior mesenteric lymph glands.

The Lymph Vessels of the Left Colic Flexure, the Descending Colon, the Iliac Colon, and the Pelvic Colon pass to the inferior mesenteric lymph glands. From those glands the greater part of the lymph is conveyed to the lumbar lymph glands, but part passes to the mesenteric lymph glands and part to the common intestinal lymph trunk.

The Lymph Vessels of the Liver.—The lymph vessels of the liver are described as forming superficial and deep groups. The superficial vessels pass to subserous plexuses from which collecting vessels arise.

The collecting vessels from the superior, anterior, and right lateral surfaces converge to a series of posterior and anterior efferent trunks.

The Posterior Collecting Trunks form three groups: (1) a right group, which runs through the right triangular ligament of the liver and then downwards and medially on the posterior wall of the abdomen, to the middle supra-pancreatic lymph glands; (2) the middle group runs towards the inferior vena cava, passes with it through the diaphragm, and ends in the posterior mediastinal lymph glands; (3) the left group passes through the left triangular ligament to the posterior left gastric glands and the posterior paracardial glands.

The Anterior Collecting Trunks are inferior and superior. The inferior pass from the anterior part of the right lobe, turn round the lower border, and end in the hepatic lymph glands. The superior group pass to the falciform ligament. Some turn posteriorly towards the inferior vena cava, pass through the diaphragm with it and end in the posterior mediastinal lymph glands; others turn forwards and downwards to the round ligament, which they accompany to the porta hepatis where they join the hepatic glands. The remaining vessels pass upwards to the anterior part of the diaphragm which they perforate, and they end in the anterior mediastinal glands.

The superficial collecting vessels of the inferior surface of the right lobe pass (*a*) backwards to the inferior vena cava and along that vessel to the posterior mediastinal glands, (*b*) to the cystic gland of the biliary chain. The collecting vessels of the lower part of the left lobe end in the hepatic glands. The collecting vessels of the caudate lobe pass partly to the posterior mediastinal glands, along the inferior vena cava; and partly to the hepatic lymph glands in the porta hepatis.

The Deep Lymph Vessels of the Liver pass to ascending and descending collecting trunks. The ascending trunks follow the hepatic veins and the inferior vena cava and end in the posterior mediastinal lymph glands. The descending collectors accompany the bile-ducts, the branches of the portal vein, and the branches of the hepatic artery, and terminate in the hepatic lymph glands.

The Lymph Vessels of the Gall Bladder.—The lymph vessels from the gall bladder terminate chiefly in the cystic gland but some pass to other members of the biliary chain.

The Lymph Vessels of the Pancreas.—The efferent vessels from the pancreas end in the adjacent glands, that is, some pass to the sub-pyloric, some to the supra-pancreatic, some to the mesenteric glands, and some to the posterior left gastric lymph glands.

The Lymph Vessels of the Spleen.—The collecting vessels from the spleen pass to the splenic lymph glands which occasionally lie near the hilum of the spleen and the left supra-pancreatic lymph glands.

The Lymph Vessels of the Kidneys.—The lymph vessels of each kidney run along the renal blood-vessels and terminate in the lumbar glands, especially in the pre- and para-aortic lymph glands.

The Lymph Vessels of the Ureters.—The lymph vessels from the abdominal part of each ureter pass to the lumbar and the common iliac and the sub-aortic lymph glands.

The Lymph Vessels of the Suprarenal Glands anastomose with the vessels of the kidneys and pass to the lumbar and to the posterior mediastinal lymph glands.

The Lymph Vessels of the Diaphragm.—The collecting lymph vessels from the diaphragm pass to the thoracic lymph glands, that is, to the anterior and posterior mediastinal lymph glands, and lower sternal glands.

The Lymph Vessels of the Posterior Wall of the Abdomen terminate in the lumbar lymph glands.

ABNORMALITIES OF THE LYMPH VESSELS.

Variations of the glands and smaller vessels of the lymphatic system are so common that they can hardly be regarded as abnormalities; variations of the larger vessels, however, are comparatively rare. This is especially the case with respect to the two terminal trunks, the thoracic duct and the right lymph duct, the abnormalities of which are interesting and important.

When the arch of the aorta is on the right side instead of on the left side, the thoracic duct terminates usually in the right innominate vein, in which case it receives the tributaries which usually open into the right lymph duct, whilst the corresponding area on the left side is drained by lymph vessels terminating in a left lymph duct which opens into the commencement of the left innominate vein. A similar arrangement of the terminal lymph trunks sometimes occurs even when the arch of the aorta is in its normal position on the left side. In either case the thoracic duct may commence in the usual way, and after reaching the level of the fifth thoracic vertebra continue upwards on the right side, instead of crossing to the left side of the vertebral column; more rarely it commences on the left side and crosses over to the right at a higher level.

In one case in which the thoracic duct opened into the right innominate vein, instead of the left, no trace of a lymph duct was discovered on the left side.

Occasionally the thoracic duct commences and terminates in the usual manner, but crosses the vertebral column immediately after its origin and ascends on the left side.

Not uncommonly there is no distinct cisterna chyli, in which case the terminal lymph vessels of the abdomen merely unite to form a larger vessel which does not present any obvious dilatation, and from which the thoracic duct is continued. The terminal lymph trunk may open into the internal jugular vein, previous to its junction with the subclavian, instead of into the commencement of the innominate vein.

Occasionally the thoracic duct is double, either in the whole or in part of its extent, and sometimes it breaks up into a plexus of vessels which may reunite into a single trunk in the upper part of the thorax. Both the thoracic duct and the right lymph duct may, before terminating, divide into branches which, though sometimes reuniting on each side into a single trunk, not infrequently open separately into the great veins at the root of the neck.

As a rule the thoracic duct joins the commencement of the left innominate vein, but it may end in the internal jugular, vertebral, or subclavian veins of the left side; whilst very rarely, it opens into the vena azygos.

DEVELOPMENT OF THE BLOOD-VASCULAR SYSTEM.

The Arteries and the Heart.

In the general account of the development of the zygote (pp. 71-74) it has been pointed out that the primitive vascular system, from which the main blood-vessels of the adult are derived, consists of—

(1) A tubular heart, separated by constrictions into five parts named, from the caudal to the cranial end, the sinus venosus, the atrium, the ventricle, the cardiac bulb, and the aortic trunk.

(2) Two ventral aortæ.

(3) Two dorsal aortæ fused in parts of their extents to form a median descending aorta.

(4) Six pairs of aortic arches, of which four pairs, the first to the fourth, connect the ventral aortæ with the unfused portions of the dorsal aortæ; one pair, the fifth, connects the ventral aortæ, for a short time, with the dorsal parts of the sixth arches; and the remaining pair, the sixth, connects the aortic trunk of the heart with the unfused parts of the dorsal aorta.

(5) Seven pairs of venous trunks, the vitelline, the umbilical, the precardinal, the post-cardinal, the ducts of Cuvier, the subcardinals, and the supracardinals, of which only three pairs, the vitelline veins, the umbilical veins, and the ducts of Cuvier, open directly into the venous sinus of the heart (Figs. 795, 796).

It was also noted (*a*) that the dorsal aortæ gave off a series of paired branches through which blood passed from the aortæ to networks of capillary vessels from which it was collected into the veins; (*b*) that the venous trunks were connected with their fellows of the opposite side, across

the median plane, by transverse anastomoses; and (*c*) that anastomoses were formed between the post-, the sub-, and the supra-cardinal veins (p. 74).

The further changes by which the heart and the blood-vessels of the embryo are converted into the heart and the blood-vessels of the adult have now to be considered.

The Development of the Heart.—During the period in which the embryo increases in length from 1·3 mm. to 2·6 mm. the heart is formed, in the septum transversum and the dorsal wall of the pericardium, by the fusion of the caudal parts of the ventral aortæ (Fig. 796).

The sinus venosus lies for a time in the septum transversum. There it receives the ducts of Cuvier, the vitelline veins, and the umbilical veins, and after a short period it is projected out of the septum transversum into the dorsal part of the pericardium.

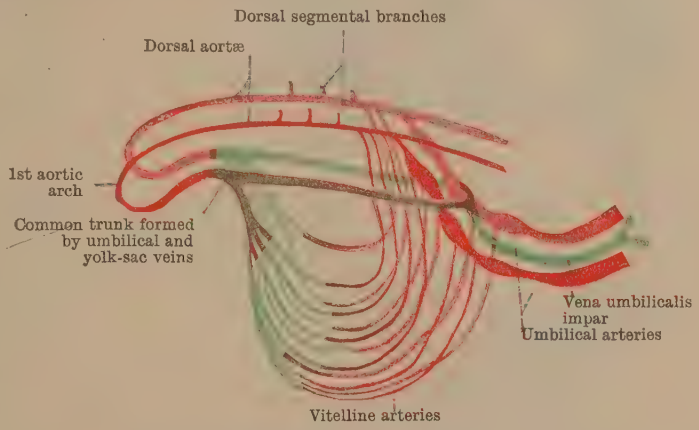

FIG. 795.—SCHEMA OF CIRCULATION OF AN EMBRYO, 1·35 MM. LONG, WITH SIX SOMITES. (After Felix, modified.)

After its formation the heart elongates more rapidly than the pericardium and, therefore, bends into the form of a loop, of which the cranial limb is formed by the aortic trunk and the bulbus cordis, the apex, which lies ventrally, by the ventricle, and the caudal limb by the atrium and the sinus venosus (Fig. 802), whilst the interval between the cranial and caudal limbs is filled by a fold of the lining pericardium which constitutes the mesocardium.

As the heart folds longitudinally it is also bent in the transverse plane, so that, for a time, the more cranial part of the ventricle with the bulbus cordis and the aortic trunk lie towards the right of the more caudal part of the ventricle and the atrium and sinus venosus, and the atrio-ventricular orifice enters what, for a period, is the left limb of the ventricle (Fig. 797).

Afterwards, as the ventricle enlarges mainly ventrally, laterally, and cranialwards, the atrio-ventricular orifice is transposed to the middle of its dorsal wall, the right segment of the sinus venosus is absorbed into the atrium, and the atrium, thus reinforced, expands round the sides of the bulbus cordis and the aortic trunk (Fig. 797).

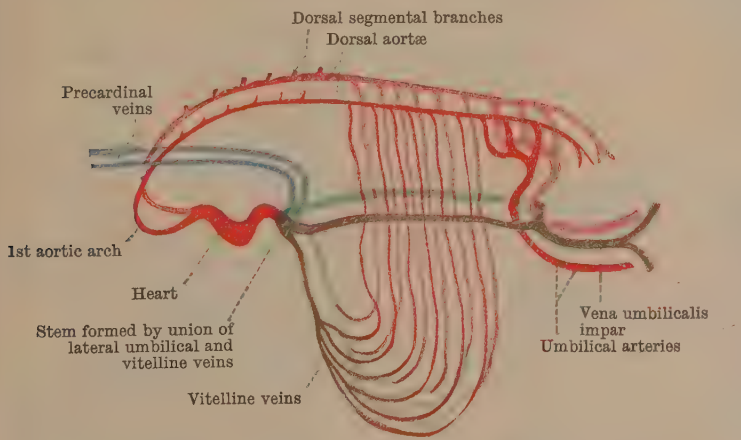

FIG. 796.—SCHEMA OF VASCULAR SYSTEM OF AN EMBRYO, 2·6 MM. LONG, WITH FOURTEEN SOMITES. (Arteries after Felix, modified.)

Subsequently the bulbus cordis is absorbed, partly into the ventricle and partly into the aortic trunk, and, thereafter, the aortic trunk is divided into the stem of the pulmonary artery and the ascending part of the aorta, whilst the mesocardium, which lay in the angle between the aortic trunk and the atrium, disappears, leaving an aperture, the transverse sinus of the pericardium, through which the right and left halves of the pericardial cavity communicate with one another dorsally and cranially to the ventricle, dorsally to the ascending aorta and the pulmonary artery, and ventrally to the atrium.

Whilst the changes in position and shape of the heart, the disappearance of the mesocardium, and the division of the aortic trunk are taking place, the cavities of the atrium, the atrio-ventricular canal, which is the constricted part of the heart through which the atrium communicates with the ventricle, and the cavity of the ventricle, are all being divided into right and left halves by means of septa, which it is convenient to consider separately although they are formed simultaneously and fuse with one another in parts of their extents.

The Division of the Atrio-ventricular Canal.—After the longitudinal folding of the

primitive cardiac tube has occurred the atrio-ventricular canal runs dorso-ventrally (from behind forwards in the erect posture) from the atrium to the ventricle. At first it is cylindrical in form, but, gradually, its cranial and caudal walls are thickened to form *endocardial cushions*, which project into the lumen of the canal, except at its right and left margins, and convert it into a cleft (Figs. 798, 800). Finally the cushions fuse, forming an atrio-ventricular septum but leaving the right and left margins of the canal intact as the *right* and *left atrio-ventricular orifices*; the right orifice forming a communication from the part of the atrium which afterwards becomes the right atrium to the part of the common ventricle which becomes later the right ventricle, whilst the left orifice connects the part of the common atrium which will become the left atrium with the part of the common ventricle which will become the left ventricle.

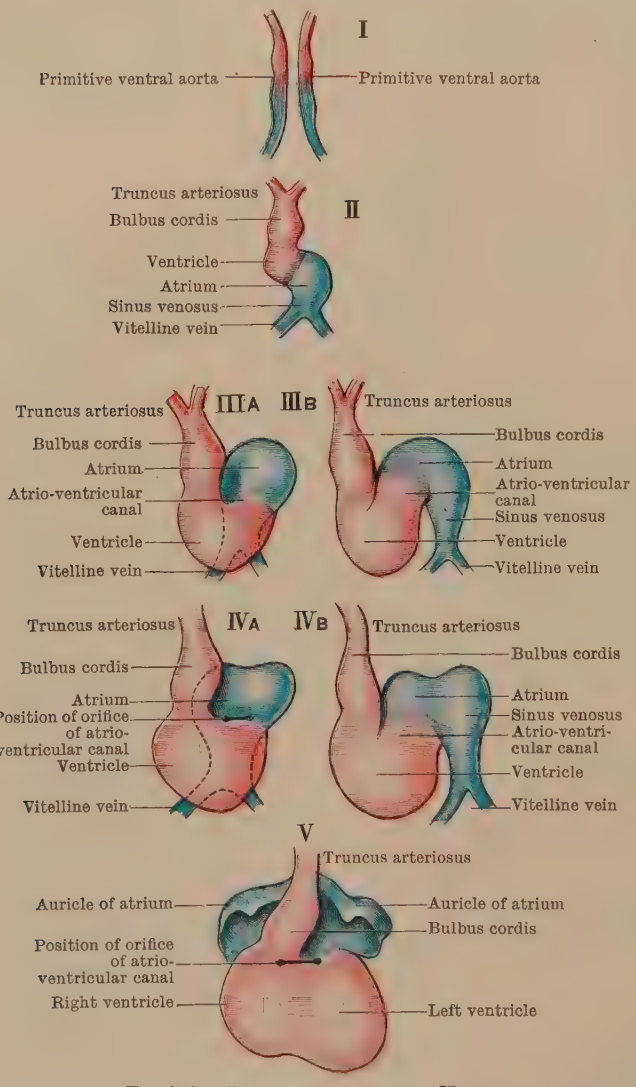

FIG. 797.—DEVELOPMENT OF THE HEART.

Diagram showing the changes of form and external appearances at different stages. Modified from His's models. III. B and IV. B are side views; the other figures represent the heart as seen from the front.

Occasionally the atrio-ventricular cushions obliterate not only the middle of the lumen of the atrio-ventricular canal but also one of its margins. In such cases only a single atrio-ventricular orifice is found in the later stages, right or left as the case may be. When such an abnormality occurs it is usually associated with incomplete formation of the interatrial and interventricular septa.

The Division of the Atrium.—The division of the primitive atrium into right and left atria is brought about by the formation and fusion of two septa, the *septum primum* and the *septum secundum*, and the fusion of both with the atrial end of the septum of the atrio-ventricular canal.

The septum primum is so called because it appears and partially disappears before the septum secundum is developed. It grows ventrally from the dorsal and cranial walls of the atrium until it meets and fuses with the septum of the atrio-ventricular canal, and, as it grows, the area of communication between the right and left parts of the atrium is gradually reduced. The aperture which is thus contracted is called the *primary foramen ovale* (Fig. 798). It is obliterated when the septum primum fuses with the septum of the atrio-ventricular canal, but before that fusion occurs an aperture called the *secondary foramen ovale* appears in the dorsal and caudal part of the septum primum (Fig. 798).

The septum secundum grows from the cranial and ventral walls of the atrium, immediately to the right of the septum primum.

When the growth of the septum secundum has caused its dorsal margin to pass dorsally beyond the dorsal margin of the secondary foramen ovale the latter margin acts as a flap valve, which permits blood to pass through the secondary foramen ovale, from the right to the left atrium, but prevents its return. That condition is retained until a short time after birth, when the right surface of the septum primum fuses with the left surface of the septum secundum and the orifice is permanently closed.

As a result of incomplete development the interatrial septum may be absent and the common atrium then communicates with both ventricles. In other cases the septum is incompletely formed and one, or other, or both of the interatrial foramina persist to adult life.

If the ventral end of the septum primum fails to fuse with the septum of the atrio-ventricular canal the primary foramen ovale persists, and is found as an aperture which lies between and immediately dorsal (posterior in the erect posture) to the atrio-ventricular apertures.

If the right surface of the septum primum fails to fuse with the left surface of the septum secundum a more or less reduced foramen ovale secundum persists. Such a condition is found in 10 per cent of adults examined in the post-mortem room.

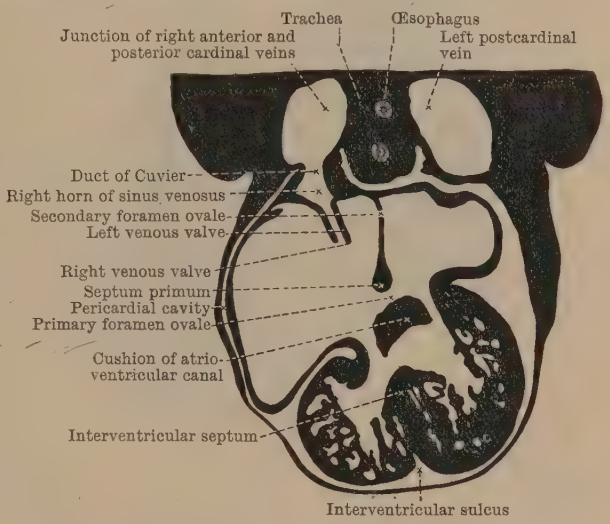

FIG. 798.—SECTION OF THE HEART OF A HUMAN EMBRYO. (Edinburgh University collection.)

The Division of the Truncus Arteriosus and the Cranial Part of the Bulbus Cordis.—It has already been noted that the bulbus cordis is absorbed partly into the arterial trunk and partly into the ventricular segment of the heart. As the absorption proceeds endocardial cushions develop in the arterial trunk and pass spirally along its inner wall into the ventricle.

At the apex of the arterial trunk, where it gives off the ventral aortæ and the sixth aortic arches, four endocardial cushions are found. They are placed ventrally, dorsally, and right and left.

The ventral and dorsal cushions disappear, in normal cases, but the right and left cushions pass spirally along the arterial trunk into the ventricle, and they fuse together to form a septum which divides the lumen of the arterial trunk into two segments.

At the apex of the arterial trunk, where the cushions were right and left, the septum divides the arterial trunk into a ventro-cranial (anterior in the erect posture) or aortic section, which communicates with the ventral aortæ, and a dorso-caudal or pulmonary section which remains continuous with the sixth aortic arches which become parts of the pulmonary arteries.

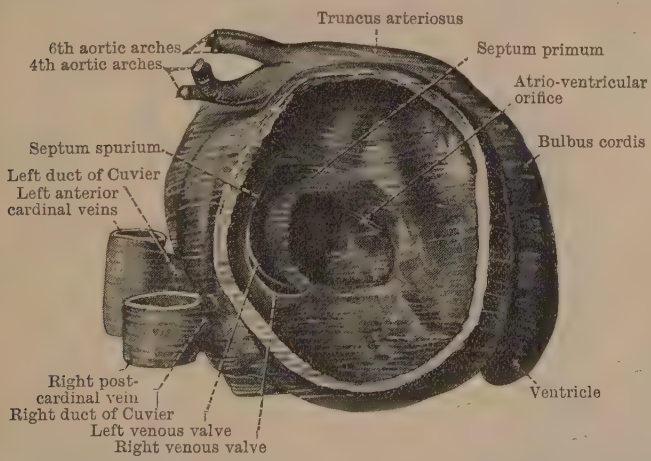

FIG. 799.—MODEL SHOWING THE INTERIOR OF THE RIGHT ATRIUM OF A HUMAN EMBRYO 5·5 MM. LONG. (Edinburgh University collection. Modelled by C. C. Wang.)

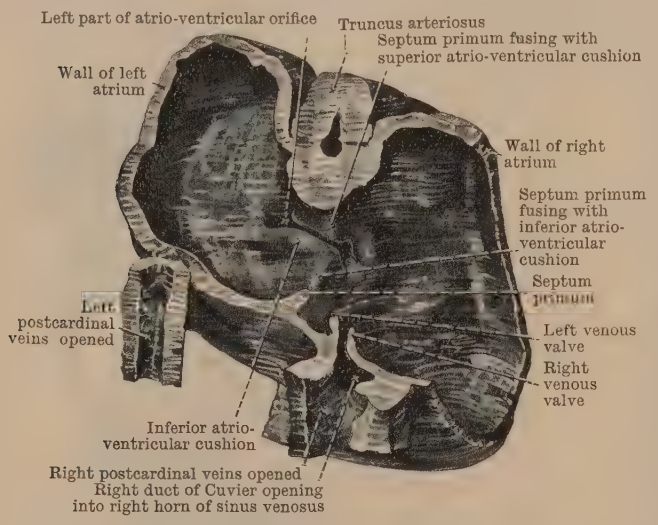
At the apex of the arterial trunk the septum has ventro-cranial and dorso-caudal surfaces and right and left borders. As it passes towards the ventricle it twists like a right-handed spiral, its right border first becoming dorsal, next left lateral, and finally ventral; consequently the surface which was originally dorso-caudal becomes ventro-cranial, and, as a result, when the ventricular end of the septum passes into the ventricle the blood from the right or ventro-cranial part of that chamber is directed into the sixth aortic arches, which become parts of the pulmonary arteries, and that from the left and more caudal part into the ventral aortæ and the four anterior aortic arches which help to form the main arterial trunks of the head, neck, and superior extremities of the adult.

After the septum is completed it is split longitudinally, and so the arterial trunk is divided into the ascending aorta and the trunk of the pulmonary artery.

The Division of the Ventricle.—As the bulbus cordis is absorbed into the ventricle and the arterial trunk, and the cavities of the arterial trunk and the atrium are divided by the formation of septa, the septum which divides the ventricle into right and left parts also appears.

It commences as a fold of the ventricle wall, immediately to the right of its most ventral point, and its position is indicated on the surface by a sulcus (Fig. 798), which sometimes remains evident in the adult, producing a bifid apex of the heart. The fold, which consists of the muscular substance as well as the endocardial lining, projects into the cavity, not only from its ventral but also from its cranial and caudal walls, hence the septum, in the early stages, is semilunar in form.



Left part of atrio-ventricular orifice
Truncus arteriosus
Septum primum fusing with superior atrio-ventricular cushion
Wall of left atrium
Wall of right atrium
Septum primum fusing with inferior atrio-ventricular cushion
Septum primum
Left postcardinal veins opened
Left venous valve
Right venous valve
Inferior atrio-ventricular cushion
Right postcardinal veins opened
Right duct of Cuvier opening into right horn of sinus venosus

FIG. 800.—VIEW OF THE INTERIORS OF THE RIGHT AND LEFT ATRIA OF A HUMAN EMBRYO 5·5 MM. LONG. (Edinburgh University collection. Modelled by C. C. Wang.)

The cranial horn of the semilune advances along the cranial wall of the ventricle until it meets the cranial margin of the ventricular part of the septum of the aortic trunk, with which it fuses. The caudal margin travels along the caudal wall of the ventricle until it meets and fuses with the septum of the atrio-ventricular canal (Fig. 801). The concave margin of the semilunar septum lies ventral to the aperture into the arterial trunk, therefore, for a time, there exists an aperture, ventral to the arterial trunk, through which the right and left ventricles communicate with one another. The aperture is closed by the extension of the septum of the arterial trunk into the ventricular area until it meets and fuses with the dorsal concave margin of the interventricular septum.

The interventricular septum of the adult consists, therefore, of two parts—a ventral and

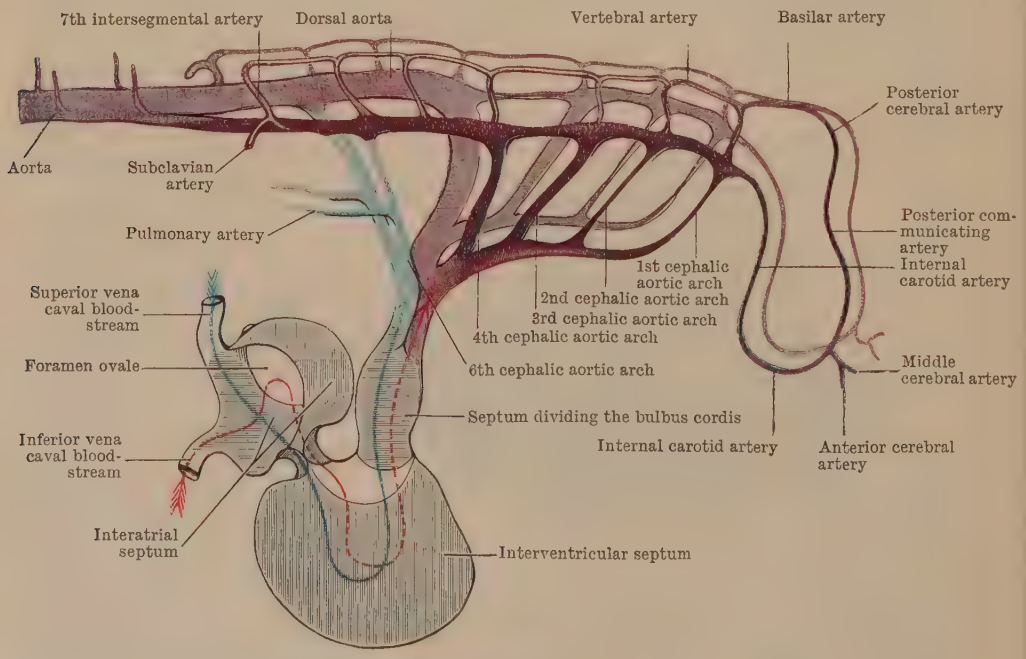


FIG. 801.—DEVELOPMENT OF THE HEART AND THE MAIN ARTERIES.

Diagram of the heart, showing the formation of its septa, and of the cephalic portion of the arterial system.

larger muscular part, formed from the wall of the ventricle, and a dorsal and smaller membranous part (pars membranacea), formed from the ventral extension of the septum of the arterial trunk.

The more common abnormalities which result from the non-completion or the modification of the developmental processes in the ventricular area :—

(1) The septum of the arterial trunk may fail to descend into the ventricular area, in which

case the pars membranacea septi is absent and an interventricular foramen exists through which the cavities of the two ventricles communicate with one another, and each ventricle opens into both the aorta and the pulmonary artery.

(2) The muscular part of the interventricular septum may be absent. There is then only one ventricular cavity which receives blood from both atria and projects it into both the pulmonary artery and the aorta.

(3) The septum of the arterial trunk may form a left-handed instead of a right-handed spiral, with the result that the pulmonary communicates with the left and the aorta with the right ventricle.

(4) The spiral twist of the septum of the arterial trunk may be incomplete, so that its ventral margin meets the dorsal margin of the ventricular septum more or less at right angles, then the pulmonary artery and the aorta both communicate with each of the ventricles.

Many other abnormalities, due to interference with or alterations of the ordinary processes of development, occur; for accounts of them readers who are interested must consult monographs on malformations of the heart.

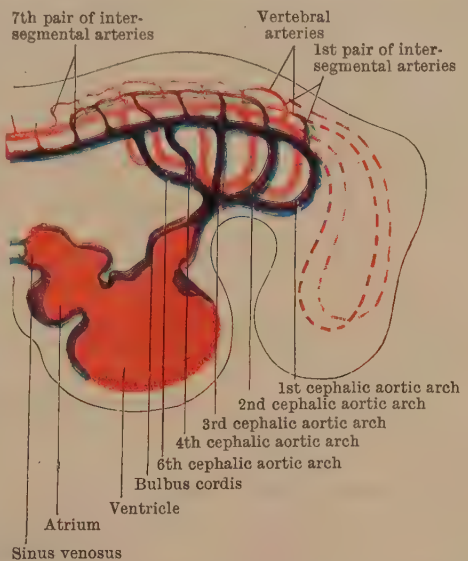

FIG. 802.—SCHEMA OF THE STAGE OF FIVE AORTIC ARCHES. The cardinal veins and ducts of Cuvier are not shown.

The Fate of the Sinus Venosus.—The sinus venosus, which constituted the most caudal part of the primitive heart, was formed, in the septum transversum, by the fusion of the terminal parts of the common vitello-umbilical trunk veins, to form a single chamber which consists of right and left cornua and an intermediate section.

Each cornu, at that time, receives a duct of Cuvier, a vitelline and an umbilical vein. Later, as the longitudinal folding of the cardiac tube occurs, the sinus venosus emerges from the septum transversum and is transposed into the caudal part of the pericardium. There it lies dorsal to the atrium into which its right cornu opens, through an orifice guarded by right and left venous valves (Fig. 798) which fuse with one another at their cranial and caudal ends.

As development proceeds, the right cornu of the sinus venosus is absorbed into the right atrium, the whole of the left and the cranial part of the right venous valves disappearing, whilst the caudal part of the right valve becomes the valve of the inferior vena cava, which is the modified termination of the right vitelline vein (see Development of the Portal System, p. 1042).

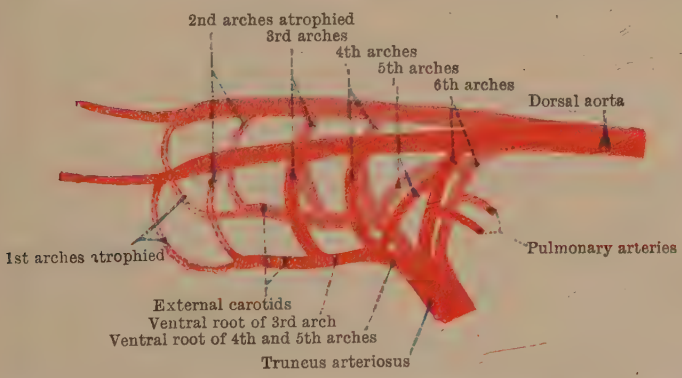

FIG. 803.—SCHEMA OF AORTIC ARCHES OF AN EMBRYO, 9 MM. LONG. (After Tandler, modified.) The second and third arches have atrophied and the transitory fifth has appeared.

The left cornu of the sinus venosus remains as the coronary sinus of the fully developed heart, and the dorsal wall of the intermediate section is projected ventrally towards the right atrium, to form the valve of the coronary sinus, which lies at the right margin of the opening through which the coronary sinus communicates with the right atrium (Fig. 724).

The Fate of the Ventral Aortæ, the Aortic Arches, and the Unfused Parts of the Dorsal Aortæ.—It has already been pointed out (see p. 73) that when the embryo is 5 mm. long it possesses five pairs of aortic arches, of which the first and second pairs connect the ventral aortæ with the unfused parts of the dorsal aortæ, whilst the third, fourth, and sixth pairs, which also pass to the unfused parts of the dorsal aortæ, arise from a common stem which springs from the apex of the truncus arteriosus (Fig. 802).

As the embryo increases from 5 mm. to 9 mm. in length, (1) the third and fourth pairs of arches are transferred to the ventral aortæ; (2) a transitory fifth pair of arches appears and for a time connects the ventral aortæ with the dorsal parts of the sixth arches; (3) the first two pairs

of arches have begun to disappear; and (4) the right and left pulmonary arteries have grown from the corresponding sixth arches into the rudiments of the lungs (Fig. 803).

As soon as two or more arches arise from the ventral aortæ it is customary, for convenience of description, to speak of the parts of the ventral aortæ which lie caudal to the various arches as the ventral roots of those arches, and the corresponding parts of the dorsal aortæ are called the dorsal roots of the arches; therefore, at the 9 mm. stage, if the fifth pair of arches are left out of consideration on account of their very transitory and unimportant nature, it may be said that first four pairs of arches have ventral roots. The sixth arches spring from the apex of the truncus arteriosus, and therefore are devoid of ventral roots; but all the arches have dorsal roots, and the dorsal roots of the sixth arches end in the descending aorta which was formed by the fusion of the more caudal portions of the primitive dorsal aortæ.

The main events of the subsequent changes which occur before the embryo is 15 mm. long may be summarised as follows:—

(1) The following parts have disappeared:—

(*a*) The dorsal roots of the third arches.
(*b*) The dorsal roots of the right fourth and sixth arches.
(*c*) The dorsal part of the right sixth arch.

(2) In the meantime the truncus arteriosus has been divided into the ascending aorta, which passes from the left ventricle to the ventral roots of the fourth pair of arches, and the pulmonary stem which connects the right ventricle with the sixth arches.

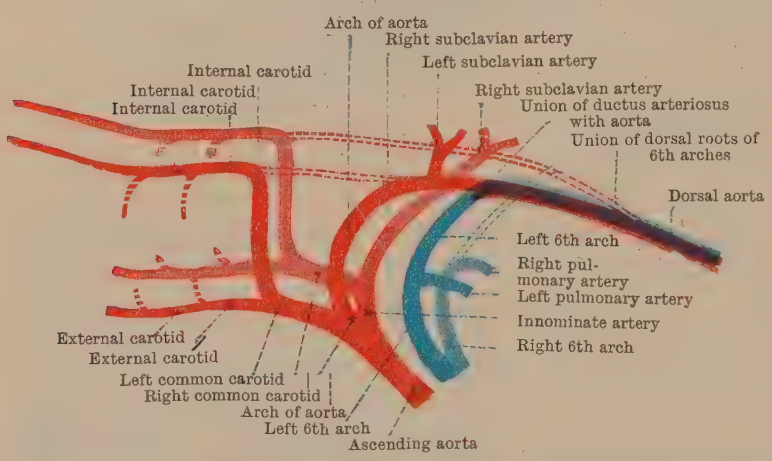

FIG. 804.—SCHEMA OF PART OF THE ARTERIAL SYSTEM OF A FŒTUS SEEN FROM THE LEFT SIDE. Parts of the first and second arches, the dorsal roots of the third arches, the dorsal part of the right sixth arch, and the dorsal roots of the right fourth and fifth arches have atrophied. The position of the fifth arch is not indicated; see Fig. 803.

(3) The ventral root of the right fourth arch has become the innominate artery.

(4) The ventral root of the left fourth arch and the fourth arch itself have been converted into the arch of the aorta.

(5) The right fourth arch has become the right subclavian artery.

(6) The ventral roots of the third arches have become the common carotid arteries.

(7) The ventral roots of the first and second arches have become the external carotid arteries.

(8) The third arches and the dorsal roots of the first and second arches have formed the internal carotid arteries.

(9) The dorsal root of the left fourth arch has become part of the arch of the aorta.

(10) The dorsal root of the left sixth arch has become the cranial part of the descending aorta.

(11) The dorsal part of the left sixth arch has become the ductus arteriosus, through which blood, which has passed from the right ventricle into the pulmonary artery, is transmitted into the aortic arch until birth. Then the dorsal part of the left sixth arch becomes the ligamentum arteriosum, and the blood which passes into the pulmonary artery runs through the lungs to the pulmonary veins, and so to the left atrium.

Many variations of the main stems of the adult arterial system are the result of modifications of the ordinary developmental changes which have been noted. Parts which usually disappear may remain, parts which usually remain may disappear, and fusions and absorptions of parts which usually remain distinct may occur.

If the dorsal roots of the right fourth and sixth arches persist, in addition to the persistence of the same parts of the left side, both right and left aortic arches are formed, and the more cranial part of the descending aorta is doubled, a condition which persists in adult reptiles.

If the dorsal roots of the right fourth and sixth arches persist and the corresponding parts on the left side disappear, the arch of the aorta is transposed from the left to the right side. This is the regular occurrence in birds.

If the right fourth arch disappears, and the dorsal roots of the right fourth and sixth arches persist, a not uncommon variation, then the right subclavian artery arises from the descending aorta caudal to the origin of the left subclavian artery.

If the ventral roots of the fourth arches of opposite sides fuse, a common stem is formed, which arises from the arch of the aorta and gives origin to the right subclavian and both common carotid arteries.

If the ventral roots of the third and fourth arches of opposite sides fuse, a common stem is formed, which springs from the arch of the aorta; it gives off the right subclavian artery and the external and internal carotid arteries of both sides.

High division of the common carotid, on either side, may be due to the disappearance of the third arch, and the dorsal roots of the second and third arches, and the persistence of the second arch.

The Branches of the External Carotid Artery.—All the typical branches of the external carotid artery are present in embryos 15·5 mm. long; little is known, however, regarding the details of their development. It is probable that the internal maxillary artery and its branches are evolved partly from the ventral part of the first aortic arch and partly from an anastomosis with the branches of a temporary *stapedial artery*, which develops from the dorsal end of the second arch; but it is not known whether the other branches of the external carotid spring as offsets from the ventral roots of the first or second arches or from the ventral parts of the arches themselves.

The Descending Aorta.—The greater part of the descending aorta is formed by the fusion of the primitive dorsal aortæ. In embryos about 2·6 mm. long, possessing twenty-three mesodermal somites, the primitive dorsal aortæ are fused together from the tenth to the sixteenth segment (Fig. 796). At a later period the fusion is continued caudalwards to the twenty-third body segment—the level of the fourth lumbar vertebra—where the common iliac arteries arise. Still later the small terminal portions of the primitive dorsal aortæ fuse together to form the unpaired middle sacral artery, which terminates at the extremity of the coccygeal region.

If the three somites which lie nearest the head-end, in embryos possessing twenty-three somites, are cephalic somites, then the point of commencement of the median aorta would be situated at the level of the seventh body somite, that is, at the situation of the future seventh cervical vertebra. The position of the anterior point of fusion of the primitive dorsal aortæ is indicated in the adult by the origin of the abnormal right subclavian artery, and is situated at the level of the fifth thoracic vertebra; therefore the anterior end of that part of the descending aorta which is formed by the process of the primitive dorsal aortæ must move caudalwards during the developmental period.

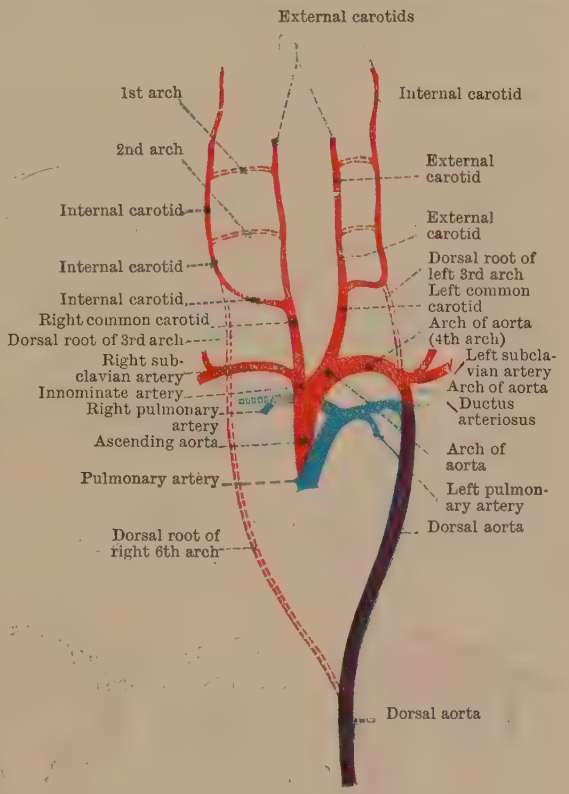

FIG. 805.—SCHEMA OF PART OF THE VASCULAR SYSTEM OF A FŒTUS SEEN FROM THE FRONT. The origin of the positions of the first and second arches, the dorsal roots of the third arches on both sides, and the dorsal roots of the fourth and fifth arches on the right side are shown in dotted lines. The positions of the fifth arches are not shown.

The Branches of the Dorsal Aortæ.—The branches given off from the primitive dorsal aortæ are dorsal, lateral, and ventral.

The dorsal branches arise either in the head region, cranial to the point where the first mesodermal somite is formed, and hence are presegmental, or more caudally in the head, and in the neck and body regions, where they lie opposite the intervals between the mesodermal somites, and are therefore intersegmental.

They supply the neural tube and its surroundings, the tissues of the head and neck, the body wall and the extremities, but they do not send branches to the viscera, therefore they are somitic arteries.

They anastomose with each other by a series of longitudinal channels which lie ventral and dorsal to the dorsal portions of the costal elements of the skeleton, and dorsal to the transverse processes of the vertebræ.

An account of their branches and anastomoses and the transformations which affect them, and more especially of those which result in the formation of the vertebral arteries and the arteries of the extremities, is given in the description of the morphology of the vascular system (see pp. 1052, 1059); but it may be stated here that the main arteries of the adult, which are derived from the dorsal branches of the primitive dorsal aortæ and their anastomoses and branches, are: (1) The intercostal and lumbar arteries and their posterior or dorsal rami; (2) parts of the subclavian arteries; (3) the axillary arteries and their continuations in the upper extremities;

(4) the vertebral arteries; (5) the spinal arteries; (6) the basilar artery; (7) the superior intercostal arteries; (8) the internal mammary and the superior and inferior epigastric arteries.

As a rule, the dorsal branches of the primitive dorsal aortæ remain separate from each other, even in the regions where the primitive dorsal aortæ themselves fuse, but occasionally in the thoracic and lumbar regions they fuse, with the result that intercostal and lumbar arteries of opposite sides arise from common stems.

The Lateral Branches of the Dorsal Aortæ are distributed to organs developed from the intermediate cell tracts—that is, to the temporary and permanent urinary organs, the pronephri and mesonephri (Wolffian bodies), which disappear; and to the metanephri, which become the permanent kidneys; and also to the suprarenal and genital glands. They become the renal, internal testicular, and ovarian arteries.

The Ventral Branches of the Primitive Dorsal Aortæ.—The vessels of this group are neither definitely segmental nor intersegmental. They pass to the walls of the entodermal portion of the alimentary canal and its diverticula, and also, in the early stages of development, to the walls of the yolk sac and the chorion and its placental derivative. They are connected together by longitudinal anastomosing channels which lie in the dorsal mesentery of the gut and also upon the wall of the gut itself. As the yolk sac atrophies the prolongations of the ventral branches which pass to its walls disappear and, simultaneously, the portions of the corresponding vessels of opposite sides, which lie in the mesentery, dorsal to the gut, and the longitudinal anastomoses which connect them, fuse together to form unpaired stem-trunks from which the three great vessels of the abdominal part of the alimentary canal are derived, namely, the cœliac, the superior mesenteric, and the inferior mesenteric arteries; but the original stem of each of these three important vessels is not that which eventually forms its origin from the abdominal part of the aorta, for the cœliac artery, which originally arose opposite the seventh cervical segment, wanders caudalwards to the twelfth thoracic segment as the roots of origin of the ventral vessels which are situated nearer the head disappear; and in the same manner the superior mesenteric is transposed from the level of the second thoracic to the level of the first lumbar segment, and the inferior mesenteric wanders from the twelfth thoracic to the third lumbar segment.

Of the three arteries mentioned the superior mesenteric retains longest its connection with the yolk sac, and it occasionally happens that a fibrous strand representing the original channel extends from one of the intestinal branches of the superior mesenteric past the side of the intestine to the umbilicus.

The Umbilical and Iliac Arteries.—It was pointed out, in the account of general features of embryology, that the umbilical arteries which carry blood to the placental area of the chorion arise, in a human embryo about 1·38 mm. long, about the level where the fourth cervical mesodermal somite will be developed at a later stage. They spring from plexuses formed, on the lateral walls of the caudal part of the primitive gut, by the anastomosis of some of the most caudally situated ventral or vitelline branches of the primitive dorsal aorta. The origins of the arteries are gradually moved caudally as the embryo grows, until, eventually, they spring from the primitive dorsal aorta, opposite the twenty-third body somite, that is the fourth lumbar segment. As each umbilical artery passes from its origin on the ventral wall of the primitive dorsal aorta to the body-stalk it lies to the medial side of the pronephric duct. The ventral origin is, however, but temporary; for, by the time the embryo has attained a length of 5 mm., and the primitive dorsal aortæ have fused to form the permanent descending aorta, a new vessel has arisen, on each side, from the lateral part of the caudal end of the aorta. This new vessel passes ventrally, to the lateral side of the Wolffian duct, and then unites, on a plane ventral to the aorta, with the primitive umbilical artery of the same side. After the union has taken place the ventral origin of the umbilical artery disappears, and the primitive umbilical artery then arises from the side of the caudal end of the aorta. From the newly formed vessel, which now constitutes the only origin of the umbilical artery, the inferior gluteal artery, which is the primitive main artery of the lower limb, arises. At a later period, and at a more dorsal level, a second branch arises from the dorsal root of origin of the umbilical artery; this is the second main vessel of the lower extremity, which becomes the **external iliac** and the **femoral arteries** of the adult. As soon as the external iliac artery is formed that portion of the umbilical stem which lies dorsal to it becomes the **common iliac artery**, and the more ventral part, which descends into the pelvis minor, becomes the **hypogastric artery.** But that portion of the original umbilical artery which runs along the side of the pelvis minor to the ventral wall of the abdomen, then cephalwards to the umbilicus and through the umbilicus to the placenta, is still called the umbilical artery. After birth, when the placental circulation ceases, the greater part of the intra-abdominal portion of the umbilical artery atrophies and

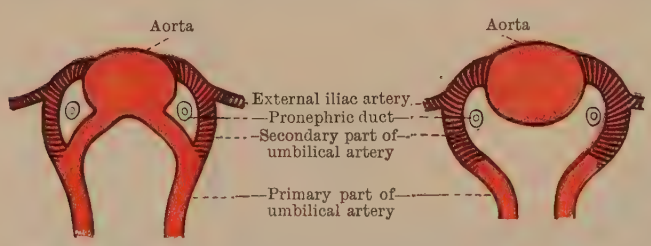

FIG. 806.—DIAGRAM SHOWING THE FORMATION OF THE SECONDARY PART OF THE PRIMITIVE UMBILICAL ARTERY.

becomes converted into the **lateral umbilical ligament**, but a portion of the part which lies in the pelvis minor remains pervious and from it springs the **superior vesical artery**.

The Blood-Vessels of the Superior Extremities.—It appears probable that, in the earliest stages of development, a number of branches arise from the sides of the primitive dorsal aortæ and pass to the rudiments of the superior extremities, where they end in vascular plexuses which are drained into the precardinal veins.

At a later period the number of connexions with the aorta, on each side, is reduced to one, and that is transferred from the aorta to the ventral branch of the seventh intersegmental artery, whilst, at the same time, the original plexus in the limb is reduced to a single trunk, which is divisible into subclavian, axillary, brachial, and volar interosseous segments. At a later period a median branch arises from the volar interosseous artery, and still later radial and ulnar branches are formed, the portion of the ulnar artery which lies between the bifurcation of the brachial and the origin of its volar interosseous branch being part of the original stem vessel.

In the early phases the blood is returned from the superior extremity by two superficial vessels, the cephalic and basilic veins, which unite at the root of the neck to form the subclavian vein, which ends in the precardinal vein. For a time the cephalic vein communicates across the front of the rudiment of the clavicle with the external jugular vein.

The deep veins which accompany the arteries are developed later.

The Blood-Vessels of the Inferior Extremities.—The development of the arteries of the inferior extremities has recently been investigated by Senior, and readers who wish to follow the details of an intricate process, or those who desire to understand the evolution of the arterial variations met with in the inferior extremities, should refer to Senior's *Communications*[1]; only a general outline of the phenomena can be given here.

It is not possible from the knowledge so far attained to assign to the arteries of the inferior extremities any segmental or intersegmental relationship.

In the first place, a primary axial artery is developed. It springs from the secondary umbilical artery, leaves the pelvis through the greater sciatic foramen, descends through the thigh, between the rudiments of the hamstrings and the adductor muscles, passes through the popliteal fossa, where its distal part lies anterior to the rudiment of the popliteus muscle, and descends along the interosseous membrane to the foot, where it terminates in a capillary plexus.

The remnants of the primitive axial artery usually present in the adult are—the inferior gluteal artery and its sciatic branch, the proximal or femoral part of the popliteal artery, and the distal part of the peroneal artery.

After the axial artery is established, a new branch springs from the secondary umbilical artery above the origin of the axial artery. The new vessel runs along the margin of the upper aperture of the pelvis minor, passes above the superior ramus of the pubis, and enters the front part of the thigh, where it divides into two branches.

The two branches end in a capillary plexus which is joined distally by a recurrent branch of the axial artery which pierces the rudiment of the adductor magnus.

That part of the new vessel which lies in the abdomen becomes the external iliac artery. The part which lies in the thigh, with one of its branches, part of the capillary plexus and the recurrent branch of the axial artery, is converted into the femoral artery of the adult.

The other terminal branch and the remainder of the capillary plexus disappear, or they are utilised in the formation of some of the branches of the femoral artery.

All the vessels of the leg and foot of the adult, except the distal part of the peroneal artery, are formed either by rami of the primitive axial artery, or their branches, or anastomosing channels, or by combinations of some of the three groups of vessels.

DEVELOPMENT OF THE VEINS.

Simultaneously, or almost simultaneously, with the formation of the arteries by which blood is distributed to all parts of the zygote, and in an essentially similar manner, a series of vessels is developed by which the blood is returned to the heart of the embryo. These vessels are the primitive veins. They form two groups which make their appearance at different periods.

The first group includes (1) the vitelline veins (right and left), which return blood from the yolk sac, and (2) the umbilical veins (impar, right, and left), by which blood is returned from the chorion and the placenta.

All the vessels of this group are partly extra-embryonic and partly intra-embryonic, and they are largely transitory.

The intra-embryonic portions of the vitelline veins take part in the formation of the cardiac end of the inferior vena cava, the hepatic veins, the capillary blood plexus in the liver, and the portal vein and its right and left branches. The extra-embryonic portions disappear.

The umbilical veins are essentially associated with the period of intra-uterine life, and they are represented in the adult body only by a fibrous cord, the round ligament of the liver, which is a remnant of the left umbilical vein.

The second group placed in their order of appearance consists of (1) the precardinal veins, (2) the postcardinal veins, (3) the ducts of Cuvier, (4) the subcardinal veins, (5) the supracardinal veins. It is mainly from these veins that the permanent veins of the head, neck, and body are evolved (for the development of the veins of the limbs see above and p. 1058).

[1] H. D. Senior, *Amer. Jour. of Anat.* vol. xxv. No. 1, Jan. 1919; *Anat. Rec.* vol. xvii. No. 5, 1920.

All the above-named veins are paired, right and left, and between the vessels of opposite sides, in the case of each pair, there are transverse anastomoses, whilst anastomoses also exist between the post-, sub-, and the supra-cardinal veins.

The precardinal veins, and a transverse anastomosis between them situated in the more cranial or upper part of the thoracic region, are transformed into (1) the cavernous sinuses of the cranium, (2) the internal jugular veins, (3) the innominate veins, (4) the extra-pericardial part of the superior vena cava, and (5) the upper or more cranial part of the left superior intercostal vein.

The other venous channels of the cranium, head and neck, and the superior extremities are later formations.

The right duct of Cuvier becomes the intra-pericardial part of the superior vena cava, and the left duct of Cuvier is converted into the oblique vein of the left atrium.

From the postcardinal veins are derived the hypogastric and common iliac veins, the inferior end of the inferior vena cava, and the terminal part of the vena azygos (Fig. 813).

The right subcardinal vein takes part in the formation of the inferior vena cava, and an anastomosis between the right and left subcardinal veins forms the major part of the left renal vein.

From the supracardinal veins are evolved part of the inferior vena cava, the greater part of the azygos vein, the hemiazygos vein, and the accessory hemiazygos vein.

The alterations, enlargements, and suppressions which occur during the transformation of the primitive into permanent veins must now be considered in detail.

The Vitelline and Umbilical Veins and their Association with the Formation of the Portal Vein, the Hepatic Capillary Plexus, the Hepatic Veins, and the Cardiac End of the Inferior Vena Cava.—In the early stages of development the vitelline veins, right and left, convey blood from the yolk-sac part of the entodermal vesicle first to the caudal ends of the corresponding primitive ventral aortæ, and next, after the caudal parts of the primitive ventral aortæ have fused to form the heart, to the sinus venosus of the primitive heart.

After the entodermal vesicle of the zygote is separated into the entodermal part of the alimentary canal of the embryo, the yolk sac, and the vitello-intestinal duct which connects the alimentary canal and the yolk sac together, each vitelline vein passes along the vitello-intestinal duct to the corresponding border of the cranial margin of the umbilical orifice where it enters the embryo, passing at once into a mass of mesoderm called the septum transversum; there it unites, for a time, with the cardiac end of the corresponding umbilical vein to form a common vitello-umbilical trunk, which terminates in the sinus venosus. At this period the sinus venosus is also situated in the septum transversum.

Subsequently, as the sinus venosus leaves the septum transversum and passes into the pericardial cavity, the common vitello-umbilical trunk is absorbed into it, and each vein thus requires its own separate termination into the sinus.

The septum transversum is a mass of mesoderm which intervenes between the pericardium and the cranial end of the ventral portion of the abdominal cavity along the line of the cranial border of the umbilical orifice. From it are derived the caudal (lower) wall of the pericardium, the ventral part of the central portion and the lateral parts of the diaphragm, the falciform ligament of the liver, the connective tissue and vascular parts of the liver, and the lesser omentum.

As the liver is developed from the mingling of the rami of a diverticulum from the ventral wall of the duodenum with the mesoderm of part of the septum transversum, the portions of the vitelline and umbilical veins which lie in the liver area of the septum transversum are expanded and, at the same time, broken up into a great number of anastomosing channels, which form for a period the main part of the liver substance and which constitute what is called **sinusoidal tissue.**

The sinusoidal tissue consists of relatively wide anastomosing blood-vessels whose walls are formed by endothelium surrounded by young connective tissue, and intervening between the channels of adjacent sinuses, spreading through the connective tissue, are ramifying strands of liver cells, which multiply and increase in size until the sinusoidal blood spaces are, for the main part, reduced to blood capillaries and the liver becomes a comparatively solid organ.

Whilst the formation of the sinusoidal spaces is taking place in the liver area the parts of the foregut are defined, and as the duodenal and stomach areas recede from the liver the lesser omentum is evolved from the caudal part of the septum transversum. Then, as the duodenum is deliminated the vitelline veins pass along its sides, on their way to the liver, and become connected around it by three transverse anastomoses, two of which lie ventral and one dorsal to the duodenum. Cranialwards of these anastomoses each vitelline vein is broken up into a caudal part, the **vena advehens,** which enters the liver substance, an area of sinusoidal channels, and a cranial part, the **vena revehens,** which passes from the liver to the heart. After a time the left vena revehens loses its direct connexion with the heart, moves across towards the right, and opens into the cranial end of the right vena revehens. When this change has occurred all the blood passing to the liver by the vitelline veins reaches the heart by the cranial extremity of the right vena revehens, which now becomes the upper end of the inferior vena cava. This also receives the ductus venosus—a new channel, which is evolved from the sinusoidal spaces, and which carries the major part of the blood from the left lateral umbilical vein to the upper end of the inferior vena cava.

In the meantime degeneration takes place in the ventral and caudal parts of the vitelline veins and the loops formed by the three transverse anastomoses between them. The ventral parts of the

veins disappear with the degeneration of the yolk sac, and the right half of the caudalward and the left part of the more cranialward situated loops also disappear. Simultaneously the superior mesenteric vein, which has been evolved in association with the formation of the intestine from the mid-gut, opens into the left vitelline vein, caudal to the dorsal transverse anastomosis, and, a little later, the splenic vein enters at the same point. The final result is the formation of the permanent **vena portæ**, which is formed from (1) the cephalic end of the left limb of the caudal loop between the vitelline veins; (2) the dorsal anastomosis between the vitelline veins; (3) the right limb of the cephalic loop formed by the vitelline veins. The right branch of the portal vein is the right vena advehens. The left branch of the portal vein is formed from the left vena advehens, and the more cranial of the two ventral anastomoses between the vitelline veins. It

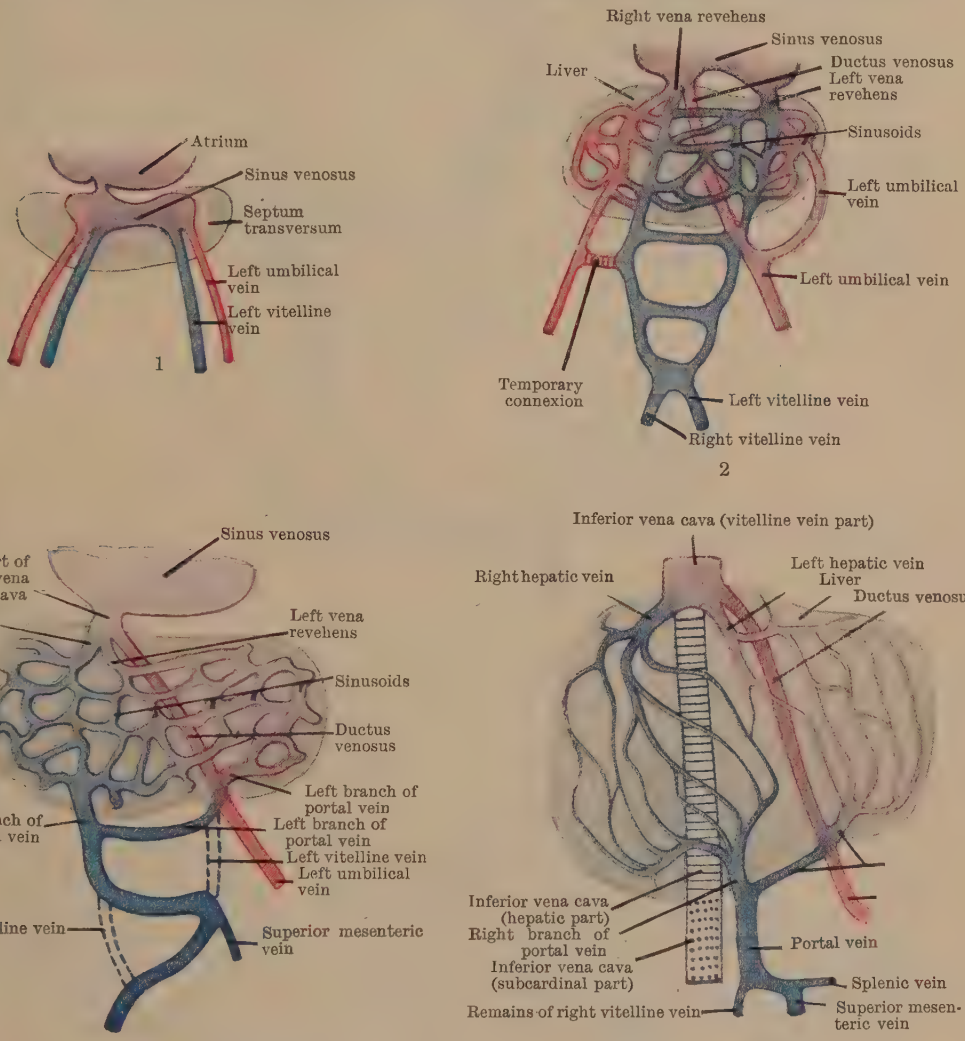

FIG. 807.—SCHEMATA, showing four stages of the development of the portal system and parts of the inferior vena cava.

is connected with the ligamentum teres of the liver, because the left lateral umbilical vein, which opened at one time into the left horn of the sinus venosus of the heart, and afterwards into the sinusoids of the liver, finally becomes connected with the left vena advehens, at the level of the cranialward ventral anastomosis between the two vitelline veins; and it is connected with the ductus venosus so that a channel may exist by which the blood from the placenta can pass to the right vena revehens without much admixture with the venous blood passing to the liver through the left branch of the portal vein and the left vena advehens. Therefore the ductus venosus is developed from the sinusoidal spaces of the liver when the left lateral umbilical vein is transferred to the left vitelline vein.

The venæ revehentes, which transfer the blood from the liver to the heart, are the cranial ends of the primitive vitelline veins. The left vena revehens, as already stated, eventually loses its connexion with the heart and ends in the right vena revehens, which receives the ductus venosus

also. The right vena revehens thus becomes the only channel by which blood is returned to the heart from the alimentary canal and from the placenta: that is, it becomes the upper or cranial end of the inferior vena cava. The intra-hepatic part of the stem of the right vena revehens becomes the right hepatic vein, and the left vena revehens becomes the left hepatic vein, which are the two vessels which pour, into the inferior vena cava, the blood which was carried from the alimentary canal to the liver by the portal vein and its branches.

The sinusoidal spaces, as already stated, become reduced to the blood capillaries of the liver, and the ductus venosus which, during fœtal life, conveyed the greater part of the placental blood to the inferior vena cava becomes reduced, after birth, to the *ligamentum venosum*, which connects the left branch of the portal vein with the upper end of the inferior vena cava.

As the cranial part of the right vitelline vein is transformed from the right vena revehens into the upper end of the inferior vena cava, an outgrowth passes caudally from it, along the dorsal aspect of the liver; this becomes connected, at its caudal end, with the right subcardinal vein, and it forms that part of the inferior vena cava which lies in the groove on the dorsal aspect of the right lobe of the liver.

The Umbilical Veins.—In the earliest stages of development there are three umbilical veins, the vena umbilicalis impar and the left and right lateral umbilical veins. The vena umbilicalis impar and the left lateral vein persist until birth, and a remnant of the latter is found, in the adult, as the ligamentum teres of the liver; the right lateral vein disappears entirely at an early stage of development.

The vena umbilicalis impar passes from the placenta to the caudal boundary of the umbilical orifice, where it terminates in the left and right lateral umbilical veins. Each of the latter

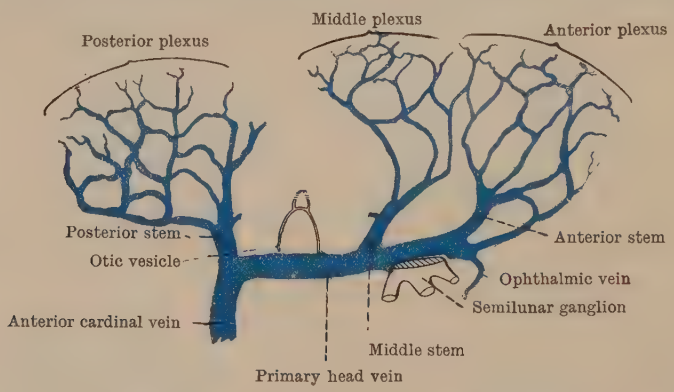

Fig. 808.—Diagram of the Primary Head Vein and its Tributaries. (After Streeter.)

unites, for a time, with the corresponding vitelline vein in the septum transversum; then it becomes directly connected with the corresponding cornu of the sinus venosus of the heart, and still later with sinusoidal spaces of the liver. The right lateral umbilical vein has also a temporary secondary connexion with the right vitelline vein, but at an early period it undergoes atrophy and all parts of it completely disappear.

The left lateral umbilical vein, which is connected first with the left vitelline vein, next with the heart, still later with the liver, and finally with the left vitelline again, at the point where the latter becomes the left vena advehens, persists until birth, and, after the disappearance of the right lateral umbilical vein, it conveys the blood from the placenta to the liver, where part of the placental blood passes into the left vena advehens and so through the left vena revehens to the inferior vena cava, and part passes into the ductus venosus, by which it reaches that portion of the cranial part of the right vena revehens which becomes the cranial or upper end of the permanent inferior vena cava.

After birth when the placental circulation ceases the left lateral umbilical vein becomes the ligamentum teres of the liver.

The Ductus Venosus.—The ductus venosus is developed as the left lateral umbilical vein loses its direct connexion with the liver and becomes united to the left vena advehens. It is formed from the sinusoidal spaces of the rudimentary liver and connects the commencement of the left vena advehens with the cranial part of the right vena revehens. It forms the more direct channel by which blood from the placenta is passed to the heart through that part of the right vena revehens which becomes the upper end of the inferior vena cava. After birth it is converted into the fibrous ligamentum venosum, which connects the left branch of the portal vein with the upper end of the inferior vena cava.

The Precardinal Veins.—The precardinal veins are the veins by which the blood is returned to the heart from the head and neck and, ultimately, from the superior extremities also, although the primitive veins of the superior extremities are, in the first place, tributaries of the postcardinal veins.

Each precardinal vein may be separated into two parts—the intra-cranial and the extra-cranial.

In the majority of vertebrates the portion of each precardinal vein which is situated in the

head region, and which afterwards becomes intra-cranial, lies to the medial side of the otic vesicle and the 5th, 7th, 8th, 9th, 10th, and 11th cerebral nerves.

At a later period that portion of the vein which lay medial to the otic vesicle and the 7th, 8th, 9th, 10th, and 11th cerebral nerves has disappeared and has been replaced by a new channel, which is placed lateral to the otic vesicle and the 7th, 8th, 9th, 10th, and 11th cerebral nerves.

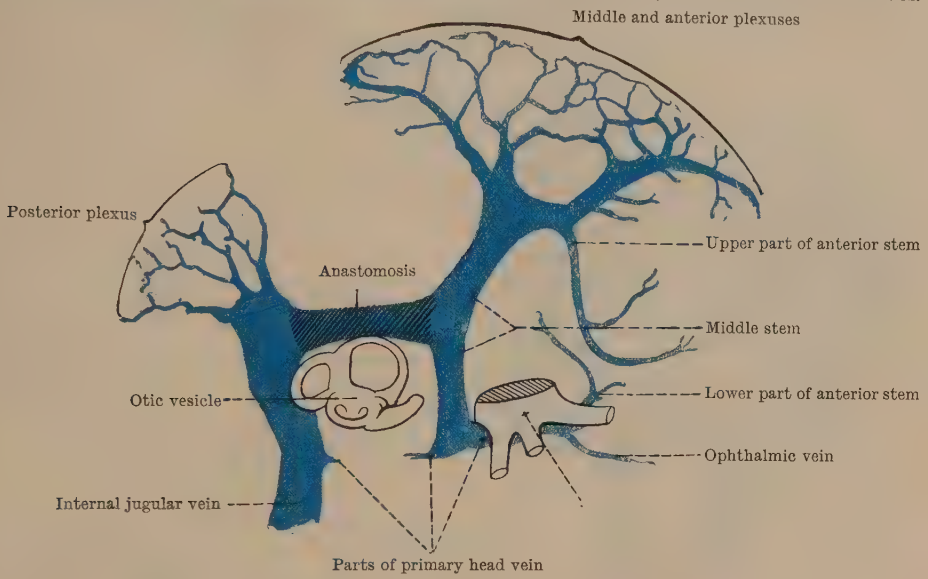

FIG. 809.—DIAGRAM OF THE HEAD VEINS OF A 21 MM. EMBRYO. (After Streeter.)

The new channel extends from the semilunar ganglion of the trigeminal nerve to the upper end of the extra-cranial part of the precardinal vein, that is, to the upper end of the internal jugular vein. This secondary vessel follows the course of the facial nerve and in part of its extent it is extra-cranial.

In the human embryo the stage in which the primitive stem vein lies to the medial side of the otic vesicle and the 7th, 8th, 9th, 10th, and 11th nerves does not seem to occur. At all events in a 3 mm. embryo in the Edinburgh University Collection, and in a 4 mm. embryo in the Collection of the Carnegie Institution of Washington (Streeter), the second stage, in which the posterior part of the cranial portion of the primitive vein lies lateral to the otic vesicle and

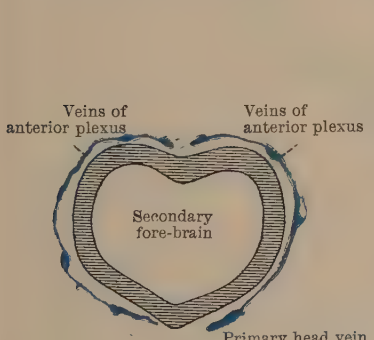

FIG. 810 A.—DIAGRAM OF A TRANSVERSE SECTION OF THE SECONDARY FORE-BRAIN AND THE VENOUS PLEXUSES.

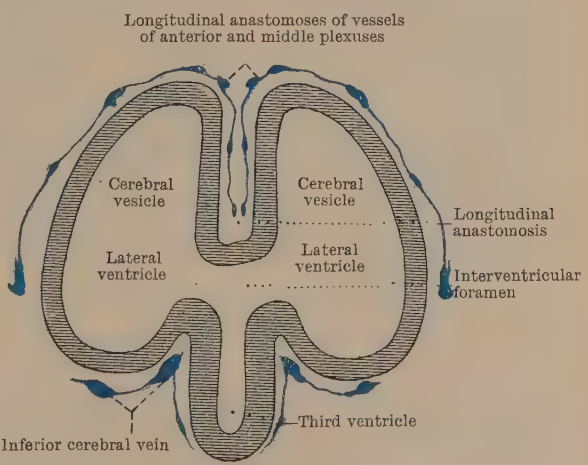

FIG. 810 B.—DIAGRAM OF A TRANSVERSE SECTION OF THE BRAIN SHOWING THE FOLDING OF THE UPPER PARTS OF THE PLEXUSES BETWEEN THE CEREBRAL HEMISPHERES.

the 7th, 8th, 9th, 10th, and 11th cerebral nerves, is already present and there is no indication of a vein medial to the otic vesicle.

In the human embryo, therefore, the primitive venous stem in the head region, on each side, consists of an anterior portion medial to the semilunar ganglion of the trigeminal nerve, and a posterior portion lateral to the otic vesicle and the 7th, 8th, 9th, 10th, and 11th cerebral nerves; for this stem Streeter has suggested the convenient term "primary head vein" (Fig. 808).

The most anterior tributaries of the primary head vein are derived from the region of the optic vesicle and remnants of them become converted into the ophthalmic vein, but in addition to the anterior tributaries there are numerous dorsal or upper tributaries which become arranged in three main groups: an anterior plexus associated with the regions of the fore-brain and the mid-brain; a middle plexus associated with the cerebellar region of the hind-brain; and a posterior plexus associated with the region of the medulla oblongata (Fig. 809).

The vessels of each plexus tend to run together as they approach the stem of the primary head vein and so three stems are formed, the anterior, middle, and posterior; they were described by Mall in 1904 (Fig. 809). This condition persists until the embryo attains a length of about 18 mm. when an anastomosis forms, above the otic vesicle, between the stems from the middle and posterior plexuses (Fig. 812), and at the same time that part of the primary head vein which lay lateral to the otic vesicle and the 7th, 8th, 9th, 10th, and 11th cerebral nerves disappears.

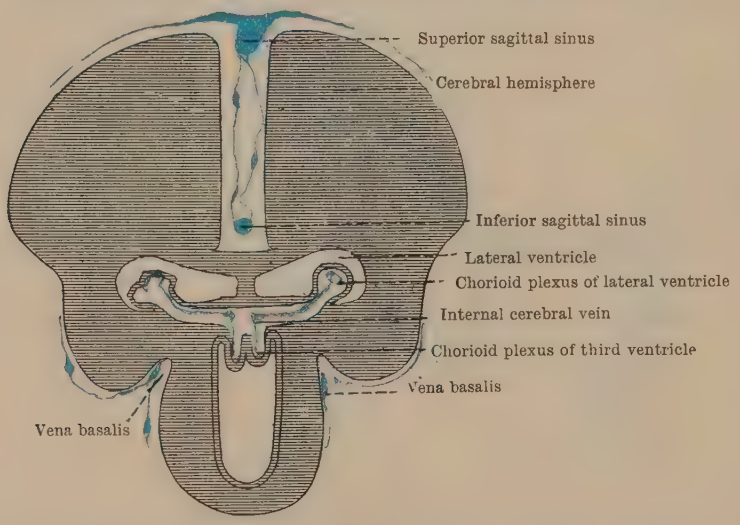

FIG. 811 A.—DIAGRAM OF A TRANSVERSE SECTION OF THE BRAIN SHOWING SAGITTAL SINUSES STILL CONNECTED BY REMAINS OF THE PLEXUSES.

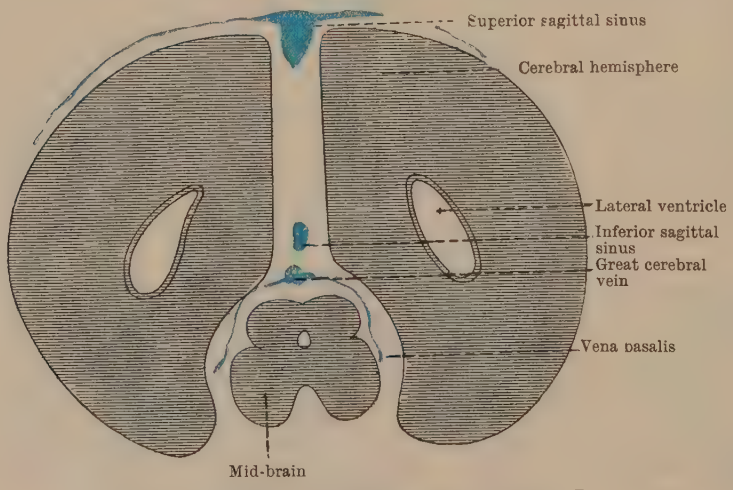

FIG. 811 B.—DIAGRAM OF A TRANSVERSE SECTION OF THE BRAIN AFTER COMPLETION OF THE SAGITTAL SINUSES.

By the time the embryo has become 21 mm. long the anastomosis mentioned has become very important, and a separation has occurred between the lower and the upper portions of the anterior stem tributary; therefore, at that period, the blood from the eye region flows backwards to the anterior end of the primary head vein, then upwards along what was the lower part of the middle stem tributary, next backwards along the anastomosis above the otic region to the posterior stem tributary, down which it passes to the upper part of the extra-cranial portion of the precardinal vein which has now become the internal jugular vein (Fig. 812). At this time the blood from the anterior and middle plexuses reaches the supra-otic anastomosis through the upper or dorsal part of the middle stem tributary (Fig. 812).

In the meantime the subdural and subarachnoid spaces have been forming, and with the formation of those spaces the main parts of the venous plexuses are carried away from the brain, with the membrane which will be transformed into the dura mater, but in part the plexuses still retain their connexions with the pia mater on the brain surface, and they afterwards establish new connexions with the veins which appear on the surfaces of the developing cerebral hemispheres. In the meantime on each side the upper or dorsal tributaries of the anterior and the middle plexus anastomose together (Fig. 811).

When the cerebral hemispheres increase in size the dura-matral tissue is compressed between them, and between the cerebral hemispheres above and the mid- and hind-brain below, in the form of folds (Figs. 811 A and B). As the folds are formed the conjoined anterior and middle

plexuses of one side are carried into relation with those of the opposite side in the median plane of the head; there the vessels of opposite sides unite together and are finally resolved into the superior and inferior sagittal sinuses and the straight sinus (Figs. 811 A and B), and at the same time some of the smaller vessels of the plexuses which retain their connexion with the pia mater are transformed into the internal cerebral veins and the great cerebral vein; and from some of the lower or ventral tributaries, on each side, is produced the inferior cerebral vein of the embryo which probably becomes the vena basalis of the adult (Figs. 811 B, 812).

Whilst the changes last mentioned are taking place the growth of the hemispheres forces the upper part of the middle stem tributary on each side backwards and then downwards until it becomes the horizontal part of the transverse sinus (Fig. 812), whilst the anastomosis above the otic region and the posterior stem tributary are converted into the sigmoid portion of the transverse sinus (Fig. 812).

By the time this stage is attained the anterior portion of the primary head vein which lies to the medial side of the semilunar ganglion has become the cavernous sinus, and the lower or ventral part of the middle stem tributary has been converted into the superior petrosal sinus (Fig. 812).

The inferior petrosal sinus appears to be an independently formed anastomosis which connects the posterior end of the cavernous sinus with the upper end of the internal jugular vein across the medial side of the otic region (Fig. 812).

The extra-cranial parts of the precardinal veins become connected together, in the upper or

FIG. 812.—DIAGRAM OF THE VENOUS SINUSES. (Only one transverse sinus is shown.)

cephalic part of the thoracic region, by a transverse anastomosis which becomes the greater part of the left innominate vein. A short distance cranialwards to this transverse connexion, the primitive vein of each upper limb ultimately opens into the corresponding precardinal vein. The portion of the precardinal vein of the right side, which lies between the entrance of the limb vein and the transverse anastomosis, becomes the **right innominate vein** (Fig. 813), and the corresponding part on the left side forms the commencement of the **left innominate vein**.

The part of the extra-cranial portion of each precardinal vein which lies cephalwards of the entrance of the limb vein forms the **internal jugular vein**; and the part of the right precardinal vein which lies caudalwards of the transverse anastomosis becomes the upper or cephalic part of the **superior vena cava**, whilst the corresponding portion of the left vein is converted into the upper or more cranial part of the **left superior intercostal vein** (Fig. 813).

The **external jugular vein** is a new formation which receives for a time the cephalic vein of the upper extremity; but the cephalic vein, which is a secondary vessel, is eventually transposed to the axillary vein, which is a part of the primitive upper limb vein.

The Postcardinal Veins, the Subcardinal Veins, the Supracardinal Veins, and the Inferior Vena Cava.—The Postcardinal Veins which appear shortly after the precardinals lie dorsal to the mesonephri and extend from the pelvic region to the thorax, where they join the precardinals to form the ducts of Cuvier. They return blood from the inferior extremities, the pelvic region, the mesonephri, and the body wall of the abdominal region and the greater part of the thoracic region. In the pelvic region they receive the external iliac and hypogastric veins, and they communicate with one another by transverse anastomoses.

In the adult only portions of them are found in the thoracic and abdominal regions. In the thorax they are represented by the most cranial part of the azygos vein, and the more caudal

part of the left superior intercostal vein, and in the abdomen by the hypogastric veins, the common iliac veins, and the commencement of the inferior vena cava, a considerable part of the left common iliac vein being derived from a transverse anastomosis.

The Subcardinal Veins appear in the abdominal region ventro-medial to the mesonephri. Each commences caudally and ends cranialwards in the corresponding post-cardinal with which it has also numerous anastomoses medial to the mesonephros, and the two subcardinal veins anastomose across the median plane with each other.

The subcardinal veins receive blood from the mesonephri, the genital glands, and the suprarenal glands.

After the subcardinals are established, a downgrowth from the cardiac end of the right vitelline vein occurs.

It is produced chiefly by a modification of the sinusoidal tissue of the dorsal part of the liver, to the right of the median plane, and it becomes the hepatic part of the inferior vena cava of the adult. Its caudal end establishes a communication with the right subcardinal vein caudal to the point where the latter receives the veins from the suprarenal gland, and at the same time a transverse anastomosis between the subcardinal veins which lies immediately caudal to the origin of the superior mesenteric artery becomes enlarged.

The result of these alterations is a great change in the venous circulation, for the blood, which previously passed from the inferior extremities and the abdominal region to the heart by way of the postcardinal veins, is short-circuited to the caudal end of the right atrium, and the thoracic parts of the postcardinal veins become relatively less important and smaller.

The enlarged anastomosis between the subcardinal veins ultimately forms part of the left renal vein, though renal veins at the stage under discussion are not existent, but at this period three parts of the permanent inferior vena cava are established: the *supra-hepatic part*, derived from the cardiac end of the right vitelline vein; the *post-hepatic part*, evolved from the sinusoidal tissue of the liver; and the *prerenal infra-hepatic part*, which is an enlarged portion of the right subcardinal vein.

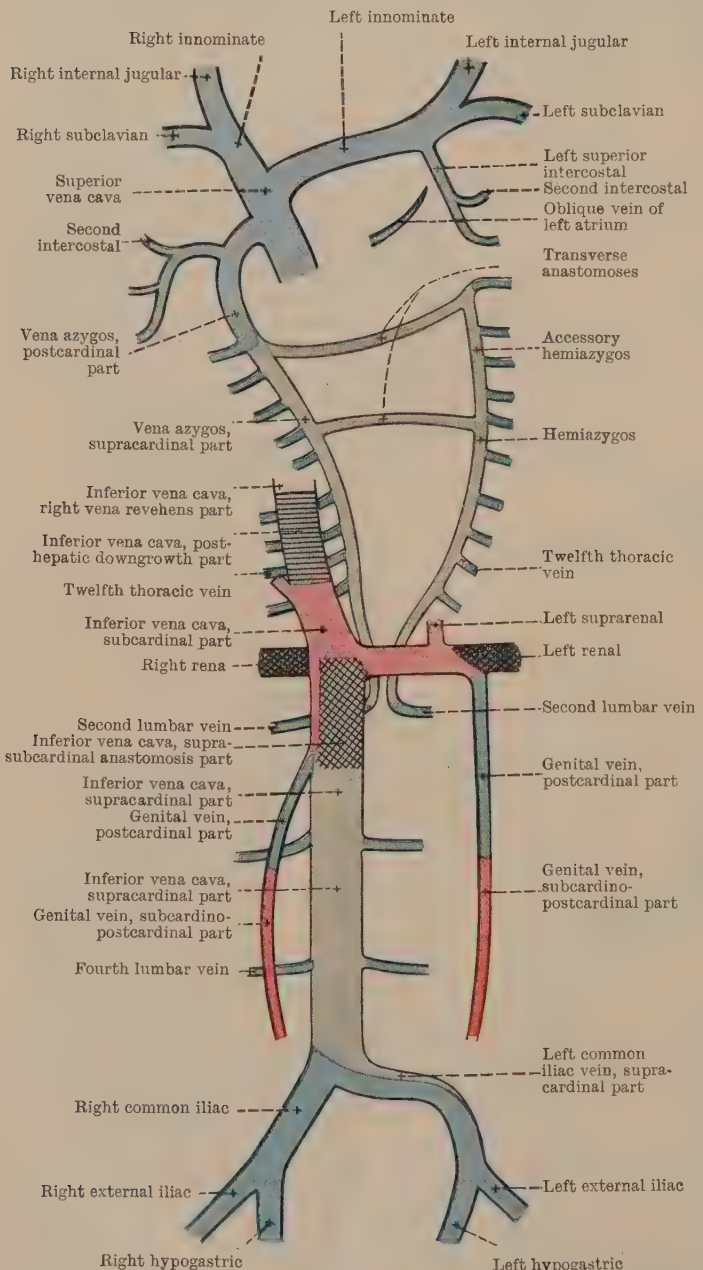

FIG. 813.—DIAGRAM OF THE COMPONENT PARTS OF THE MAIN VENOUS TRUNKS, SHOWING THEIR DERIVATION. (After Huntington and M'Clure.)

Blue = Precardinal and postcardinal system.
Red = Subcardinal system.
Grey = Supra-cardinal system.
Cross-patching = Supra-subcardinal anastomosis and renal veins.

After the post-hepatic portion of the inferior vena cava has joined the right subcardinal vein, the part of the latter which lies cranial to the union becomes the right suprarenal vein, and the part of the left subcardinal which lies cranial to the enlarged intersubcardinal anastomosis becomes the left suprarenal vein.

About the same time the part of each subcardinal vein which lies caudal to the enlarged intersubcardinal anastomosis disappears, and the blood from the corresponding genital gland now passes to the corresponding postcardinal vein through what was a subcardino-postcardinal anastomosis.

The Supracardinal Veins.—There now appears in the thoracic and abdominal regions another pair of longitudinal venous channels, the supracardinal veins, which lie dorso-lateral to the descending aorta and which anastomose with each other through transverse channels. They communicate at their cranial ends, in the thoracic region, and at their caudal ends, in the abdominal region, with the corresponding postcardinals, and at the level of the enlarged intersubcardinal anastomosis with the enlarged postcardinal subcardinal anastomoses by which blood is conveyed from the right postcardinal vein to the inferior vena caval part of the right subcardinal vein, and from the left postcardinal vein to the enlarged intersubcardinal anastomosis.

By this time the kidneys have attained their abdominal positions, and the renal veins open into the postcardinal-subcardinal anastomosing channels, formed around the aorta at the level of the cranial ends of the kidneys.

Thus a venous ring is formed around the aorta at the level of the kidneys, and it plays a part in the formation of the permanent veins. A detailed statement of the changes by which the postcardinals, the subcardinals, the supracardinals, and the venous interrenal circumaortic venous ring become transformed into permanent venous stems would occupy more space than is available in a Text-Book of Anatomy, but the student who is interested in the process and in the explanation of the anomalies which may result from modifications of them can consult a paper in which they are described and upon which the account here given is based;[1] here only a summary of the ordinary results can be given.

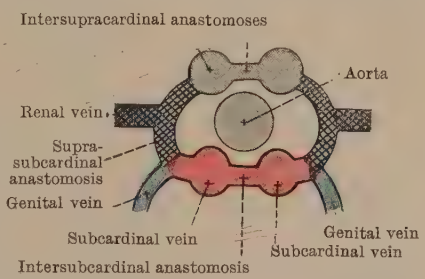

FIG. 814.—DIAGRAM OF THE CIRCUMAORTIC VENOUS COLLAR. (After Huntington and M'Clure.)

(1) The caudal parts of the postcardinals remain and are represented by the hypogastric veins, the common iliac veins; the right also enters into the formation of the caudal end of the inferior vena cava, and the interpostcardinal anastomosis at the level of the fifth lumbar vertebra takes part in the formation of the left common iliac vein.

(2) It has already been noted that after the post-hepatic part of the inferior vena cava joins the right subcardinal vein, the postcardinals cranial to that level almost entirely disappear, remnants of them persisting in the adult as the terminal part of the vena azygos and the caudal part of the right superior intercostal vein.

In the abdominal region between the caudal end of the inferior vena cava and the entrances of the genital veins into the postcardinals, the postcardinals disappear, but a small part of each postcardinal cranial to the entrance of the genital vein persists, and forms with the genital vein the testicular or ovarian vein in the adult.

(3) The postcardinal-subcardinal anastomosis which lies at the level of the main intersubcardinal anastomosis persists. On the right side it takes part in the formation of the inferior vena cava, and on the left side it forms part of the left renal vein.

(4) The persistent parts of the right subcardinal are the part of the inferior vena cava from the renal vein to the liver and the right suprarenal vein, whilst the persistent part of the left subcardinal is the left suprarenal vein.

(5) The intersubcardinal anastomosis immediately caudal to the superior mesenteric artery becomes part of the left renal vein; the other intersubcardinal anastomoses disappear.

(6) The right supracardinal-subcardinal anastomosis takes part in the formation of the inferior vena cava; the left disappears.

(7) Parts of the supracardinals persist both in the thoracic and abdominal regions.

In the thoracic and the cranial part of the abdominal region, on the right side the supracardinal becomes the azygos vein, and on the left side the hemiazygos and the accessory hemiazygos, whilst two of the thoracic intersupracardinal anastomoses persist as those sections of the hemiazygos veins which cross the front of the vertebral column on their way to join the azygos vein.

In the abdominal region the supracardinals fuse together and form that part of the vena cava inferior which lies caudal to the entrance of the right spermatic or ovarian vein, fusing at the level of the inferior fifth lumbar vertebræ with the part of the right postcardinal vein which enters into the formation of the inferior vena cava and the part of the interpostcardinal anastomosis which takes part in the formation of the left common iliac vein.

(8) The right renal vein is the efferent vein passing from the kidney to the right suprasubcardinal anastomosis.

[1] The development of the veins in the domestic cat, with special reference to the share taken by the supracardinal veins in the development of the postcava and the azygos vessels, and to the interpretation of the variant conditions, etc., *Anat. Rec.* vol. xx. No. 1, Dec. 1920.

The left renal vein is a composite structure in which the efferent vessels of the kidney, a postsubcardinal anastomosis and the intersubcardinal anastomosis immediately caudal to the superior mesenteric artery take part.

(9) The testicular or ovarian vein is a vein from the genital gland plus part of a postcardinal vein.

(10) **The inferior vena cava** has a multiple origin. Its component parts from its cardiac to its caudal end are (1) the right vitelline vein; (2) the posthepatic section derived from the sinusoids of the liver; (3) the right subcardinal section from the liver to the renal veins; (4) the section extending from the renal veins to the right testicular or ovarian vein which is formed by the fusion of a postcardinal anastomosis united with the right supra-subcardinal anastomosis; (5) the section extending from the entrance of the right testicular or ovarian vein to the fifth lumbar vertebra formed from the fused supracardinal veins; (6) the caudal end formed partly by the right postcardinal.

THE DEVELOPMENT OF THE LYMPH VASCULAR SYSTEM.

Very little is known regarding the origin of the vessels of the lymph vascular system in man, but during recent years numerous investigations have been made with the object of discovering the various phases of the development of the lymph vascular system in other mammals; some of the main points are, however, still subjects of dispute.

It is generally admitted that the terminal parts of the great lymph vessels, that is, the terminal part of the thoracic duct and the right lymphatic duct, are derived from venous channels, which, for a time, lose their connexion with the larger veins and become modified into terminal lymph sacs which obtained a secondary union with the great veins at the root of the neck; but regarding the origin of the thoracic duct and the cisterna chyli and the peripheral lymph vessels there is, as yet, no agreement. According to Florence Sabin, and those who agree with her, the peripheral lymph vessels are outgrowths from a series of lymph sacs, themselves of venous origin, and from veins. Of the lymph sacs the two cervical, a retro-peritoneal, a cisterna chyli, and two posterior sacs, lying along the inferior gluteal veins, are recognised in human embryos of about 24 mm. length. The origin of these sacs, in the human embryos, has not been proved, but it appears probable that the cervical sacs are derived as in other mammals from venous capillary vessels. There is no agreement, however, concerning the origin of the other sacs, for whilst, on the one hand, Florence Sabin appears to believe that they have an origin like that of the jugular lymph sacs and that the thoracic duct is developed in the same manner, Huntington, on the other hand, believes that, with the exception of the jugular or cervical lymph sacs, all the other lymph vessels, including the thoracic duct, are developed neither as outgrowths from lymph sacs nor by the modification of venous capillaries, but by the formation of endothelial lined spaces in the mesodermal tissues. The spaces are at first entirely closed but afterwards attain union with one another and with the terminal lymph vessels.

According to the view upheld by Florence Sabin and her supporters, the lymph vessels are outgrowths from the venous system, and are therefore lined with endothelium which is genetically the same as that in the veins. According to Huntington this is not the case; for his observations lead him to believe that the endothelium of the lymph vessels is formed, *in situ*, from the mesodermal cells, and it has therefore no direct genetic connexion with the endothelium of the veins, which is derived from the original hæmohistoblastic tissue. The evidence brought forward by the supporters of the opposite views is interesting and instructive upon many points, but the question must still be regarded as an open one.

The Development of Lymph Glands.—Lymph glands are developed from plexuses of lymph vessels. The transformation is brought about by the aggregation of numerous lymphocytes in the connective tissue strands of the plexuses and the transformation of the lumina of the vessels into the peripheral and central portions of the lymph sinus. The stroma, the capsule, and the proper substance of a lymph gland are therefore formed from the fibro-cellular reticulum of the lymphatic plexus, and the cavity of the lymph sinus is formed from the lumina of lymph capillaries. The rudimentary lymph glands possess blood vascular as well as lymphatic capillary networks, and if the blood vascular network preponderates over the lymph vascula the developing gland has a reddish appearance and is known as a hæmal gland. Such glands are found in man as well as in other mammals, and it would appear from the observations of H. S. Harrison and Swale Vincent that hæmal glands are merely rudimentary forms of true lymph glands (*Jour. of Anat. and Phys.* vol. 31).

THE FŒTAL CIRCULATION.

During the period of fœtal life food and oxygen are transmitted from the maternal blood to the fœtal blood in the placenta, where the maternal blood flows in near relation to the walls of the fœtal blood-vessels; and the effete products produced by the action of the cells of the fœtal tissues, including carbonic acid, are passed from the fœtal to the maternal blood in the same place.

Lungs are present in the fœtus, but they do not function as respiratory organs until birth; therefore, although the blood-vessels necessary for pulmonary respiration are present, the only blood that flows through them is that which is necessary for their nutrition and growth.

It is because there is no necessity for a pulmonary circulation before birth, and because there

is necessity that the blood which will pass through the lungs after birth shall be transmitted elsewhere before birth, that the foramen ovale in the interatrial septum and the ductus venosus which connects the left branch of the pulmonary artery with the aorta remain patent until birth.

Moreover, as it is necessary that food and oxygen shall be obtained from the mother's blood in the placenta, and that effete products of the fœtus shall be transferred from the fœtal to the

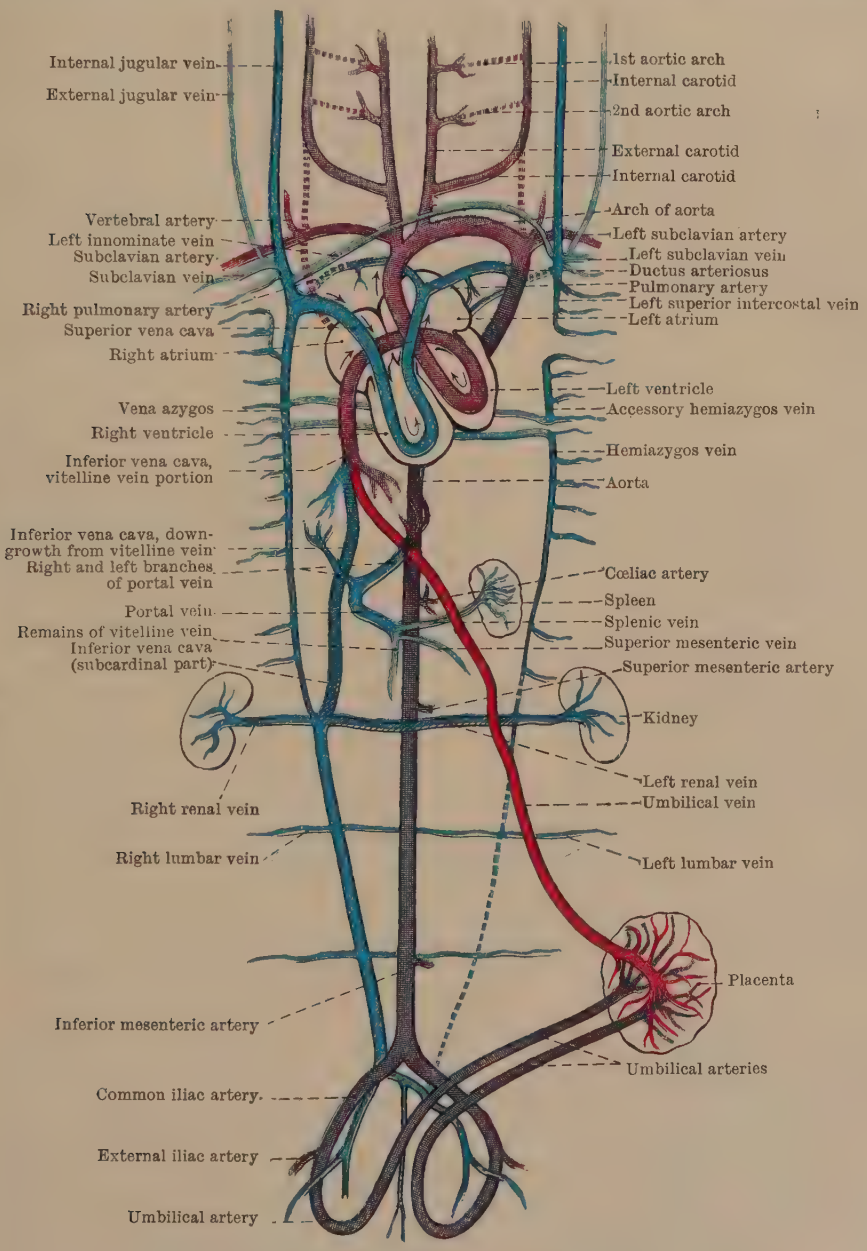

FIG. 815.—DIAGRAM OF THE COURSE OF THE FŒTAL CIRCULATION.

maternal blood also in the placenta, the umbilical branches of the hypogastric arteries, which carry fœtal blood to the placenta, and the left umbilical vein, which returns it from the placenta to the fœtus, persist until birth. As a consequence, the course of the circulation before and after birth is different.

After birth blood passes from the body generally into the right atrium, which passes it on into the right ventricle, whence it is forced, through the lungs, to the left atrium, and thence to the left ventricle, by which it is propelled through the systemic vessels back to the right atrium.

In the fœtus, on the other hand, food- and oxygen-laden blood passes from the placenta to the inferior vena cava, partly directly by the left umbilical vein and the ductus venosus, and partly

indirectly by the left umbilical vein to the liver and thence to the inferior vena cava. In the inferior vena cava it mixes with venous blood returning from the inferior extremities and the lower parts of the body walls, the renal organs, and the genital glands, and so it becomes mixed blood. The mixed stream passes from the inferior vena cava through the right atrium and the foramen ovale to the left atrium, thence to the left ventricle, which forces it through the aorta into all parts of the body and limbs.

The blood from the head and neck, the superior extremities, and the upper parts of the body wall returns by the superior vena cava to the right atrium, through which it passes into the right ventricle, which ejects it, through the pulmonary artery and the ductus arteriosus, into the aorta, beyond the origin of the left subclavian artery, where it mixes with the blood from the left ventricle; a minute quantity only enters the lungs.

In the fœtus, therefore, pure oxygenated blood is only found from the umbilicus to the inferior vena cava, in the left umbilical vein and the ductus venosus. In the upper part of the inferior vena cava the blood becomes a mixture by blending with the blood returning from the lower limbs and the lower part of the body. The mixed stream, which may be termed the less venous stream, directed by the valve of the inferior vena cava, passes through the right into the left atrium, thence through the left ventricle into the aorta. From the aorta some of it passes into the head and neck and the superior extremities, the remainder passes into the descending aorta and becomes the more venous stream because it is joined, beyond the origin of the left subclavian artery, by the venous stream from the head and neck and the superior extremities, which has passed from the superior vena cava through the right atrium, the right ventricle, the pulmonary artery, and the ductus arteriosus.

From the descending aorta part of the more venous stream passes to the walls of the thorax, to the abdomen and its contents, and to the inferior extremities; the remainder passes through the hypogastric arteries and their umbilical branches to the placenta.

It is obvious, from what has been stated, that the blood in the descending aorta, which is supplied to the lower part of the trunk and the lower limbs, contains relatively less oxygen and food material and more effete matters than that in the ascending aorta and the arch of the aorta, which is transmitted to the head and neck and the superior extremities, and, as a consequence, the growth of the head, neck, and superior extremities is more rapid than that of the inferior extremities. The liver, on the other hand, which receives purer blood than any other part of the fœtus, grows with extreme rapidity and attains a relatively very large size.

MORPHOLOGY OF THE VASCULAR SYSTEM.

In conformity with the general plan of the vertebrate body, the vascular system is essentially segmental in character. The segmental character of the intercostal and lumbar vessels is obvious; that of the vessels of the head, neck, and pelvis is less obvious but is still distinguishable in the vessels of the head.

The intersegmental arteries and veins form a series of bilaterally symmetrical vessels, each of which is united to the vessels of adjacent segments by segmental channels, which anastomose with one another, through the portions of the intersegmental vessels which they connect together, and thus form longitudinal trunks. The longitudinal trunks are mainly, though not exclusively, segmental. From them the main stem vessels of the individual are formed, and from or to these latter the intersegmental vessels appear to proceed as branches or tributaries.

In the course of development the longitudinal trunks become the most important trunks in the individual, and they are formed before the branches and tributaries make their appearance.

THE SEGMENTAL ARTERIES AND THEIR ANASTOMOSES.

The main longitudinal trunks are the primitive aortæ. The descending aorta is formed, in the greater part of its extent, by the fusion of the dorsal parts of the primitive aortæ, and from it the intersegmental, lateral, and ventral arteries arise in pairs.

In a typical portion of the body of the embryo there are three arteries on each side. One arises from the dorsal surface of the primitive dorsal aorta, *i.e.* from the dorsal longitudinal trunk, and runs laterally and ventrally in the tissues developed from the somatic mesoderm; it is distributed to the body wall, including the vertebral column and its contents, and is termed a **somatic intersegmental artery.** A second vessel arises from the side of the primitive dorsal aorta; it is distributed to the structures developed from the intermediate cell mass, viz., the suprarenal gland, the kidney, and the ovary or the testis, and it is accordingly termed a **lateral** or an **intermediate visceral artery.** The third artery, which is known as the **splanchnic artery**, springs from the ventral surface of the aorta. It runs in the tissues developed from the splanchnic mesoderm, and supplies the wall of the alimentary canal.

The **somatic intersegmental arteries** form, in the early embryo, a regular series of paired vessels throughout the cervical, thoracic, lumbar, and sacral regions. It is, however, only in the thoracic and lumbar regions that their original characters are retained. The paired vessels pass dorsally, by the sides of the vertebræ, and divide into dorsal and ventral branches which accompany the corresponding anterior and posterior divisions of the spinal nerves.

The **ventral branches** run ventro-laterally, between the ribs, in the thoracic region, and in corresponding positions in the lumbar region, and together with the stems they form the main parts or trunks of the vessels in the thoracic and lumbar regions. They are connected together,

near their commencements, by a series of pre-costal anastomoses which pass in front of the necks of the ribs, and they are also connected together, near their terminations, by ventral anastomosing channels which run, in the thoracic region, behind the costal cartilages, and in the lumbar region behind or in the substance of the rectus abdominis muscle. Each ventral branch gives off a lateral offset which is distributed like the lateral cutaneous branch of a spinal nerve, and the ventral branch together with the stem of the intersegmental artery forms the trunk of an intercostal or lumbar artery in the adult.

The **dorsal branches**, which are present before the ventral branches, run dorsally between the transverse processes of the vertebræ, and form the posterior branches of the intercostal arteries and the dorsal branches of the lumbar arteries of the adult; they are connected, behind the necks of the ribs, by post-costal anastomoses, and again, behind the transverse processes of the vertebræ, by post-transverse anastomosing channels. Moreover, each dorsal branch, as it passes by the corresponding intervertebral foramen, gives off a spinal offset which enters the spinal canal, along the corresponding nerve-root, and divides into a dorsal, a ventral, and a neural branch. The dorsal branches of these spinal arteries are connected together along the ventral surfaces of the laminæ by pre-laminar anastomoses, and the ventral branches are united on the dorsal surfaces of the vertebral bodies (or centra) with their fellows above and below by post-central anastomoses; they are also united with their fellows of the opposite side by transverse communicating channels. The neural branches of the spinal arteries divide similarly into dorsal and ventral branches; the dorsal branches of each side are connected together by post-neural anastomoses, which form the posterior spinal arteries; and the ventral branches unite, in the median line, both with their fellows above and below and with those of the opposite side, forming a single longitudinal pre-neural trunk, the anterior spinal artery.

In the thoracic and lumbar regions of the body the somatic intersegmental arteries persist, and form the intercostal and lumbar arteries. These vessels spring from the dorsal aspect of the descending aorta, usually in pairs. The corresponding vessels of opposite sides, however, occasionally fuse together at their origins, simultaneously with the fusion of the dorsal longitudinal trunks to form the descending aorta, and then the arteries of opposite sides arise by common stems.

The pre-costal anastomoses between the ventral branches of the somatic intersegmental arteries are only represented in the thoracic region by the superior intercostal arteries; in the lumbar region they disappear entirely. The anastomoses between the anterior ends of the ventral branches of the somatic intersegmental arteries persist as the internal mammary and superior and inferior epigastric arteries.

The lateral offsets of the ventral branches are represented by the cutaneous arteries which accompany the lateral cutaneous branches of the spinal nerves, and the lateral branch of the seventh somatic intersegmental artery forms the greater part of the arterial stem of the upper limb.

The post-costal and post-transverse anastomoses usually disappear in the thoracic and lumbar regions, but the post-costal anastomoses occasionally persist in the upper thoracic region, and take part in the formation of the vertebral artery, which in such cases arises from the first or

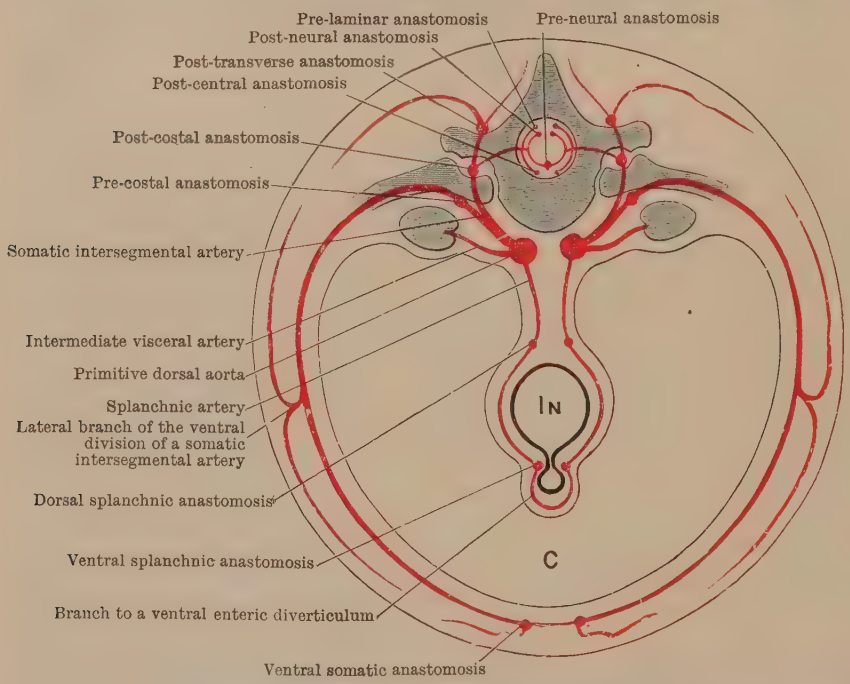

FIG. 818.—DIAGRAM SHOWING THE ARRANGEMENT AND COMMUNICATIONS OF THE SEGMENTAL AND INTERSEGMENTAL ARTERIES AT AN EARLY STAGE OF DEVELOPMENT.

C, Cœlom; IN, Intestine.

second intercostal artery. In some carnivora the post-costal longitudinal vessels persist in the upper thoracic region, and form, on each side, a trunk which is connected with the first aortic intercostal, and which supplies the first five intercostal spaces.

The pre-laminar, the post-central, and the pre- and post-neural anastomoses persist, the latter two aiding in the formation of the thoracic and lumbar portions of the anterior and posterior spinal arteries respectively.

It is in the cervical region, however, that the most interesting changes occur. The first six pairs of somatic intersegmental arteries lose their connexions with the dorsal roots of the aortic arches, *i.e.*, in other words, with the longitudinal anastomosing channels in that region. The seventh pair, however, persist in their entirety; and from them are formed, on the right side, a portion of the subclavian trunk, and on the left side the whole of the subclavian stem from its commencement up to the origin of the vertebral artery. On each side the ventral branch of the seventh intersegmental artery forms that portion of the subclavian artery which lies between the origins of the vertebral and internal mammary arteries, and also the trunk of the internal mammary artery as far as the upper border of the first costal cartilage. The remainder of the internal mammary artery represents the ventral longitudinal anastomoses between the ventral branches of the seventh and the following somatic intersegmental arteries. The continuation of the subclavian artery, beyond the inner margin of the first rib, is the persistent and enlarged lateral offset of the ventral branch of the seventh somatic intersegmental artery, which is continued into the upper limb, caudal or postaxial to the shoulder girdle. The thyreo-cervical trunk and the superior intercostal artery, both branches of the subclavian artery,

are persistent pre-costal anastomoses, and the ascending cervical artery belongs to the same series of vessels. The vertebral artery, which appears as a branch of the subclavian in the adult, is, morphologically, somewhat complex. The first part represents the dorsal branch of the seventh somatic intersegmental artery; the second part, that passing through the cervical transverse processes, consists of the persistent post-costal anastomoses between the dorsal branches of the first seven intersegmental arteries; a third part, that lying on the arch of the atlas, is the spinal branch of the first somatic intersegmental artery and its neural continuation; whilst finally the upper part of the vertebral artery, the part in the cranial cavity, appears to represent a prolongation of the pre-neural anastomoses, which still farther upwards are probably represented by the basilar artery. As already stated, the post-costal anastomoses below the seventh intersegmental artery occasionally persist, and in such cases the vertebral may lose its connexion with the subclavian, and spring from one or other of the posterior branches of the upper intercostal arteries.

The profunda cervicis artery is to be regarded as a remnant of the post-transverse longitudinal anastomoses.

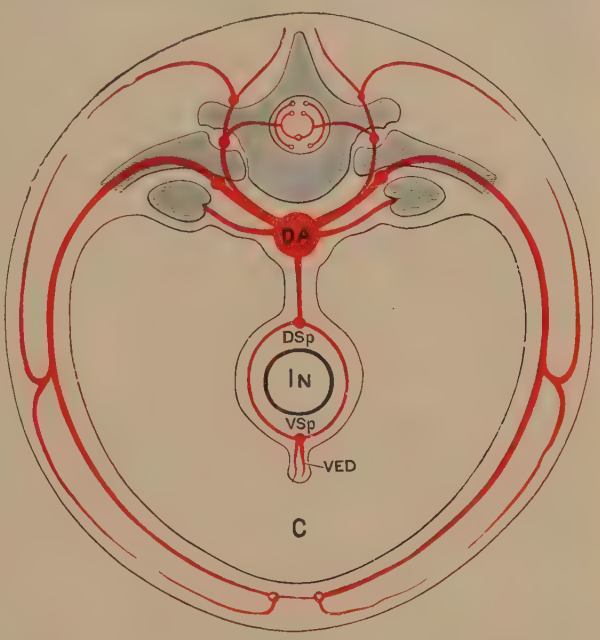

FIG. 819.—DIAGRAM OF THE SEGMENTAL AND INTERSEGMENTAL ARTERIES AT A LATER PERIOD OF DEVELOPMENT THAN IN FIG. 818.

C, Cœlom; D.A, Dorsal aorta; D.Sp, Dorsal splanchnic anastomosis; IN, Intestine; V.E.D, Branch to ventral enteric diverticulum; V.Sp, Ventral splanchnic anastomosis.

The origin of the seventh somatic intersegmental artery from the dorsal longitudinal trunk is, at first, some distance caudal to the sixth aortic arch, but, simultaneously with the elongation of the neck and the retraction of the heart into the thoracic region, it is shifted cranialwards until it is opposite the dorsal end of the fourth aortic arch.

The middle sacral artery is formed by the fusion of two vessels, each of which springs from the dorsal surface of the aorta. It is regarded as the direct continuation of the descending aorta.

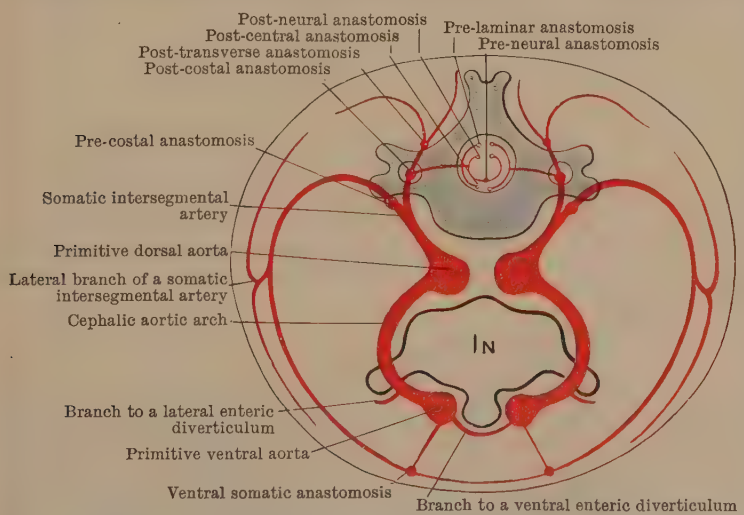

FIG 820.—DIAGRAM SHOWING THE ARRANGEMENT AND COMMUNICATIONS OF THE SEGMENTAL ARTERIES IN THE REGION OF THE CEPHALIC AORTIC ARCHES.

IN, Intestine.

The **lateral** or **intermediate visceral arteries** supply the organs derived from the intermediate cell mass. They form a somewhat irregular series of vessels in the adult, but presumably in the primitive condition there was a pair in each segment of the body; many of these disappear, however, and the series is only represented in the adult by the suprarenal, the right renal, part of the left renal, and the testicular or ovarian arteries—possibly, also, by some of the branches of the hypogastric arteries.

The **splanchnic arteries** arise in the embryo from the ventral aspects of the primitive dorsal aortæ, and are not strictly either segmental or intersegmental in arrangement. They are

distributed to the walls of the alimentary canal. Each anastomoses with its immediate neighbours on the dorsal wall and the ventral walls of the gut.

After the fusion of the dorsal longitudinal trunks to form the descending aorta, the roots of each pair of the splanchnic arteries fuse into a common stem, or either the right or left artery altogether disappears, whilst at a later period the majority of the splanchnic arteries lose their direct connexion with the descending aorta; those which retain their connexion are the cœliac artery and the superior and inferior mesenteric arteries.

The bronchial and œsophageal arteries are later formations. They appear to correspond morphologically with the more primitive splanchnic arteries, but the developmental history is not known.

The left gastric branch of the cœliac artery, as it passes from its origin to the small curvature of the stomach, represents a right splanchnic artery; the remainder of the left gastric artery and the right gastric branch of the hepatic are remnants of the ventral anastomoses between the splanchnic arteries cephalwards of the umbilicus.

The splenic artery is a branch given off from a splanchnic artery to an organ developed in the mesogastrium, and the hepatic is a branch from the ventral splanchnic anastomoses to the hepatic diverticulum from the wall of the duodenal portion of the fore-gut.

The superior and inferior mesenteric arteries represent at their origins splanchnic branches, and in the remainder of their extent they represent the dorsal anastomoses on the gut wall.

The Aorta, Pulmonary Artery, and other Chief Stem Vessels.

The heart and the majority of the great arterial trunks of the body, including the aorta, the innominate, part of the right subclavian, the common, external, and greater parts of the internal carotids, and the pulmonary arteries, are all modified portions either of the primitive aortæ or of the aortic arches. The developmental changes, which result in the formation of the vessels named, are described in the preceding chapter, and the morphology of these vessels is obviously the same as that of the trunks from which they are derived.

It will be sufficient, therefore, to point out that the primitive aortæ may be regarded as the greatly enlarged pre-central or pre-vertebral longitudinal anastomoses between the successive intersegmental arteries of each side; obviously, therefore, each primitive aorta, like the rest of the longitudinal anastomoses, consists chiefly of segmental elements. The origins of the intersegmental vessels enter into its formation only in so far as they connect the segmental vessels together, and so complete the longitudinal anastomoses.

The first cephalic aortic arches are simply portions of the primitive aortæ. The other aortic arches have possibly a different morphological significance, but their exact nature is not definitely settled.

The second, third, fourth, fifth, and sixth cephalic aortic arches of each side are developed in the undivided mesoderm of the head region, caudal to the first arch. They spring from the part of the primitive aorta which, after the head fold is formed, lies on the ventral aspect of the fore-gut, and they extend, at the side of the pharyngeal part of the fore-gut, to the dorsal aorta. Thus in some respects they may be looked upon as segmental vessels. In addition to the vessels already mentioned, there are given off from the ventral aortæ and the aortic arches a series of branches which supply ventral and lateral diverticula from the alimentary canal; these are represented in the adult by the superior thyreoid, the thyreoidea ima.

Iliac Arteries and their Branches.—The common iliac arteries are formed from the secondary roots of the umbilical arteries, and their exact morphological position is uncertain. The true morphological position of the hypogastric arteries is not yet defined. They also are parts of the secondary roots of the umbilical arteries, and they give off both somatic and splanchnic branches; therefore they do not correspond either with somatic intersegmental or with splanchnic arteries. The branches of the hypogastric artery are arranged in two groups—(1) a visceral set which supplies the walls of the hind-gut and the genital organs, and (2) a parietal set which is distributed to the body wall and to the hind-limbs. The branches distributed to the gut probably represent the splanchnic vessels, more or less homologous with ordinary splanchnic branches of the primitive aortæ, and the parietal branches are possibly the homologues of intersegmental arteries.

The Limb Arteries.

In all probability the vessels of both the upper and the lower limbs are derived originally from several somatic intersegmental arteries, the majority of which, however, have atrophied. The upper limb is supplied in man by the lateral offset from the ventral branch of the seventh somatic intersegmental artery. It passes into the extremity caudal to the shoulder girdle, courses through the arm, enters the cubital fossa, and is continued through the forearm, in the early stages, as the volar interosseous artery, which terminates in the deep part of the palm, in the deep volar arch. At a later period, ontogenetically, a median artery appears as a branch of the parent stem, and it terminates in a superficial volar arch; still later the radial and ulnar branches are formed. The latter grow rapidly, soon exceeding in size the parent stem, and they terminate in the superficial and deep volar arches. The interosseous and median arteries decrease, and generally lose their direct connexions with the volar arches. The dorsal interosseous artery is also a secondary branch from the parent stem, and the digital arteries are offsets from the volar arterial arches.

The chief arteries of the lower extremities spring directly from the secondary roots of the umbilical arteries, and may be looked upon as being essentially intersegmental; whether they represent the whole or only parts of typical somatic intersegmental arteries, however, is not clear.

The arteries of the lower limbs certainly show no very obvious indications of division into dorsal and ventral branches, though such indications are not entirely wanting. In their comparative absence it is supposed that the dorsal branches have been either suppressed or incorporated with the common stems; that similarly the ventral branches and their lateral offsets are indistinguishably fused, and that probably both are represented in a limb artery.

The original stem vessel of the lower limb is the inferior gluteal artery, which is continued distally, caudal to the pelvic girdle, into the popliteal and peroneal arteries, and so to the sole of the foot, where it ends in a vascular plexus. Subsequently the external iliac artery is given off from the secondary root of the umbilical artery, dorsal to the origin of the inferior gluteal, and, passing into the limb cranialward of the pelvic girdle, it becomes the greater part of the femoral artery. This vessel ultimately unites with the proximal part of the popliteal artery, and after this communication is established the distal part of the inferior gluteal atrophies and loses its connexion with the popliteal, which henceforth appears to be the direct continuation of the femoral trunk; therefore, whilst the main artery of the upper limb is formed by the prolongation of the lateral branch of one segmental artery, the corresponding vessel of the lower extremity is developed from representatives of, probably, two somatic segmental arteries, the external iliac and femoral trunks being the representatives of one, whilst the popliteal and its continuation, the peroneal, are parts of another.

The first main artery of the leg, ontogenetically, is the peroneal, which is continued into the plantar arch; after a time, however, the posterior and anterior tibial branches are evolved. As a rule, they soon preponderate in size, and they terminate in the plantar arch, whilst the original trunk diminishes and loses its direct connexion with the arch.

The peroneal artery corresponds in position and development with the common interosseous trunk and the volar interosseous artery in the forearm. The posterior tibial apparently corresponds with the median artery; it develops in a similar way, and has similar relations to homologous nerves, the tibial nerve representing the combined median and ulnar nerves of the upper extremity.

The anterior tibial artery represents the dorsal interosseous, whilst the radial and ulnar arteries of the upper extremity are not represented in the lower limb.

MORPHOLOGY OF THE VEINS.

Two dorsal longitudinal vessels, one on each side, connect the successive intersegmental veins together. They do not, however, in any part of their course, fuse together to form a single vessel comparable to the descending aorta.

Of these dorsal longitudinal vessels, that on the right side greatly enlarges, and from it the main stem vessels which return blood from the body walls, the head and neck, and the limbs, are almost entirely formed. The left dorsal longitudinal vessel remains relatively small—in parts, indeed, it altogether disappears—and the blood conveyed to it by the corresponding intersegmental veins is transmitted, across the median plane, to the chief functional stem by later developed and superadded transverse communicating channels, which are formed between the more primitive longitudinal anastomoses.

The primitive dorsal longitudinal anastomosing channels include on each side—(1) the precardinal vein, (2) the postcardinal vein, and (3) the duct of Cuvier; the last-named vessel, which opens into the sinus venosus of the primitive heart, is, originally, part of the anterior cardinal vein; it becomes enlarged and receives a special name after the union of the posterior with the anterior cardinal vein.

The cardinal veins return blood not only from the limbs and body wall, but they are also, in the early stages, the only vessels by which blood is returned from the derivatives of the intermediate cell tract, *i.e.* the kidneys, the genital glands, and the suprarenal glands. At a later period other longitudinal anastomoses, called the subcardinal veins, appear, and into these a large part of the blood from the derivatives of the intermediate cell tract is poured. Still later supracardinal veins are formed. It is from these vessels, and communications which are established between them, that the chief veins of the head and neck and the body are formed. Moreover, it must not be forgotten that the veins of the extremities are, like the extremities themselves, secondary structures, and that they are developed at a later period than the veins of the trunk, with which, however, they ultimately communicate.

In the light of these facts the morphology of the chief veins of the head and neck, the trunk and limbs, may now be considered.

The cavernous sinuses are remnants of the primary head vein. The other blood sinuses of the cranium are either secondarily formed vessels, or anastomoses between the tributaries of the anterior cardinal veins, or anastomoses between those tributaries and other newly formed veins.

The internal jugular veins are also portions of the precardinal veins.

The right innominate vein is a part of the right precardinal vein. A small part of the left innominate vein is formed from the left precardinal vein, the greater part is derived from a transverse anastomosis between the two precardinal veins.

Other remnants of the precardinal veins are the upper parts of the superior vena cava and left superior intercostal vein.

The basilic vein and its prolongations, the axillary vein and the subclavian vein, are derived from the ulnar or post-axial primitive veins of the superior extremities. The external jugular vein is a secondary formation, and the cephalic vein is the radial or pre-axial vein of the upper extremity which opens first into the external jugular vein and at a later period into the axillary vein.

The superior vena cava represents the lower part of the anterior cardinal vein and the right duct of Cuvier, and the oblique vein of the left atrium represents the left duct of Cuvier.

The azygos vein is derived partly from the right precardinal and partly from the right supracardinal vein. The vertical parts of the hemiazygos and accessory hemiazygos veins are remnants of the left supracardinal vein, whilst the transverse portions of the hemiazygos and accessory hemiazygos veins represent transverse anastomoses between the supracardinal veins.

The inferior vena cava is a compound structure representing parts of different structures. Its upper end is the transformed cephalic end of the right vitelline vein. The portion posterior to the liver is a secondary outgrowth from the right vitelline vein. The part between the liver and the right renal vein represents a part of the right subcardinal vein. Next comes a part formed from an anastomosis between the right postcardinal combined with a supra-subcardinal anastomosis. This is followed by a section consisting of fused supracardinal veins, and the right postcardinal vein enters into the formation of its caudal end.

The right common iliac vein is a part of the right posterior cardinal vein, but the left is a compound structure. Its lower part probably represents a portion of the left posterior cardinal vein, but the greater part is a persistent transverse anastomosis between the posterior cardinal veins.

The hypogastric veins are remnants of the posterior cardinal veins.

The popliteal and the inferior gluteal veins are remnants of the primitive fibular vein of the lower limb, and the external iliac vein is the trunk formed by the union of the tibial and the deep veins of the lower limb which are secondary formations.

Visceral Veins.—The portal vein represents portions of both vitelline veins and of the middle anastomosis between them.

The right gastric vein is a splanchnic ventral longitudinal anastomosing vein. The left gastric vein is partly a ventral and partly a dorsal splanchnic longitudinal anastomosis, and the superior and inferior mesenteric veins are dorsal splanchnic longitudinal venous anastomoses, the splenic vein being merely a tributary from a lymphoid organ developed in the dorsal meso-gastrium.

The anterior facial vein is a combination of somatic and splanchnic veins of several segments, and the internal maxillary vein is probably of similar nature. The thyreoid and bronchial veins return blood from organs developed from diverticula from the walls of the alimentary canal; they are, therefore, more or less modified splanchnic veins; so also apparently are the vesical and the middle and inferior hæmorrhoidal veins.

The cardiac veins are simply "vasa vasorum," and they belong therefore to the splanchnic group of vessels, but it is impossible to say whether they are segmental or intersegmental. The coronary sinus into which they open is a portion of the sinus venosus of the heart, and therefore of an originally segmental vessel.

The hepatic veins are parts of the primitive vitelline veins; and the pulmonary veins are splanchnic veins returning blood from diverticula of the gut.

It is noteworthy that some parts of the splanchnic venous system, *i.e.* the portal vein and the coronary sinus, are portions of the most primitive vascular system, and that others—the thyreoid, bronchial, mesenteric, vesical, and hæmorrhoidal veins—appear to belong to a somewhat secondary group of splanchnic veins of combined segmental and intersegmental character; moreover, some of the secondary group of veins open into the primary splanchnic veins, *e.g.* the superior and inferior mesenteric into the portal vein; some open into the dorsal longitudinal anastomosing veins, *e.g.* the vesical and hæmorrhoidal veins open into the postcardinal veins, which are intersegmental anastomoses; others again open into the internal jugular, which is part of the precardinal vein.

Veins of the Limbs.—The veins of the limbs, like the arteries, were probably at one time intersegmental in character, but we have no indisputable proof that this was the case. Looked at from an embryological standpoint, the most primitive limb veins are a superficial distal arch and a post-axial trunk vein in each extremity; at a later period digital veins are connected with the distal arch, and a pre-axial trunk is formed. In the upper extremity the distal arch and its tributaries remain as the dorsal venous arch and the digital veins, and the post-axial vein becomes the basilic, axillary, and subclavian veins. The pre-axial vein of the upper extremity is represented in the adult by the cephalic vein; the latter vessel originally terminated in the external jugular vein, above the clavicle, the union with the axillary portion of the post-axial vessel being a secondary condition; the primary condition is, however, frequently retained in man, and is constant in many monkeys. The anastomosis between the pre-axial and post-axial veins in the region of the elbow, and the connexion of the anastomosing channels, is brought about by newly-formed vessels of secondary character.

The distal arch in the lower extremity and the tributaries connected with it remain in the adult as the dorsal venous arch of the foot and the digital veins. The post-axial vein becomes the small saphenous vein, which was originally continued proximally as the popliteal and inferior gluteal veins to the hypogastric portion of the posterior cardinal vein.

The pre-axial vein of the lower limb becomes the great saphenous vein, which is continued

proximally to the cardinal portion of the left common iliac vein as the proximal part of the femoral and the external iliac veins.

The venæ comites of the arteries in both the upper and lower extremities are secondarily developed vessels which become connected with the upper portions of the pre-axial venous trunks.

ABNORMALITIES AND VARIATIONS OF THE VASCULAR SYSTEM.

Abnormalities are of special interest to the anatomist because of their morphological significance, and the vascular system is, perhaps more than any other, rich in such abnormalities, many of which are of great practical importance.

With the exception of those irregularities which are directly due to the effect of morbid conditions and external influences, all abnormalities are the result of modifications of normal developmental processes. The exceptions referred to are, however, very numerous; thus disease and external influences may lead to the obliteration of vessels, a condition which is invariably associated with the enlargement of collateral vessels, and it will be obvious that abnormalities so produced may occur in almost any situation.

Abnormalities which are determined by, or are dependent upon, modifications of the usual developmental processes are of greater interest. In the human subject they are generally due either to the retention of conditions which, normally, are only transitory in ontogenetic development, or to the acquirement of conditions which, though not as a rule present at any time in man, occur normally in some animals.

There are, in addition, other variations from the normal, such as the division of the axillary artery into radial and ulnar branches; the higher or lower division of the brachial artery; the formation of "vasa aberrantia," *e.g.* of long slender vessels connecting the axillary or brachial to the radial, ulnar, or interosseous arteries; the altered position of certain vessels, *e.g.* the transference of the subclavian artery to the front of the scalenus anterior, or of the ulnar artery to the front of the superficial flexor muscles; all of which, though undoubtedly due to alterations of ordinary developmental processes, still do not represent any known conditions met with, either temporarily or permanently, in man or in other animals. Their occurrence cannot at present be adequately explained, and their retention in the adult is entirely dependent upon their utility.

To the first and the last of these different groups of abnormalities it is not necessary to refer further, whilst with regard to the rest they have been already sufficiently indicated after the account of the heart and vessels. They can only, however, be fully understood and explained on the basis of a comprehensive knowledge of the development and morphology of the vascular system, to the chapters on which the reader is referred. Those who require more detailed information should consult special monographs.[1]

ABNORMALITIES OF VEINS.

Abnormalities or variations of veins are more frequently met with than those of arteries, and they are due to similar causes.

THE RESPIRATORY SYSTEM.

THE ORGANS OF RESPIRATION AND VOICE.

By the late D. J. Cunningham, F.R.S.,
Professor of Anatomy, University of Edinburgh.

Revised by Richard J. A. Berry, F.R.C.S.,
Professor of Anatomy, University of Melbourne.

The organs of respiration are the larynx and trachea, which, together, constitute a median air-passage; the two bronchi or branches into which the thoracic end of the trachea divides; and the two lungs to which the bronchi conduct the air. In connexion with the lungs there are also the pleural membranes—two serous sacs which line the portions of the thoracic cavity which contain the lungs, and at the same time give a thin coating to those organs.

The larynx opens above into the inferior or caudal part of the pharynx, and the air which passes in and out from the air-passages likewise traverses the pharynx, the nasal cavity, and also the oral cavity if the mouth be open. This connexion between the digestive and respiratory systems is explained by the fact that the respiratory apparatus is secondarily developed, as an outgrowth, from the ventral aspect of the primitive fore-gut of the embryo. In most mammals the superior or cranial aperture of the larynx opens into the part of the pharynx which lies immediately dorsal, or posterior, to the nasal cavities. In man, however, the superior opening of the larynx is placed below, that is inferior or caudal to, the communication between the mouth and pharynx, and both nasal and oral breathing may be carried on with very nearly equal ease.

LARYNX.

The **larynx** or **organ of voice** is the upper part of the air-passage, specially modified for the production of voice. Above it opens into the pharynx, whilst below its cavity becomes continuous with the lumen of the trachea or windpipe.

Position and Relations of the Larynx.—In the natural position of the neck, and whilst the organ is at rest, the larynx is placed on the ventral side of the bodies of the fourth, fifth, and sixth cervical vertebræ. Its highest point, represented by the tip of the epiglottis, extends to the inferior border of the body of the third cervical vertebra, whilst its lowest limit (the inferior border of the cricoid cartilage) usually corresponds to the inferior border of the body of the sixth cervical vertebra. From the vertebral column the larynx is separated, not only by the prevertebral muscles and the prevertebral fascia, but also by the dorsal wall of the pharynx—indeed the dorsal surface of the larynx forms the inferior part of the ventral or anterior wall of the pharynx, and is covered by the lining mucous membrane of that section of the alimentary canal.

The larynx lies below the hyoid bone and the tongue, and in the interval between the great vessels of the neck. It forms a more or less marked projection on the ventral side of the neck, and, in the median plane, it approaches very closely to the surface, being merely covered by skin and the two layers of fascia. Laterally

it is more deeply placed. There, it is overlapped by the sterno-cleido-mastoid muscle, and is covered by the two strata of thin ribbon-like muscles which are attached to the thyreoid cartilage and the hyoid bone; and it is hidden, to some extent, by the upper prolongations of the lateral lobes of the thyreoid gland.

The position of the larynx is influenced by movements of the head and neck. Thus it is elevated or raised when the head moves dorsally, and depressed when the chin is carried downwards towards the chest. Again, if the finger is placed upon it during deglutition, it will be noted that the larynx moves to a very considerable extent. The pharyngeal muscles attached to it, and more especially the stylo-pharyngeal muscles, are chiefly responsible for bringing about these movements. During singing, changes in the position of the larynx may also be noted, a high note being accompanied by a slight upward movement, and a low note by a similarly slight downward movement of the organ.

The position of the larynx is not the same at all periods of development and growth. In the fœtus, shortly before birth, it lies much nearer the head, and its inferior border corresponds to the inferior border of the fourth cervical vertebra. Its permanent position is not reached until the period of puberty is attained (Symington). In the early stages of growth all the thoracic viscera undergo a gradual subsidence and the larynx follows them. Indeed, it cannot do otherwise, seeing that the bifurcation of the trachea between infancy and puberty moves downwards towards the caudal end of the body more than the depth of one thoracic vertebra.

General Construction of the Larynx.—The wall of the larynx is constructed upon a somewhat complicated plan. There is a framework composed of several cartilages. These are connected together, at certain points, by distinct joints and also by elastic membranes. Two elastic cords, which stretch in a ventro-dorsal direction from the ventral to the dorsal wall of the larynx, form the groundwork of the vocal folds. Numerous muscles also are present. These operate upon the cartilages of the larynx, and thereby not only bring about changes in the relative position of the vocal folds, but also produce different degrees of tension of these folds. The cavity of the larynx is lined with mucous membrane, under which, in certain localities, are collected masses of mucous glands.

CARTILAGINES LARYNGIS.

Three single cartilages and three pairs of cartilages enter into the construction of the laryngeal wall. They are named as follows:—

Single cartilages { Thyreoid. / Cricoid. / Epiglottis. }

Paired cartilages { Arytænoids. / Corniculate cartilages (Santorini). / Cuneiform cartilages. }

Cartilago Thyreoidea.—The **thyreoid cartilage**, the largest of the laryngeal cartilages, is formed of two quadrilateral plates termed the **laminæ**, which meet ventrally at an angle, and become fused along the median plane. Dorsally the laminæ diverge from each other, and enclose a wide angular space which is open dorsally. The *ventral borders* of the laminæ are fused only in their inferior parts. Above they are separated by a deep, narrow V-shaped median notch, called the **incisura thyreoidea** or **thyreoid notch.** In the adult male the angle formed by the meeting of the ventral borders of the two laminæ, especially in its upper part, is very projecting, and with the margins of the thyreoid notch, which lies above, constitutes a marked subcutaneous prominence in the neck, which receives the name of the **prominentia laryngea** (O.T. **Adam's Apple**).

The angle which is formed by the meeting of the two laminæ of the thyreoid cartilage varies, to some extent, in different individuals of the same sex, and shows marked differences in the two sexes and at different periods of life. In the adult male the average angle is said to be 90°; in the adult female it is 120°; whilst in the infant the laminæ meet in the form of a gentle curve, convex ventrally.

The *dorsal border* of each lamina of the thyreoid cartilage is thick and rounded, and is prolonged beyond the superior and inferior borders in the form of two slender cylindrical processes, termed cornua. The **superior cornu** is longer than the inferior cornu. It is directed upwards, towards the head, with a slight dorso-medial inclination, and ends in a rounded extremity, which is joined to the tip of the great cornu of the hyoid bone by the lateral hyo-thyreoid ligament. The **inferior cornu** is shorter and stouter than the superior cornu. As it proceeds downwards it curves slightly towards the median plane, and upon the medial face of its extremity there is a circular, flat facet, by means of which it articulates with a similar facet on the lateral aspect of the cricoid cartilage.

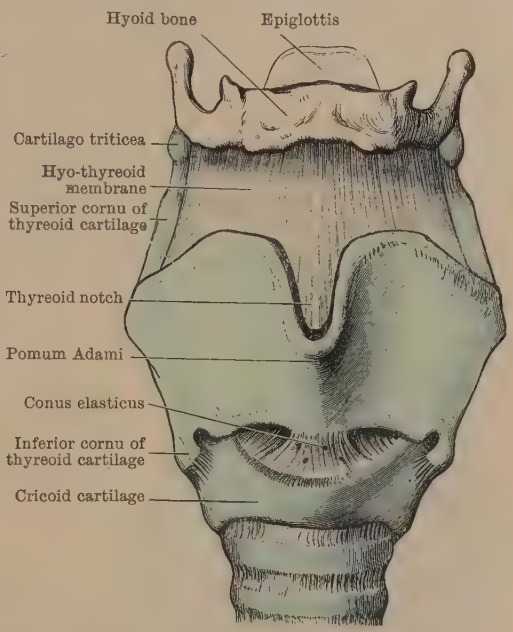

FIG. 821.—VENTRAL ASPECT OF THE CARTILAGES AND LIGAMENTS OF THE LARYNX.

The *superior border* of each lamina is, for the most part, slightly convex, and, ventrally, it dips suddenly to become continuous with the margin of the thyreoid notch. Dorsally, where it joins the superior cornu, it exhibits a shallow notch or concavity. The *inferior border* is almost straight, but it is marked off by a projection, termed the **inferior thyreoid tubercle**, into a short dorsal part, which shows a shallow concavity close to the inferior cornu and a longer part which lies ventral to the tubercle, and is also concave, but to a less degree.

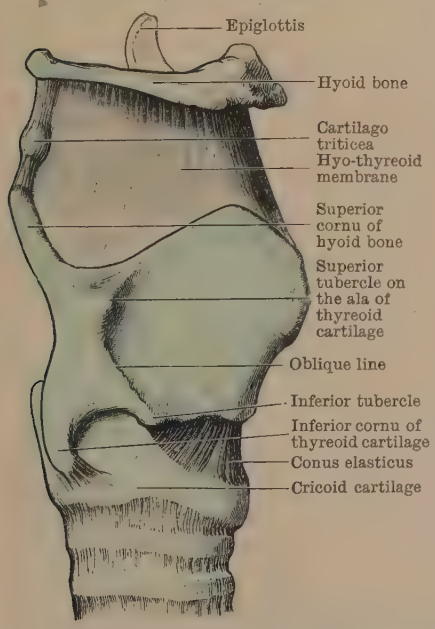

FIG. 822.—PROFILE VIEW OF THE CARTILAGES AND LIGAMENTS OF THE LARYNX.

The *lateral surface* of each lamina is divided into two unequal areas by the **oblique line**. This line begins above at the **superior thyreoid tubercle**, a prominence situated immediately below the superior border, and a short distance ventral to the root of the superior cornu. From the tubercle the oblique line proceeds forwards and downwards to end in the inferior tubercle on the inferior border of the lamina. The area which lies dorsal to the oblique line is much smaller than that which lies on its ventral side. It is covered by the inferior constrictor muscle of the pharynx. The larger ventral area is for the most part covered by the thyreo-hyoid muscle. To the oblique line are attached the sterno-thyreoid, thyreo-hyoid, and inferior constrictor muscles. The *medial surface* of the lamina of the thyreoid cartilage is smooth and slightly concave.

Cartilago Cricoidea.—The **cricoid cartilage** is shaped like a signet-ring. Dorsally there is a broad, thick plate, somewhat quadrilateral in form, termed the **lamina**; whilst ventrally and laterally the circumference of the ring is completed by a curved band, called the **arch**. The lumen of the ring enclosed by these parts is circular below, but the upper part of the ring is compressed laterally, so that the lumen becomes elliptical. The upper border of the **lamina** presents a faintly marked median notch. On either

side of this there is an oval facet which looks more laterally than upwards; it articulates with the base of the arytænoid cartilage. The dorsal surface of the lamina is divided by an elevated median ridge into two depressed areas which give attachment to the posterior crico-arytænoid muscles. The ventral part of the arch of the cricoid is in the form of a narrow band, but as it proceeds dorsally towards the lamina its upper border rises rapidly, and in consequence the arch becomes much broader. The *inferior border* of the cricoid is nearly straight, although it frequently presents a median ventral projection and two lateral projections. It is joined to the first ring of the trachea by an elastic membrane—the crico-tracheal ligament. On the *lateral surface* of the cricoid cartilage, at the place where the arch joins the lamina, a vertical ridge runs downwards from the arytænoid articular facet. On this, a short distance from the inferior border of the cartilage, a prominent circular articular facet is visible, for articulation with the inferior cornu of the thyreoid cartilage (Fig. 824, p. 1067). The *medial surface* of the cricoid cartilage is smooth, and is covered with mucous membrane.

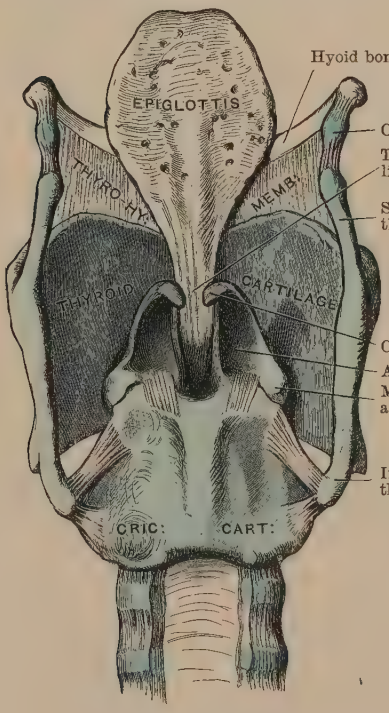

FIG. 823.—DORSAL ASPECT OF THE CARTILAGES AND LIGAMENTS OF THE LARYNX.

The narrow band-like part of the arch of the cricoid cartilage lies below the inferior border of the thyreoid cartilage, whilst the lamina is received into the interval between the dorsal portions of the laminæ of the thyreoid cartilage.

Cartilagines Arytænoideæ.—The **arytænoid cartilages** are placed one on each side of the median plane, and rest upon the upper border of the lamina of the cricoid cartilage, in the interval between the dorsal portions of the laminæ of the thyreoid cartilage. Each presents a somewhat pyramidal form, the pointed **apex** of which is directed upwards, and at the same time curves dorsally and medially. It supports the corniculate cartilage (Santorini). Of the three surfaces, the medial one faces the corresponding surface of the opposite cartilage, from which it is separated by a narrow interval; another looks dorsally; whilst the third is directed laterally and ventrally. The *medial surface*, which is the smallest of the three, is triangular in outline. It is narrow, vertical, and even, and is clothed with the lining mucous membrane of the larynx. The *dorsal surface* is smooth and concave in the cranio-caudal direction; it lodges and gives attachment to the transverse arytænoid muscle. The *ventro-lateral surface* is the most extensive of the three (Fig. 824, p. 1067). Its middle part is marked by a deep depression in which is lodged a mass of mucous glands. Upon this surface of the arytænoid cartilage the vocalis and thyreo-arytænoid muscles are inserted, whilst a small tubercle a short distance above the base gives attachment to the ventricular ligament—the feeble supporting ligament of the ventricular fold (O.T. false vocal cord). The three surfaces of the arytænoid cartilages are separated from each other by a ventral, a dorsal, and a lateral border. The *lateral border* is the longest, and it pursues, as it is traced from the apex to the base, a sinuous course. Reaching the base of the cartilage, it is prolonged laterally and dorsally in the form of a stout prominent angle or process, termed the **muscular process**. Into the ventral side of this process is inserted the lateral crico-arytænoid muscle; whilst into its dorsal aspect the posterior crico-arytænoid muscle is

inserted. A small nodule of yellow elastic cartilage, called the **sesamoid cartilage**, is frequently found on the lateral border of the arytænoid cartilage, where it is held in position by the investing perichondrium. The *ventral border* of the arytænoid is vertical, and at the base of the cartilage is prolonged ventrally into a small sharp-pointed process called the **vocal process**, which receives this name because it gives attachment to the vocal ligament or supporting band of the vocal fold (O.T. true vocal cord). The **base** of the arytænoid cartilage presents on its inferior surface, particularly in the region of the muscular process, an elongated concave facet for articulation with the facet on the superior border of the lamina of the cricoid cartilage.

Cartilagines Corniculatæ (Santorini).—The **corniculate cartilages of Santorini** are two minute conical nodules of yellow elastic cartilage which surmount the apices of the arytænoids, and prolong the upper curved ends of these cartilages in a dorso-medial direction. Each corniculate cartilage is enclosed within the dorsal part of the corresponding ary-epiglottic fold of mucous membrane.

Cartilagines Cuneiformes (Wrisbergi).—The **cuneiform cartilages of Wrisberg** are not always present. They are two minute rod-shaped pieces of yellow elastic cartilage, each of which occupies a place in the corresponding ary-epiglottic fold, immediately ventral to the arytænoid cartilage and the corniculate cartilage of Santorini. On the superficial surface of each a collection of mucous glands is present, and this tends to make the cartilage stand out in relief under the mucous membrane.

Cartilago Epiglottica.—The **epiglottis** is supported by a thin, leaf-like lamina of yellow fibro-cartilage, the **epiglottic cartilage**, which is placed dorsal to the root of the tongue and the body of the hyoid bone, and ventral to the aperture of the larynx. When divested of the mucous membrane, which covers it dorsally and also to some extent ventrally, the epiglottic cartilage is seen to present the outline of a bicycle-saddle, and to be indented by pits and pierced by numerous perforations. In the pits glands are lodged, whilst through the foramina, blood-vessels and, in some cases, nerves pass. The *broad end* of the epiglottic cartilage is directed upwards, and is free. Its *margins* are, to a large extent, enclosed within the ary-epiglottic fold. The *ventral surface* is free only in its upper part. This part is covered with mucous membrane, and looks towards the pharyngeal part of the tongue. The *dorsal surface* is covered throughout its whole extent with the lining mucous membrane of the laryngeal cavity. The *inferior pointed extremity* is prolonged downwards in the form of a strong fibrous band, termed the thyreo-epiglottic ligament.

Ossification of the Cartilages of the Larynx.—The thyreoid and cricoid cartilages and the greater part of the arytænoid cartilages are composed of the hyaline variety of cartilage. The apical parts, and also the vocal processes of the arytænoid cartilages, the corniculate cartilages of Santorini, the cuneiform cartilages, and the epiglottis, are formed of yellow fibro-cartilage, and at no period of life do they exhibit any tendency towards ossific change. The thyreoid, cricoid, and basal portions of the arytænoids, as life advances, become more or less completely transformed into bone. In males over twenty years of age, and in females over twenty-two years of age, the process will usually be found to have begun (Chievitz). It is impossible, however, by an examination of the laryngeal cartilages, to form an estimate of the age of the individual, although in old age it is usual to find the thyreoid, cricoid, and the hyaline parts of the arytænoids completely ossified. It would appear that the process is somewhat slower in the female than in the male. The thyreoid is the first to show the change; then, but almost at the same time, the cricoid; and lastly, a few years later, the arytænoids.

ARTICULATIONS, LIGAMENTS, AND MEMBRANES OF THE LARYNX.

Crico-thyreoid Joints. — These are diarthrodial joints, and are formed by the apposition of the circular facets on the tips of the inferior cornua of the thyreoid cartilage with the elevated circular facets on the sides of the cricoid cartilage. An articular capsule surrounds each articulation, and this is lined with a synovial layer. On the dorsal aspect of the joint a strengthening band is present in the capsule. The movements which take place at the crico-thyreoid joints

are of a twofold character, viz., gliding and rotatory. In the first case the thyreoid facets glide upon the cricoid surfaces in different directions. The rotatory movement is one in which the thyreoid cartilage rotates to a slight extent around a transverse axis which passes through the centres of the two joints.

Crico-arytænoid Joints.—These also are diarthrodial articulations. In each case there is a joint cavity surrounded by an articular capsule, which is lined with a synovial layer. The cricoid articular surface is convex, whilst that of the arytænoid is concave; both are elongated or elliptical in form, and they are applied to each other so that the long axis of the one intersects or crosses that of the other at an acute angle. In no position of the joint do the two surfaces accurately coincide—a portion of the cricoid facet is always left uncovered. The capsule of the joint is strengthened dorsally by a band which is inserted into the dorso-medial part of the base of the arytænoid cartilage, and plays a somewhat important part in the mechanism of the joint; it effectually arrests excessive ventral movement of the arytænoid cartilage.

The movements which take place at the crico-arytænoid joints are of a two-fold kind, viz., gliding and rotatory. The ordinary position of the arytænoid during easy, quiet breathing is one in which it rests upon the lateral part of the cricoid facet. By a gliding movement it can move upon the cricoid facet, and advance towards the median plane and its fellow of the opposite side. The gliding movements, therefore, are of such a character that the two arytænoid cartilages approach or retreat from each other and from the median plane. In the rotatory movement the arytænoid cartilage revolves around a vertical axis. By this movement the vocal process is swung laterally or medially, so as to open or close the rima glottidis.

The **joint between the arytænoid and the corniculate cartilage (Santorini)** may either partake of the nature of an amphiarthrosis or of a diarthrosis. The tips of the two corniculate cartilages can generally be made out to be connected to the upper border of the lamina of the cricoid cartilage by a delicate Y-shaped band of connective tissue termed the **corniculo-pharyngeal ligament.**

Hyo-thyreoid Membrane.—This is a broad, membranous, and somewhat elastic sheet which occupies the interval between the hyoid bone and the thyreoid cartilage. It is not equally strong throughout. It presents a central thick portion and cord-like right and left dorsal margins, whilst in the intervals between these it is thin and weak (Figs. 821 and 822, p. 1063). The **central thickened part,** or the **middle hyo-thyreoid ligament,** is largely composed of elastic fibres. Below it is attached to the margins of the thyreoid notch, whilst above it is fixed to the dorsal part of the upper border of the body of the hyoid bone. The upper part of its ventral surface, therefore, is placed dorsal to the dorsal hollowed-out surface of the body of the hyoid bone; a synovial bursa of variable extent is placed between them, and in certain movements of the head and larynx the upper border of the thyreoid cartilage moves towards the head on the dorsal side of the hyoid bone. On each side of the strong central part the hyo-thyreoid membrane is thin and loose, and is there attached, below, to the upper border of the thyreoid cartilage, and above, to the medial aspect of the great cornu of the hyoid bone. It is pierced by the internal ramus of the superior laryngeal nerve and by the superior laryngeal vessels. The dorsal border of the hyo-thyreoid membrane on each side is thickened, round, and cord-like, and is chiefly composed of elastic fibres; it is termed the **lateral hyo-thyreoid ligament,** and extends from the tip of the great cornu of the hyoid bone to the extremity of the upper cornu of the thyreoid cartilage. In this ligament there is usually developed a small oval cartilaginous or bony nodule, which receives the name of the **cartilago triticea.** The deep surface of the lateral part of the hyo-thyreoid membrane is covered with the pharyngeal mucous membrane, and its central part lies ventral to the epiglottis, but separated from it by a mass of adipose tissue (Fig. 827, p. 1070).

Conus Elasticus.—The **elastic cone,** or the crico-thyreoid membrane, is a very important structure, which it is convenient to consider in three parts, viz., one median and two lateral, all of which are directly continuous with one another, and differ only in the nature of their upper connexions. The **median part** (crico-

thyreoid ligament) is strong, tense, and elastic. It is triangular in shape, and is attached by its broad base to the upper border of the arch of the cricoid cartilage, whilst its apex is fixed to the medial part of the lower border of the thyreoid cartilage (Fig. 824, p. 1067). It is pierced by minute apertures, and is crossed superficially by the crico-thyreoid branch of the superior thyreoid artery. The median part of the elastic cone, therefore, closes, ventrally, the interval between the cricoid and thyreoid cartilages. The **lateral part**, on each side, presents very different connexions. It is not attached to the inferior border of the thyreoid cartilage, but slopes upwards and medially on the inner side of the thyreoid lamina, and thus diminishes materially the transverse or frontal width of the cavity of the larynx. Its attachments are very definite. *Inferiorly* it is fixed to the superior border of the cricoid cartilage immediately subjacent to the lining mucous membrane of the larynx; *above* it is directly continuous with the vocal ligament or supporting band of the vocal fold. That ligament, indeed, may be looked upon as constituting the superior thickened free border of the lateral part of the elastic cone. *Ventrally* the lateral part of the elastic cone is attached to the inferior half of the medial surface of the lamina of the thyreoid cartilage, close to the angle, and, *dorsally*, to the inferior border of the vocal process of the arytænoid cartilage. In contact with the *outer surface* of the lateral part of the elastic cone, and separating it from the thyreoid lamina, are the lateral crico-arytænoid muscles; the *inner surface* is clothed with the lining mucous membrane of the larynx.

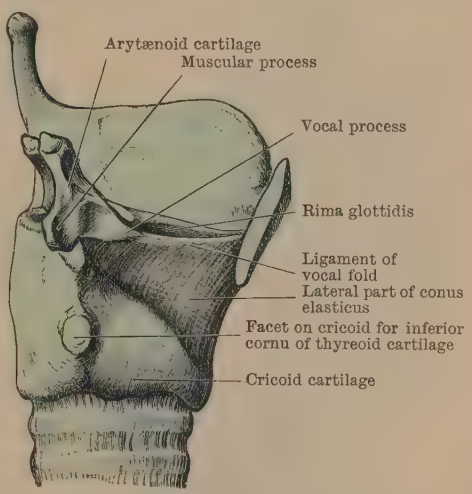

FIG. 824. — DISSECTION TO SHOW THE CONUS ELASTICUS. The right lamina of the thyreoid cartilage has been removed.

The **vocal ligament** (O.T. **inferior thyreo-arytænoid lig.**) is formed in connexion with the superior border of the elastic cone, and constitutes the supporting ligament of the vocal fold. It is attached *ventrally*, close to its fellow of the opposite side, to the middle of the angular depression between the two laminæ of the thyreoid cartilage. From there it stretches *dorsally*, and becomes incorporated with the tip and superior border of the vocal process, which projects ventrally from the base of the arytænoid cartilage. The vocal ligament is composed of yellow elastic fibres, and embedded in its ventral extremity there is, frequently, a minute nodule of elastic cartilage. Its medial border is sharp and free, and is clothed with mucous membrane, which in that position is very thin and tightly bound down to the ligament.

The **ventricular ligament** supports the ventricular fold. It is weak and indefinite, but somewhat longer than the vocal ligament. *Ventrally* it is attached to the angular depression between the two laminæ of the thyreoid cartilage, above the vocal ligament and close to the attachment of the thyreo-epiglottic ligament; it extends, *dorsally*, to be fixed to a tubercle on the ventro-lateral surface of the arytænoid cartilage, a short distance above the vocal process. It is composed of connective tissue and elastic fibres which are continuous with the fibrous tissue in the ary-epiglottic fold.

The **epiglottis** is bound by ligaments to the base of the tongue, to the wall of the pharynx, to the hyoid bone, and to the thyreoid cartilage. The **glosso-epiglottic fold** is a prominent median fold of mucous membrane which proceeds from the middle of the ventral free surface of the epiglottis to the root of the tongue. The **pharyngo-epiglottic folds** are similar elevations of mucous membrane which proceed from the lateral margins of the epiglottis to the lateral walls of the pharynx at the side of the tongue. Between the two layers of mucous

membrane which form each of these folds is a certain amount of elastic tissue. By the three folds the depression between the root of the tongue and the epiglottis is marked off into two fossæ, termed the **epiglottic valleculæ**. From the lateral margins of the epiglottis there also pass off the **ary-epiglottic folds** to the arytænoids.

The **hyo-epiglottic ligament** is a short, broad elastic band, somewhat broken up by adipose tissue, which connects the ventral surface of the epiglottic cartilage to the upper border of the hyoid bone (Fig. 827, p. 1070). The **thyreo-epiglottic ligament** is strong and thick (Fig. 832, p. 1075). Composed mainly of elastic tissue, it proceeds downwards, from the inferior pointed extremity of the epiglottic cartilage, and is attached to the angular depression between the two laminæ of the thyreoid cartilage, below the median notch.

A triangular interval is left between the ventral surface of the epiglottis and the hyo-thyreoid membrane. This is imperfectly closed above by the hyo-epiglottic ligament, and contains a pad of soft fat (Fig. 827, p. 1070).

CAVUM LARYNGIS.

The **cavity of the larynx** is smaller than might be expected from an inspection of its exterior. On looking into its interior, through the laryngeal aperture, it is seen to be subdivided into three portions by two pairs of elevated folds of mucous membrane, which extend ventro-dorsally, and project medially from each lateral wall of the cavity. The upper pair of folds are the **ventricular folds** (O.T. **false vocal cords**); the lower, more definite pair, are the **vocal folds** (O.T. **true vocal cords**) (Fig. 826). The latter are the chief agents in the production of the voice, and the larynx is so constructed that changes in their relative position and in their degree of tension are brought about by the action of the muscles and the recoil of the elastic ligaments.

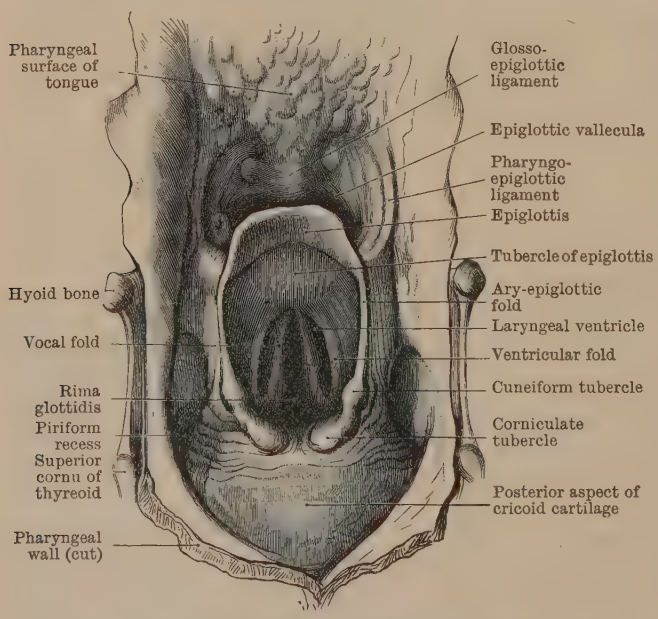

FIG. 825.—ADITUS LARYNGIS, EXPOSED BY THE REMOVAL OF THE DORSAL WALL OF THE PHARYNX.

Aditus Laryngis. — The **laryngeal aperture** is a large obliquely placed opening, which slopes rapidly in a dorsal and downwards direction and looks upwards and dorsally into the laryngeal part of the pharynx. Somewhat triangular in outline, the basal part of the aperture, placed superiorly and ventrally, is formed by the free border of the epiglottis. The opening rapidly narrows as it runs downwards, and it ends in the interval between the two arytænoid cartilages. The sides of the aperture are formed by two sharp and prominent folds of mucous membrane, the **ary-epiglottic folds**, which stretch between the lateral margins of the epiglottis, ventrally, and the arytænoid cartilages dorsally. The two layers of mucous membrane which compose the ary-epiglottic folds, enclose, between them, some connective tissue, muscular fibres belonging to the ary-epiglottic muscles, and in their dorsal parts the cuneiform and corniculate cartilages, which latter surmount the arytænoid cartilages. These small nodules of cartilage raise the dorsal part of

the ary-epiglottic fold in the form of two rounded eminences, termed respectively the cuneiform and corniculate tubercles.

On each side of the laryngeal opening there is, in the pharynx, a small recess, directed downwards, which presents a wide entrance, but rapidly narrows towards the bottom. It is termed the **piriform recess**, and is of importance to the surgeon, because foreign bodies introduced into the pharynx are liable to be caught in this little pocket. On the medial side the piriform recess is bounded by the arytænoid cartilage and the ary-epiglottic fold, whilst on the lateral side it is limited by the inner surface of the laminæ of the thyreoid cartilage, clothed with the pharyngeal mucous membrane.

Vestibulum Laryngis.—The **vestibule of the larynx** is the **uppermost compartment** of the cavity of the larynx. It extends from the laryngeal aperture to the ventricular folds. In its inferior part it exhibits a marked lateral compression. Its width, therefore, diminishes in the vertical direction, whilst, owing to the obliquity of the laryngeal aperture, its depth rapidly diminishes ventro-dorsally. *Ventrally* it is bounded by the dorsal surface of the epiglottis, clothed with mucous membrane. This wall passes obliquely from its superior end in an inferior ventral direction, and becomes narrower as it approaches the ventral ends of the ventricular folds. The superior part of the dorsal surface of the epiglottis is convex, owing to the manner in which the upper margin is curved ventrally towards the tongue; below the convexity there is a slight concavity, and still lower a marked bulging or convexity, over the superior part of the thyreo-epiglottic ligament. This swelling, the **epiglottic tubercle**, forms a conspicuous object in laryngoscopic examination of the larynx. Each *lateral wall* of the vestibule of the larynx is formed by the medial surface of the corresponding ary-epiglottic fold. For the most part it is smooth and slightly concave, and it diminishes considerably in vertical depth as it passes dorsally. In its dorsal part the mucous membrane stands out in two elongated vertical elevations, placed one dorsal to the other (Fig. 833, p. 1076). The more ventral elevation is formed by the subjacent cuneiform cartilage with the mass of glands associated with it; the more dorsal elevation is produced by the upper part of the arytænoid cartilage and the corniculate cartilage (Santorini). The *dorsal wall* of the laryngeal vestibule is narrow, and corresponds to the interval between the upper parts of the two arytænoid cartilages. Its width, to a large extent, depends on the position of those cartilages, and when they are placed near each other the mucous membrane which covers the dorsal wall is thrown into longitudinal folds.

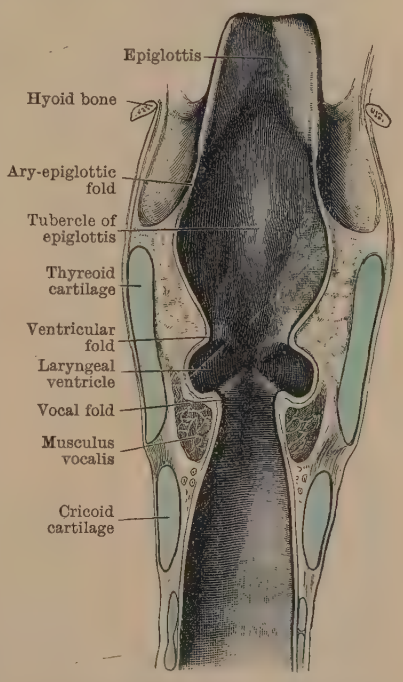

FIG. 826.—FRONTAL SECTION THROUGH THE LARYNX TO SHOW ITS COMPARTMENTS.

The **middle compartment of the larynx** is much the smallest of the three. It is bounded above by the ventricular fold and below by the vocal folds, whilst it communicates between those folds with the vestibule on the one hand and the inferior compartment on the other.

The **ventricular folds** (O.T. **false vocal cords**) are two prominent folds of mucous membrane which extend ventro-dorsally on the lateral walls of the laryngeal cavity. Ventrally they reach the angle between the two laminæ of the thyreoid cartilage, but dorsally they do not extend so far as the dorsal wall of the larynx. They come to an end at the inferior extremity of the elongated swelling produced by the cuneiform cartilage. The ventricular fold is soft and somewhat flaccid, and presents a free border which is slightly arched—the concavity looking

downwards. Within the fold of mucous membrane which forms this fold are contained: (1) the feeble ventricular ligament; (2) numerous glands which are chiefly aggregated in its middle part; and (3) a few muscle fibres.

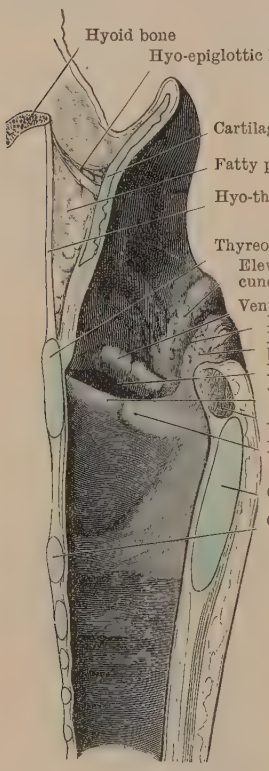

FIG. 827.—SECTION THROUGH LARYNX IN THE MEDIAN PLANE TO SHOW THE SIDE WALL OF THE RIGHT HALF.

The interval between the ventricular folds is termed the **rima vestibuli** and is considerably wider than the **rima glottidis**, or the interval between the two vocal folds. It follows, therefore, that when the cavity of the larynx is examined from above with the laryngoscope all four folds are distinctly visible.

The **vocal folds**, or **true vocal cords**, placed below the ventricular folds, extend from the angle between the laminæ of the thyreoid cartilage ventrally, to the vocal processes of the arytænoid cartilages dorsally. The vocal fold is sharp and prominent, and the mucous membrane which is stretched over it is very thin and firmly bound down to the subjacent ligament. In colour it is pale, almost pearly white, whilst, dorsally, the point of the vocal process of the arytænoid, which stands out clearly in relief, presents a yellowish tinge. In cross-section the vocal fold is prismatic in form, and its free border looks upwards as well as medially.

The vocal folds are the agents by means of which the voice is produced. The ventricular folds are of little importance in this respect; indeed, they can in great part be destroyed and no appreciable difference in the voice result.

Rima Glottidis.—This name is applied to the elongated fissure by means of which the middle compartment of the larynx communicates with the lower compartment. It is placed somewhat below the middle of the laryngeal cavity, of which it constitutes the narrowest part. Ventrally it corresponds to the interval between the vocal folds; dorsally it corresponds to the interval between the bases and vocal processes of the arytænoid cartilages. It is composed, therefore, of two distinct parts: (1) a narrow ventral portion, between the vocal folds, involving more than half of its length, and called the **intermembranous part** of the rima glottidis; (2) a broader, shorter portion, between the arytænoid cartilages, and termed the **intercartilaginous part**. By changes in the position of the arytænoid cartilages the form of the rima glottidis undergoes constant alterations. In ordinary easy breathing it is somewhat lanceolate in outline. The intermembranous part presents, under these conditions, the form of an elongated triangle the base of which is directed dorsally and corresponds to an imaginary

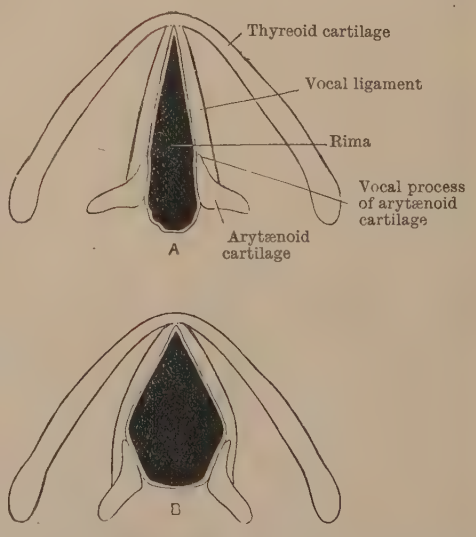

FIG. 828.—DIAGRAM OF RIMA GLOTTIDIS.
A. During ordinary easy breathing. B. Widely opened.

line drawn between the points of the vocal processes of the arytænoid cartilages, whilst the intercartilaginous part is somewhat quadrangular. When the glottis is opened widely the broadest part of the fissure is at the extremities of the vocal processes of the arytænoids, and there each side of the rima glottidis presents a marked angle. The two vocal folds, on the other hand, may be approximated to each other so closely, as in singing a high note, that the intermembranous part is reduced to a linear chink.

The length of the rima glottidis differs very considerably in the two sexes, and upon this depends the different character of the voice in the male and female. According to Moura, the following are the average measurements in the quiescent condition of the rima :—

Male—Length of entire rima glottidis, 23 mm. { intermembranous, 15·5 mm. / intercartilaginous, 7·5 mm.

Female—Length of entire rima glottidis, 17 mm. { intermembranous, 11·5 mm. / intercartilaginous, 5·5 mm.

By stretching the vocal folds, however, the length of the rima glottidis in the male may be increased to 27·5 mm., and in the female to 20 mm.

The position of the rima glottidis may be indicated on the surface by marking a point on the middle line of the neck 8·5 mm. below the thyreoid notch in the male and 6·5 mm. in the female. This is the average position (Taguchi).

The lateral wall of the larynx, in the interval between the ventricular and the vocal folds, exhibits a marked pocket-like depression or recess called the **ventricle of the larynx**. The ventricle passes upwards, so as to undermine somewhat the ventricular fold, and its mouth is somewhat narrower than its cavity. Ventrally it reaches to the angle between the laminæ of the thyreoid cartilage, whilst dorsally it ends at the ventral border of the arytænoid cartilage.

Under cover of the ventral part of the ventricular fold a small slit-like aperture may be detected; this leads upwards from the laryngeal ventricle into a small diverticulum of mucous membrane, termed the **appendix**, which passes upwards, between the ventricular fold and the lamina of the thyreoid cartilage. The laryngeal appendix is of variable extent, but as a rule it ends blindly at the level of the upper border of the thyreoid cartilage.

The **lowest compartment** of the cavity of the larynx leads caudally into the trachea. Above it is narrow and compressed laterally, but it gradually widens out until it becomes circular, in correspondence with the trachea, with which it is continuous. It is bounded by the sloping medial surfaces of the elastic cone and by the medial aspect of the cricoid cartilage—both covered with smooth mucous membrane. In the operation of laryngotomy the opening is made through the crico-thyreoid ligament in the ventral wall of this compartment.

Tunica Mucosa Laryngis.—The **mucous membrane** which lines the larynx is continuous above with the lining of the pharynx, and below with the mucous membrane of the trachea. Over the dorsal surface of the epiglottis it is closely adherent, but elsewhere, above the level of the vocal folds, it is loosely attached by submucous tissue which extends into the ary-epiglottic folds. As it passes over the vocal folds the mucous membrane is very thin, and is tightly bound down.

It is important to bear these facts in mind, because, in certain inflammatory conditions, the lax submucous tissue in the upper part of the larynx is liable to become infiltrated with fluid, producing what is known as œdema glottidis. This may proceed so far as to cause occlusion of the upper part of the cavity. The close adhesion of the mucous membrane to the vocal folds, however, prevents the œdema extending beyond the level of the rima glottidis, and the surgeon is thus able to relieve the patient by making an opening through the ventral part of the elastic cone into the cavity of the larynx.

Above the level of the rima glottidis the laryngeal mucous membrane is extremely sensitive, and when touched by a foreign body there is an immediate response in the shape of an explosive cough. In the lower compartment of the larynx the mucous membrane is lined with columnar ciliated epithelium. Over the vocal folds this is replaced by squamous epithelium. In the ventricle of the larynx and in the inferior part of the vestibule of the larynx the columnar ciliated epithelium again reappears. The upper part of the epiglottis and the upper parts of the lateral walls of the vestibule are covered with squamous epithelium similar to that present in the mouth and pharynx.

The mucous membrane of the larynx has a plentiful supply of acinous glands, and in only one place, viz., over the surface of the vocal folds, are these completely absent. For the most part the glands are aggregated in groups.

THE MUSCLES OF THE LARYNX.

Of the many muscles connected with the larynx, two groups may be recognised, extrinsic and intrinsic.

The **extrinsic muscles** reach the larynx, to which they are attached and upon which they act, from other parts, and, strictly speaking, include all those attached to the hyoid bone, which is physiologically a part of the larynx.

Of the **intrinsic muscles** all are composed of striated muscular fibres, and are innervated by the accessory nerve through the laryngeal branches of the vagus. They all lie, with the exception of the crico-thyreoid muscle, under cover of the thyreoid cartilage. In this group there are ten, and occasionally eleven, series of muscles, which may be classified physiologically as follows :—

a. Acting upon the vocal folds—
Tension.—The crico-thyreoids.
Relaxation.—The (external) thyreo-arytænoids.
The vocal muscles.

b. Acting upon the rima glottidis—
Dilatation.—The posterior crico-arytænoids.
Closure.—The transverse arytænoids.
The oblique arytænoids.
The lateral crico-arytænoids.

c. Acting upon the aditus and vestibule of the larynx—
Closure.—The ary-epiglottics, assisted by some of the foregoing.
Dilatation.—The thyreo-epiglottics.

d. Acting upon the ventricular folds—
The ventricular muscle.

The inconstant cerato-cricoids complete the list of intrinsic muscles.

The muscles of the larynx have, however, another function to perform besides vocalisation and regulating the amount of air passing to and fro through the glottis. During deglutition it is requisite that the communication between the pharynx and larynx should be closed, to prevent the fluid or solid parts of the food entering the respiratory passages. In the process of closing the laryngeal entrance the epiglottis stands erect, whilst the dorsal wall formed by the arytænoids is carried ventrally, the arytænoid cartilages are closely approximated, glide ventrally, and are then inclined towards the epiglottis. The result of this is that the laryngeal opening is converted into a T-shaped fissure. The median limb of the T is formed by the interval between the closely applied arytænoid cartilages, whilst the cross limb, which lies ventrally, is bounded ventrally (anteriorly) by the epiglottis and dorsally by the ary-epiglottic folds. The apices of the arytænoid cartilages, with the corniculate cartilages (Santorini), are pressed against the tubercle of the epiglottis, whilst the lateral margins of the epiglottis are pulled dorsally so as to make the transverse limb of the fissure distinctly concave in a dorsal direction. The muscles chiefly concerned in producing these movements are the thyreo-arytænoid and the transverse arytænoid muscles. These form a true sphincter vestibuli. The thyreo-epiglottic and ary-epiglottic muscles also come into play. They pull upon the epiglottis so as to produce tight application of its tubercle to the arytænoid cartilages and the corniculate cartilages (Santorini), and they also curve its margins dorsally so as to increase its dorsal concavity.

Innervation of the Larynx.—The nerve supply of the larynx is derived from the superior and inferior (laryngeal) branches of the vagus nerve.

The superior laryngeal nerve is the "sensory" or receptor nerve from the mucous membrane of the larynx, and also gives off a branch which furnishes

"motor" or effector fibres to the crico-thyreoid muscle. All the other muscles of the larynx receive their "motor" or effector nerve fibres from the recurrent (laryngeal) nerve. As this last nerve recurs, on the left side around the arch of the aorta, it is frequently involved in aneurism of the aortic arch, so that this question of the innervation of the larynx and its muscles is of more than ordinary clinical importance, and should be carefully noted. If the recurrent (laryngeal) nerve be divided or compressed on one side, the voice is lost, because the corresponding vocal fold cannot be adducted. Breathing is also somewhat laboured, because the vocal fold cannot be abducted. Under these conditions, and as seen on the living subject with the laryngoscope, the paralysed vocal fold does not move on phonation to the middle line as it should do, nor does it move away from it on inspiration. When the recurrent (laryngeal) nerve is more gradually affected it is the abductor muscle — the posterior crico-arytænoid—which fails first.

Paralysis of the superior laryngeal nerve, much less common than that of the recurrent (laryngeal) nerve, leads to loss of laryngeal sensation, and also causes hoarseness, because the paralysis of the crico-thyreoid muscle leads to deficient tension of the vocal folds.

Attachments of the Laryngeal Muscles.—The following are the unimportant details of the attachments of the laryngeal muscles :—

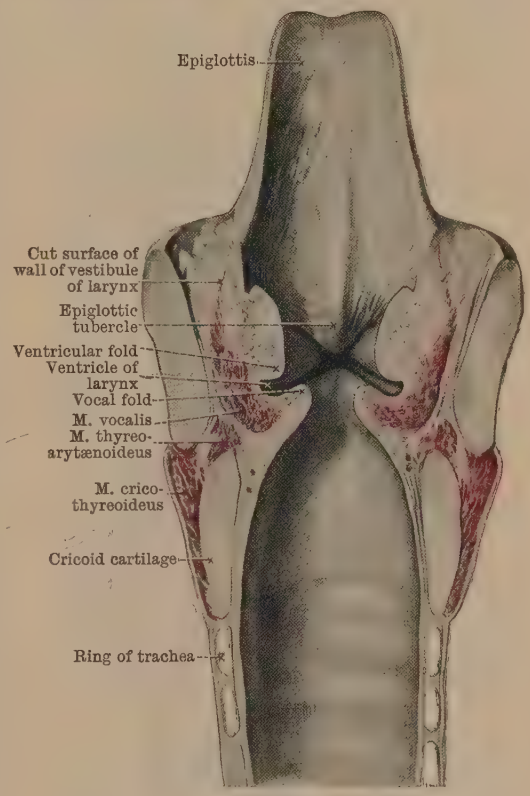

FIG. 829.—FRONTAL SECTION OF THE LARYNX, SHOWING MUSCLES.

The **crico-thyreoid muscles** are a pair of quadrangular muscles which lie on the cricoid cartilage and bridge over the crico-thyreoid interval, and are, therefore, the only intrinsic laryngeal muscles which are visible in an ordinary dissection of the neck. Each is covered laterally and in part by the thyreoid gland and the sterno-thyreoid and the sterno-hyoid muscles. Between the two muscles of opposite sides there is an intermediate triangular area left in which the crico-thyreoid ligament is visible.

Each crico-thyreoid muscle **arises** from the lower border and lateral surface of the arch, of the cricoid cartilage, and from this origin its fibres radiate dorsally and upwards to be *inserted* into the inferior border and medial surface of the lamina of the thyreoid cartilage, as far as its inferior cornu, and also into the inferior cornu itself. As a general rule each muscle is divided into two parts, viz., (1) a **pars recta** composed of those fibres which are inserted into the lamina of the thyreoid cartilage; and (2) a **pars obliqua** formed of those fibres which are inserted into the inferior cornu. The muscle is closely associated with the inferior constrictor muscle of the pharynx, and sometimes shows a certain amount of continuity with it.

The (**external**) **thyreo-arytænoid muscle** is a thin, quadrangular muscle, which is only separable from the corresponding vocal muscle, with which it forms a common mass, by artificial means.

It lies in the lateral wall of the larynx, between the lamina of the thyreoid cartilage on its lateral side, and the ventricle of the larynx, the vocal muscle, and the elastic cone on its medial side; its inferior border is in contact with the lateral crico-arytænoid muscle, whilst its superior border extends farther upwards than the vocal fold, and is in contact with the inferior border of the thyreo-epiglottic muscle.

It **arises** from the inferior half of the medial surface of the lamina of the thyreoid cartilage, close to its ventral angle, and also from the lateral part of the elastic cone. The muscular fibres pass dorsally and upwards to be **inserted** into the lateral border and muscular process of the arytænoid cartilage; some of the fibres, however, turn round this cartilage and become continuous with the transverse arytænoid muscle.

By its **action** the muscle rotates the arytænoid cartilage and draws it ventrally in such a way

that its vocal process is carried ventrally and medially and the vocal fold is rendered somewhat flaccid. The muscle thus antagonises the crico-thyreoid. The main action of the muscle must, however, be that of a constrictor of the supraglottic region of the larynx.

The **vocal muscle** of each side is a triangular, somewhat prismatic muscle, which forms with the thyreo-arytænoid a common muscular mass separable only with difficulty into its two constituent portions. The vocal muscle lies within the vocal fold, closely applied to the lateral aspect of the vocal ligament, and receives its prismatic form from this adaptation. Of its three surfaces, the *medial* lies adjacent to the vocal ligament and the elastic cone; the *upper* surface is bounded by the labium vocale and the entrance to the ventricle of the larynx; whilst the *lateral* surface is bounded by, and is in contact with, the thyreo-arytænoid muscle.

The vocal muscle **arises** from the inferior part of the angular depression between the two laminæ of the thyreoid cartilage, and also from the corresponding vocal fold, whence the fibres run dorsally to be **inserted** into the lateral aspect of the vocal process and the depression on the ventro-lateral surface of the arytænoid cartilage.

It follows that the **action** of the muscle is to draw the vocal process of the arytænoid cartilage ventrally, thereby relaxing the vocal fold and ligament.

The **posterior crico-arytænoid muscles** are a pair of triangular muscles, each of which lies on the dorsal surface of the lamina of the cricoid cartilage, under cover of the tela submucosa of the pharynx. Each **arises**, by a broad origin, from the medial and inferior part of the depression on the dorsal surface of the lamina of the cricoid cartilage at the side of the median ridge; from that origin its fibres converge upwards and laterally to be **inserted** into the dorsal surface and apex of the muscular process of the corresponding arytænoid cartilage. In their course from origin to insertion the muscular fibres display very different degrees of obliquity. The most superior fibres are short and nearly horizontal; the intermediate fibres are the longest and are very oblique; whilst the most inferior fibres are almost vertical in their direction.

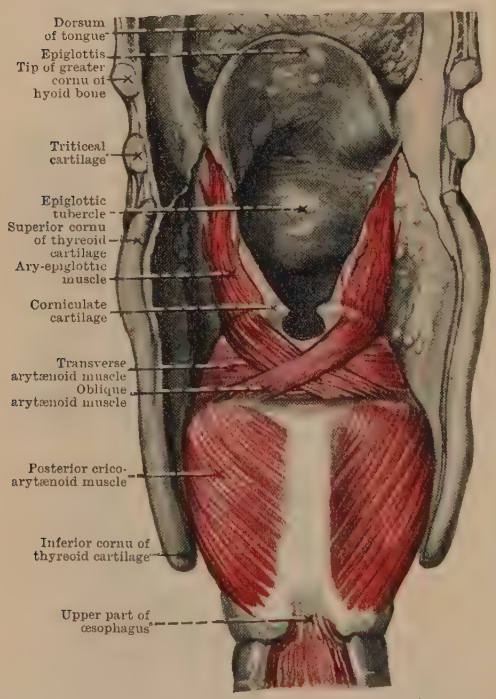

FIG. 830.—DISSECTION OF THE MUSCLES ON THE DORSAL ASPECT OF THE LARYNX.

By its action the posterior crico-arytænoid draws the muscular process of the arytænoid cartilages medially and dorsally, swings the vocal process and the vocal fold laterally, and thereby opens the rima glottidis.

The **transverse arytænoid muscle** is a thick, oblong, unpaired muscle which lies in the dorsal wall of the larynx and bridges across the interval between the two arytænoid cartilages. The ventral surface of the muscle is in contact with the dorsal concave surfaces of the arytænoid cartilages, and between them with the mucous membrane of the larynx. Its dorsal surface is partly concealed by the oblique arytænoid and by the submucous tissue of the pharynx. The inferior border extends to the lamina of the cricoid cartilage, and its upper border does not quite reach the apices of the arytænoid cartilages.

The **attachments** of the muscle are, on both sides, to the dorsal surface of the muscular process and the lateral edge of the arytænoid cartilages. All the fibres run in a frontal (coronal) direction, and some turn round the arytænoid cartilage to become continuous with the thyreo-arytænoid. The transverse arytænoid and the thyreo-arytænoid muscles form, together, a sphincter of the glottis.

By its action the transverse arytænoid muscle approximates the arytænoid cartilages, thereby tending to close the rima glottidis. Its assistance in the sphincter action of the thyreo-arytænoid muscle has already been pointed out.

The **oblique arytænoid muscles** are a pair of muscles which lie in the dorsal wall of the larynx, immediately dorsal to the transverse arytænoid and ventral to the submucous tissue of the pharynx.

Each muscle consists of a bundle of muscular fibres which **arise** from the dorsal aspect of the muscular process of the corresponding arytænoid cartilage. From their origins the two fleshy slips proceed upwards and medially, and cross each other in the median plane like the two limbs of the letter X. Reaching the apex of the arytænoid cartilage of the opposite side, many, but not all, of the fibres are **inserted** there, but others receiving a fresh attachment *arise* from the apex of the arytænoid cartilage as the **ary-epiglottic muscle** and extend ventrally and upwards in a series of arches within the ary-epiglottic fold to terminate in the thyreo-epiglottic ligament and the lateral margin of the epiglottic cartilage; and as the muscle approaches the latter

structure its fibres are joined by the fibres of the thyreo-epiglottic muscle. With its superior border are also commingled some fibres from the stylo-pharyngeal muscle.

Action.—The oblique arytænoid and ary-epiglottic muscles combined act as a rudimentary sphincter muscle for the aditus and the vestibule of the larynx, that is for the superior aperture of the larynx, inasmuch as they extend from the base of one arytænoid cartilage to the apex of the arytænoid cartilage of the opposite side, and then on to the epiglottis within the ary-epiglottic fold.

The **lateral crico-arytænoid muscles** are a pair of triangular muscles, each of which lies in the lateral wall of the larynx upon the elastic cone and concealed by the lamina of the thyreoid cartilage, the thyreoid gland, and the infra-hyoid muscles.

Each muscle **arises** from the upper border and the lateral surface of the arch of the cricoid cartilage as far dorsally as the facet which supports the base of the arytænoid cartilage, and also from the lateral part of the elastic cone.

From this origin the muscular fibres run dorsally and upwards, and converge to be **inserted** into the ventral surface of the muscular process of the arytænoid cartilage. The muscle is not infrequently inseparable from the (external) thyreo-arytænoid muscle.

By its **action** the lateral crico-arytænoid muscle draws the muscular process of the arytænoid cartilage ventrally and downwards, thus turning the vocal process of the same cartilage medially, and tending thereby to stretch the vocal fold and to approximate it to its fellow of the opposite side, thus assisting in closure of the rima glottidis.

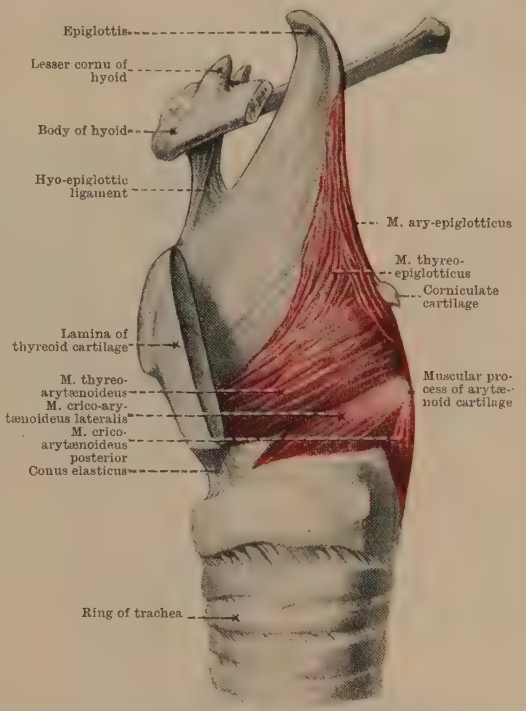

FIG. 831.—DISSECTION OF THE MUSCLES OF THE SIDE WALL OF THE LARYNX.

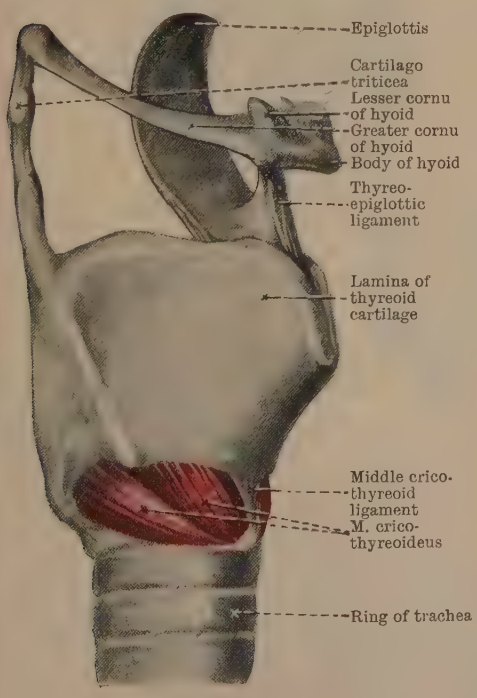

FIG. 832.—THE CRICO-THYREOID MUSCLE OF THE RIGHT SIDE.

The **thyreo-epiglottic muscles** are a pair of thin, oblong, very variable muscles, which lie in the side walls of the larynx. Each is bounded below by the thyreo-arytænoid, medially by the thyreo-epiglottic ligament and the ventricle of the larynx, and laterally by the lamina of the thyreoid cartilage.

Each thyreo-epiglottic muscle **arises** from the medial surface of the lamina of the thyreoid cartilage, immediately above the origin of the thyreo-arytænoid. From this origin the fibres run in arches, upwards and dorsally, to be **inserted** partly into the margin of the ary-epiglottic fold, and partly into the lateral margin of the epiglottis, being intermingled with the fibres of the ary-epiglottic muscle.

By its **action** the thyreo-epiglottic muscle of the larynx widens the aditus and the vestibule.

The **ventricular muscle** is composed of several bundles of fibres, visible under the microscope, which pass, in a vertical direction, from the lateral edge of the arytænoid cartilage to the lateral margin of the cartilage of the epiglottis. There are also intermingled with it fibres from the thyreo-arytænoid and ary-epiglottic muscles.

Growth - Alteration and Sexual Differences in the Larynx.—A considerable amount of variation may be noticed in the size of the larynx in different individuals. This is quite independent of stature, and explains to a great extent the difference in

the pitch of the voice in different persons. But quite apart from these individual variations, there is a sexual difference in the size of the larynx. The male larynx is not only absolutely, but also relatively, larger than the female larynx in all its diameters, but more particularly in the ventro-dorsal diameter; and to a large extent the increase in that direction is produced by the strong development of the laryngeal prominence in the male. The greater ventro-dorsal diameter of the male larynx necessarily implies a greater length of the vocal folds and a lower or deeper tone of the voice in the male than in the female.

In a newly born child the larynx, in comparison with the rest of the body, is somewhat large (C. L. Merker), and it continues to grow slowly and uniformly up to the sixth year of childhood. At that period there is a cessation of growth until puberty is reached, and then a stage of active growth supervenes. Up to that time the larynx in both sexes is similar in its dimensions, and although the growth which now occurs affects both the male and the female larynx, it is much more rapid and much more accentuated in the male than in the female. As a result the voice of the male "breaks" and assumes its deep tone.

Growth activity of the larynx, at puberty, is intimately connected with the development of the sexual organs. In a male subject who has been castrated when young, the larynx attains a size which exceeds that of the female only to a small degree, and the high pitch of the voice is retained.

Appearance of the Interior of the Larynx when examined by the Laryngoscope.

When the cavity of the larynx is illuminated and examined by laryngoscopic mirrors, the parts which surround the superior aperture of the larynx, as well as the interior of the organ, come into view. Not only this, but when the vocal folds are widely separated it is possible to inspect the interior of the trachea as far as its bifurcation.

In such an examination the arched upper border of the epiglottis is a conspicuous object, whilst, dorsal to that, the bulging on the ventral wall of the vestibule, formed by the tubercle

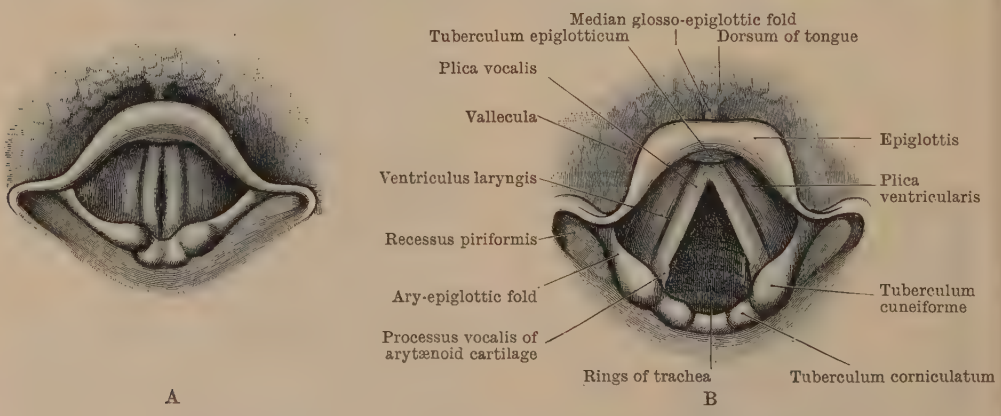

Fig. 833.—Cavity of the Larynx, as seen by means of the laryngoscope.
A. Rima glottidis closed. B. Rima glottidis widely opened.

of the epiglottis, may also be a feature of the picture. The median glosso-epiglottic fold with the glosso-epiglottic vallecula on either side of it, can also be inspected in the interval between the epiglottis and the base of the tongue. The sharp ary-epiglottic folds are clearly visible, and in the dorsal portion of each can be seen the two prominent tubercles which are formed by the enclosed cuneiform and corniculate cartilages. Dorsal to those tubercles is the dorsal wall of the pharynx, whilst to their lateral side the deep piriform recess may be seen. In the interior of the larynx the ventricular and the vocal folds are easily recognised, and the interval between the two, or, in other words, the entrance into the laryngeal ventricle, appears as a dark line on the lateral wall of the larynx. The ventricular folds are red and fleshy-looking; the vocal folds during phonation are tightly stretched and pearly white—the white colour being usually more apparent in the female than in the male. The outline and yellowish tinge of the vocal process at its attachment to the vocal fold, and the outline of the ventral part of the base of the arytænoid cartilage to a slight extent as well, can be made out in a successful laryngoscopic examination. The vocal folds during ordinary inspiration are seldom at rest, and with the laryngoscope their movements may be studied. It should be borne in mind that the picture afforded by the laryngoscope does not give a true idea of the level at which the different parts lie. The cavity appears greatly shortened, and its depth diminished.

TRACHEA.

The **trachea** or **windpipe** is a wide tube which is kept permanently patent by a series of bent cartilaginous bars embedded in its wall. These bars are deficient dorsally, and consequently the tube is not completely cylindrical: its dorsal wall is flattened. The trachea begins at the inferior border of the cricoid cartilage, opposite the inferior margin of the sixth cervical vertebra. From that level it extends, through the neck, into the superior mediastinum of the thorax, and it ends, at the level of the superior border of the fifth thoracic vertebra, by dividing into the right and left bronchi. The length of the trachea in the male is from four to four and a half inches, and in the female from three and a half to four inches, but even in the same individual it varies considerably in length with the movements of the head and neck.

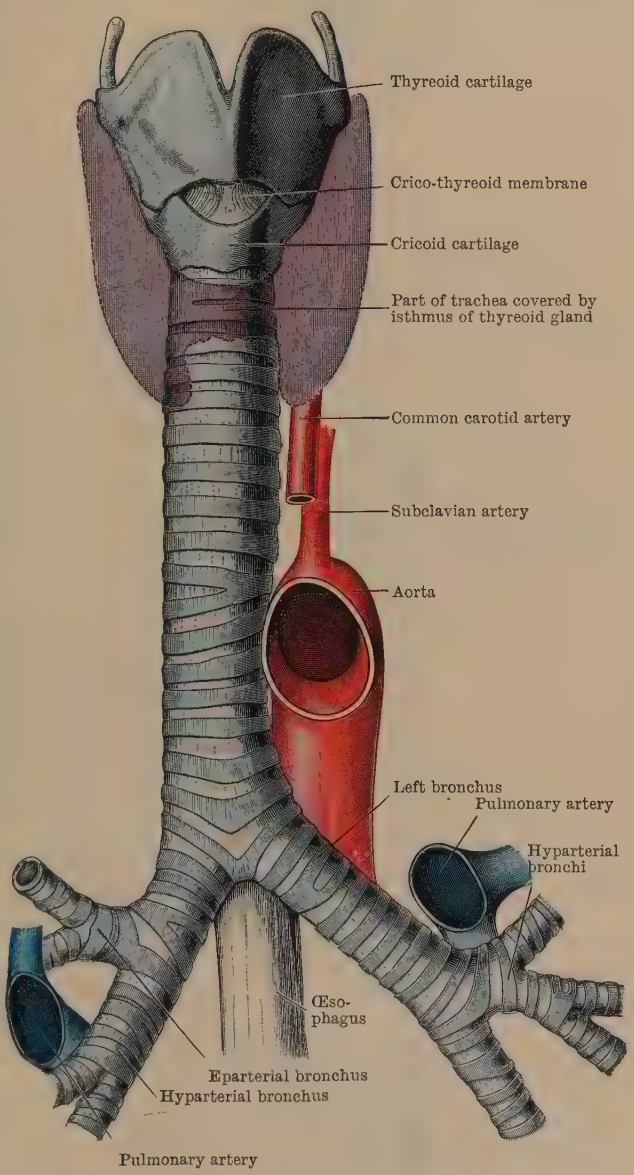

FIG. 834.—THE TRACHEA AND BRONCHI.

The thyreoid gland is indicated by a dotted line and a purple tint.

The inferior end of the trachea is fixed in position. This is a necessary provision to prevent dragging on the roots of the lung during movements of the head and neck. The remainder of the tube is surrounded by a quantity of loose areolar tissue, and possesses a considerable amount of mobility. Further, its wall is highly elastic, and thus when the head is thrown back the tube elongates through stretching, and when the chin is depressed its length is diminished by the recoil of its wall.

The trachea does not present an absolutely uniform calibre throughout its whole length. About its middle it exhibits a slight expansion or dilatation, and from that the calibre diminishes towards both extremities. Close to the bifurcation it is again slightly expanded (Braune and Stahel).

These differences in the calibre of the tube are determined by the surroundings of the trachea. The cervical part is narrowed owing to its being clasped by the thyreoid gland. Further, a short distance above its bifurcation, an impression, sometimes strongly marked, is usually seen on the left side of the trachea. It is due to the close contact of the aortic arch as it passes dorsally against that part of the tube.

It is evident therefore that the second slight diminution in calibre which is described by Braune and Stahel is produced by the proximity of the aorta. Lejars gives the average ventro-dorsal diameter of the trachea in the living person as 11 mm., and the transverse diameter as 12·5 mm. In the dead subject the lumen of the tube is considerably greater.

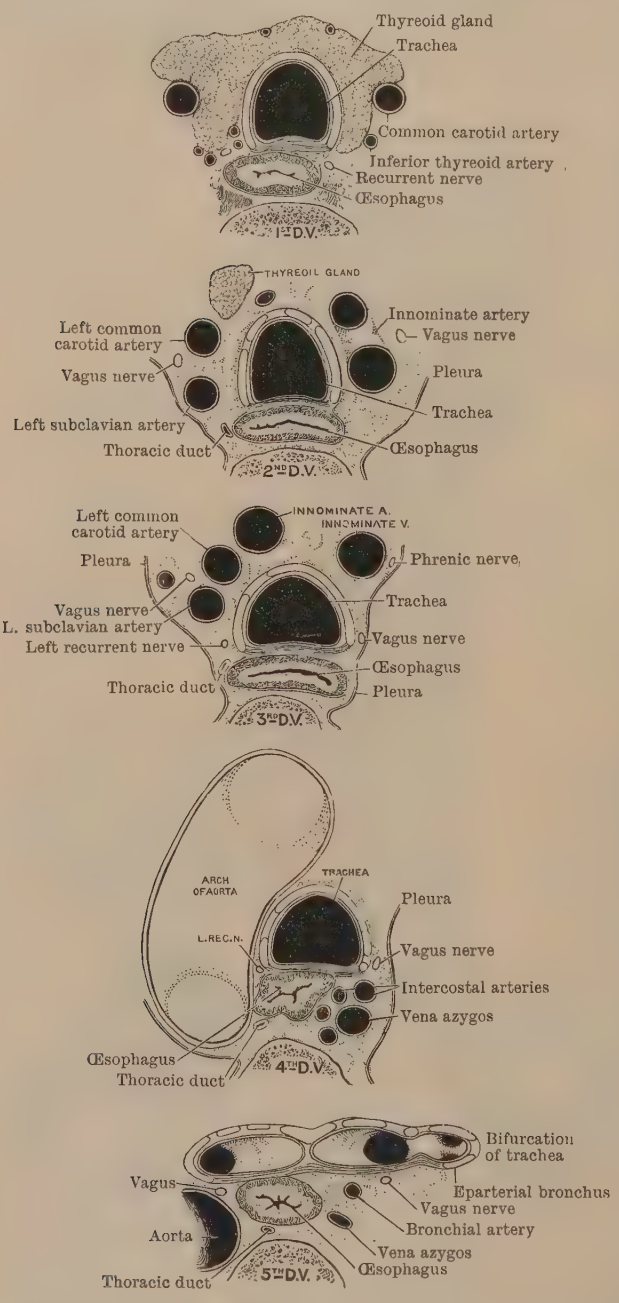

FIG. 835.—TRANSVERSE SECTIONS through the trachea and its immediate surroundings at the level of each of the upper five thoracic vertebræ.

The trachea adheres rigorously to the median plane except towards its termination, where it deviates very slightly to the right. As it passes downwards it recedes rapidly from the surface. This is due to its following the curvature of the vertebral column, from which it is separated by the œsophagus alone.

Relations of the Trachea.—In the study of the relations of the trachea it is convenient to consider it in the two stages of cervical and thoracic.

When the chin is held so that the face looks directly forwards the **cervical part** of the trachea measures from 2 to 2½ inches in length; but when the head is thrown dorsally or backwards the length is considerably increased. It is clasped by the thyreoid gland, the isthmus of which is applied to its ventral surface, and covers the second, third, and fourth rings; while on each side the corresponding lobe of the thyreoid gland is applied to the side of the trachea and extends downwards to the fifth or sixth ring. On either side of the cervical part of the trachea is the common carotid artery, whilst the recurrent nerve passes upwards in the groove between the trachea and the œsophagus. Dorsally the trachea is in relation to the œsophagus, which intervenes between it and the bodies of the vertebræ and deviates somewhat to the left as it passes downwards.

In addition to the isthmus of the thyreoid gland two thin muscular strata, composed of the sterno-hyoid and the sterno-thyreoid muscles, as well as the deep cervical fascia and integument, separate the cervical part of the trachea from the surface. In the median plane of the neck there is a narrow diamond-shaped space

between the medial margins of these muscles, within which the trachea is covered merely by the integuments and fasciæ. It is important to note that in the inferior part of the neck the cervical fascia is in two layers—viz., a strong stratum applied to the ventral surface of the sterno-hyoid and sterno-thyreoid muscles, and a weaker superficial layer stretching across between the two sterno-cleido-mastoid muscles. Dorsal to these muscular and fascial layers the inferior thyreoid veins pass downwards on the ventral surface of the trachea, and sometimes the occasional thyreoidea ima artery passes upwards on the ventral aspect of the tube. At the superior border of the manubrium sterni the innominate artery may be seen crossing the trachea obliquely.

The **thoracic part** of the trachea is situated in the dorsal part of the superior

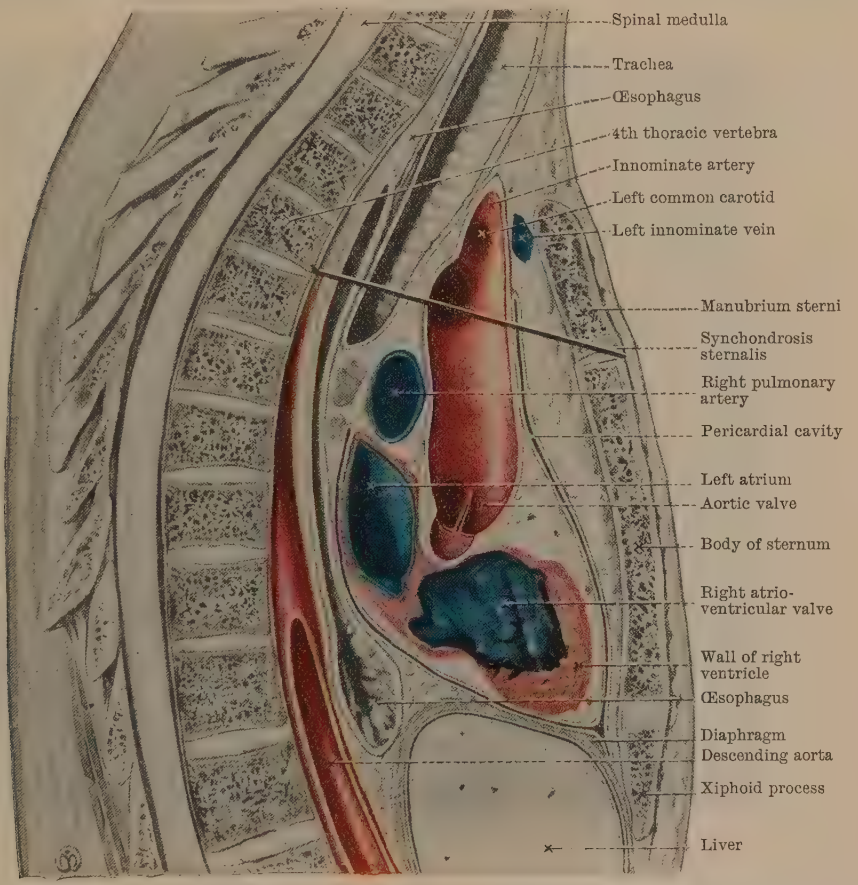

FIG. 836.—SAGITTAL SECTION THROUGH THE THORAX OF AN OLD MAN. The superior border of the manubrium sterni and the bifurcation of the trachea are lower than in the average adult.

mediastinum, being separated from the bodies of the vertebræ by the œsophagus alone. Immediately above its bifurcation the deep cardiac plexus of nerves is placed on the ventral and lateral aspects of the trachea. At the level of the fourth thoracic vertebra the aortic arch is very intimately related to it, lying first on the ventral side of the tube, and thereafter on its left side. The three great vessels which spring from the aortic arch are also placed in close proximity to the trachea. The innominate and the left common carotid arteries lie at first ventral to the trachea, and then gradually diverging as they proceed upwards, come to lie on either side of it—the innominate to the right, and the left common carotid to the left. Ventral to these vessels are the left innominate vein and the remains of the rhymus. On the right side the thoracic part of the trachea is in relation to the tight vagus nerve, and is clothed by the right mediastinal pleura; on the left side are the left subclavian artery and the left recurrent nerve.

Structure of the Wall of the Trachea.—The walls of the trachea and bronchi are composed of (1) a fibro-elastic membrane in which the tracheal cartilages are embedded; (2) within this, and on the dorsal aspect of the tube, a layer of muscular tissue, termed the musculus trachealis; (3) a submucous coat; and (4) the lining mucous membrane.

The **fibro-elastic membrane** is strong and dense. It passes round the whole circumference of the tube, and becomes continuous, above, with the perichondrium which invests the cricoid cartilage. Embedded in its substance are the **tracheal cartilages.** These vary in number from 15 to 20, and are composed of hyaline cartilage. They are horseshoe-shaped, the dorsal fourth of the circumference being deficient, so that dorsally each cartilage ends in two rounded extremities. The outer surface of each tracheal cartilage is flat and even, and does not project much beyond the level of the membrane in which it is embedded; the inner surface, however, is convex in the vertical direction, and conse-

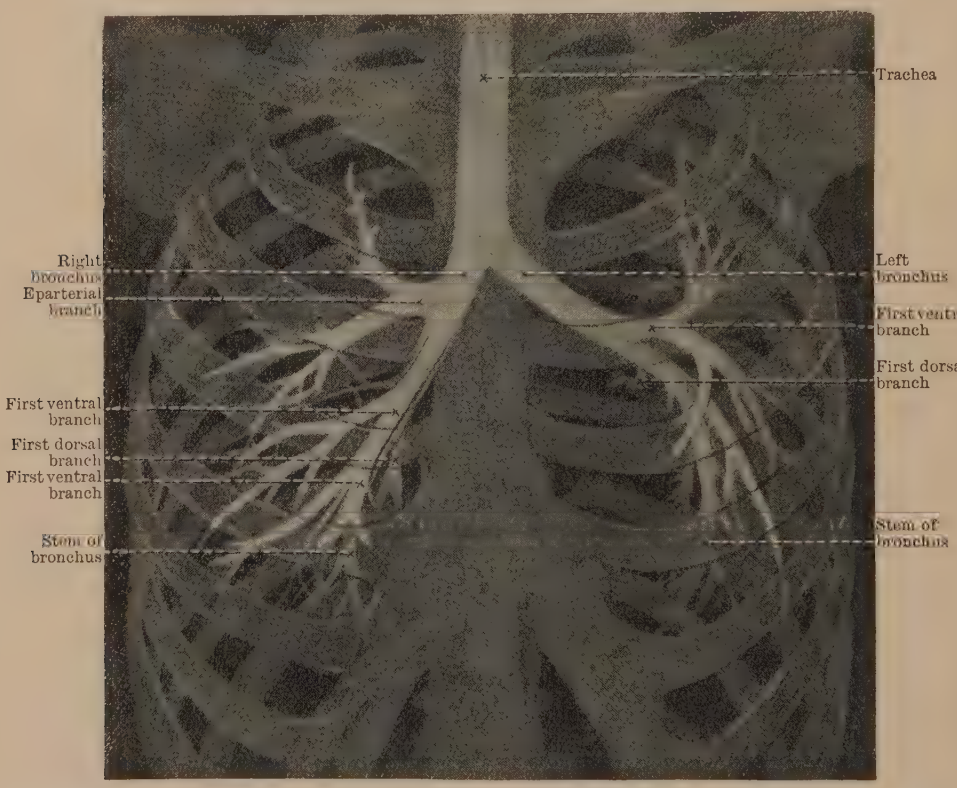

FIG. 837.—DRAWING OF A STEREOSCOPIC SKIAGRAPH OF THE TRACHEA AND BRONCHI INJECTED WITH STARCH AND RED LEAD.

quently it bulges slightly into the lumen of the tube. The intervals between the tracheal cartilages are somewhat narrower than the cartilages themselves, and neighbouring ones frequently show a more or less complete fusion, whilst others present other irregularities, such as a tendency to bifurcate. The lowermost tracheal cartilage is specially adapted to the tracheal bifurcation. In the median plane, ventrally, it inclines downwards, and from this median peak a cartilaginous strip is carried backwards in the fork between the two bronchi.

The **m. trachealis** is a continuous layer of involuntary muscular tissue, placed in the dorsal part of the wall of the trachea internal to the fibro-elastic membrane. The muscular bundles are arranged transversely, and are attached to the extremities of the tracheal cartilages, and also to their inner surfaces for a short distance beyond their extremities. In the intervals between the cartilages the transverse muscular bundles are attached to the fibro-elastic membrane. It is evident that, by its contraction, this muscle will reduce the lumen of the tube.

The **mucous membrane** is laid smoothly over the interior of the tube upon a layer of submucous areolar tissue. Lymph tissue enters largely into the composition of the

tracheal mucous membrane, and its inner surface is lined with pseudo-stratified columnar ciliated epithelial cells. The action of the cilia exercises an important influence in producing an upward movement of the mucus which is present on the surface of the mucous membrane.

Numerous longitudinal bundles of elastic tissue are present in the dorsal wall of the trachea, more particularly in its inferior part, between the mucous membrane and the trachealis muscle.

In connexion with the submucous coat there is a plentiful supply of mixed glands, containing both mucous and serous cells. These are placed in the submucous tissue, and also, on the dorsal aspect of the tube, on the exterior of the m. trachealis as well as amidst its muscular bundles. They send their ducts to the surface of the mucous membrane, where they open by trumpet-shaped mouths.

BRONCHI.

The two chief **bronchi** proceed obliquely downwards and laterally from the termination of the trachea, each towards the hilum of the corresponding lung. Like the trachea, they are kept permanently patent by the presence of cartilages in their walls. These cartilages are deficient dorsally, so that each bronchus exhibits a flattened dorsal surface, in every respect similar to the trachea. The two bronchi differ from each other, not only in the relations which they present to surrounding structures, but also in length, in width, and in the direction which they pursue (Fig. 837, p. 1080).

The first collateral branch of the right bronchus or the eparterial bronchus arises much nearer the trachea than the first branch of the left bronchus. This difference determines the length of the primary divisions of the trachea, and, although there is much variation in the matter, it may be said that, as a rule, the left bronchus is at least twice as long as the right bronchus. According to Henle there are from six to eight cartilages in the right, and from nine to twelve in the left, bronchus. A difference is also noticeable in the calibre of the two tubes. The right is wider than the left in the proportion of 100 to 78·4 (Braune and Stahel), and this asymmetry is clearly due to the fact that the right lung is more bulky than the left. The right bronchus, as it passes towards the hilum of the right lung, takes a more vertical course than the left bronchus. It therefore lies more in the line of the trachea, and to this, as well as to its greater width, is due the greater tendency which foreign bodies exhibit, when introduced into the trachea, to drop into the right bronchus, in preference to the left. The average angle which the right bronchus forms with the median plane is 24·8°, whilst the angle formed by the left bronchus with the median plane is 45·6°. The more horizontal course of the left bronchus is probably determined by the projection of the heart to the left side of the median plane (Merkel).

Relations of the Bronchi.—Arching above the right bronchus, from behind forwards, is the vena azygos, whilst arching above the left bronchus, from before backwards, there is the arch of the aorta. Occupying the interval between the bronchi there is a cluster of bronchial lymph glands, and an irregular chain of similar glands is carried along each tube towards the hilum of the lung. On the dorsal aspect of each bronchus the vagus nerve breaks up into the posterior pulmonary plexus, whilst the left bronchus, as it proceeds downwards and laterally, crosses the ventral surfaces of the œsophagus and descending thoracic aorta. The most interesting relation is, however, that presented on each side by the corresponding pulmonary artery. On the left side the pulmonary artery crosses ventral or anterior to the left bronchus on the superior side of its first collateral branch, and then turns round its lateral side to gain its dorsal aspect. All the left bronchial branches, therefore, are placed inferior to the left pulmonary artery, and are in consequence termed **hyparterial**. The right pulmonary artery, on the other hand, crosses ventral to the continuation of the right bronchus, inferior to its first collateral branch. This branch is therefore termed the **eparterial bronchus**, whilst all the others are classified as hyparterial.

Structure of the Walls of the Bronchi.—The walls of the bronchi present a structure similar to that seen in the trachea.

CAVUM THORACIS.

The **cavity of the thorax** is divided into two large lateral chambers, which contain the lungs, by a median partition termed the **mediastinal septum**, which extends from the vertebral column to the ventral thoracic wall. From the fact that each of these chambers is lined by an extensive and separate serous membrane called the **pleura**, they receive the name of the **pleural cavities**.

Septum Mediastinale.—The **mediastinal septum** is built up of several structures which lie in, or in close proximity to, the median plane. The more important of these are the heart, enveloped in its pericardium, the thoracic aorta, with the great vessels which spring from its arch, the pulmonary artery, and the great veins in the neighbourhood of the heart, the thymus or its remains, the trachea, œsophagus, and thoracic duct, and the vagi and phrenic nerves.

Cavum Pleuræ.—The pleural cavities, in which the two lungs lie, comprise much the larger part of the thoracic cavity. Each **pleural cavity** is bounded *inferiorly* by the corresponding cupola of the diaphragm; and as the right cupola rises to a higher level than the left, the right pleural cavity presents a smaller vertical depth than the left. *Ventrally*, the wall of each pleural chamber is formed by the costal cartilages and the sternum; *laterally*, by the bodies of the ribs and the intercostal muscles as far as the costal angles; *dorsally*, by the portions of the ribs, with the intervening intercostal muscles, which lie medial to the costal angles; and *medially*, by the bodies of the vertebræ and the mediastinal septum, which completely shuts off the one chamber from the other.

The mediastinal septum is not uniformly median in position. Owing to the projection of the heart to the left side, and to the position of the thoracic aorta on the left side of the median plane, the left pleural chamber, although it is deeper than the right, is reduced in width. The two pleural cavities, therefore, are very far from being symmetrical in form, and consequently the mediastinal septum tends to extend to the left of the median plane of the body.

Each pleural cavity is completely lined by a separate serous membrane termed the **pleura**. The portion of this membrane which clothes the mediastinum or intervening partition forms the lateral boundary of an area termed the **mediastinal** or **interpleural space**, within which the parts which build up the mediastinal septum are placed.

PLEURÆ.

The pleura of each side not only lines the corresponding pleural cavity, but at the pulmonary root, it is prolonged on to the lung so as to give it a complete investment. It is customary, therefore, to recognise a **pulmonary** or **investing part** (pleura pulmonalis) and a **parietal** or **lining part** (pleura parietalis). The inner surface of the pleura (*i.e.* that surface which is turned towards the interior of the cavity) is coated with squamous endothelium, and presents a smooth, glistening, and polished appearance; further, it is moistened by a small amount of serous fluid. In consequence of this the surface of the lung covered by pulmonary pleura can glide on the wall of the cavity, lined as it is by parietal pleura, with the least possible degree of friction. In the pathological condition known as pleurisy the inner surface of the pleura becomes

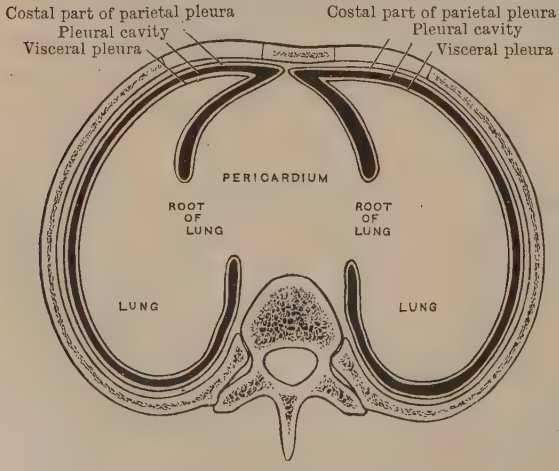

FIG. 838.—DIAGRAM SHOWING ARRANGEMENT OF PLEURAL SACS AS SEEN IN TRANSVERSE SECTION.

roughened by inflammatory exudation, and the so-called "friction sounds" are heard when the ear is applied to the chest.

Pleura Pulmonalis.—The **pulmonary pleura** is very thin, and is so firmly bound down to the surface of the lung that it cannot be detached without laceration of the pulmonary substance, and then only in small pieces. It dips into the fissures of the lungs, lines them down to the very bottom, and thus completely separates the different lobes of the lungs from each other. The pulmonary pleura becomes continuous with the mediastinal pleura at the root of the lung, and also through the ligamentum pulmonale.

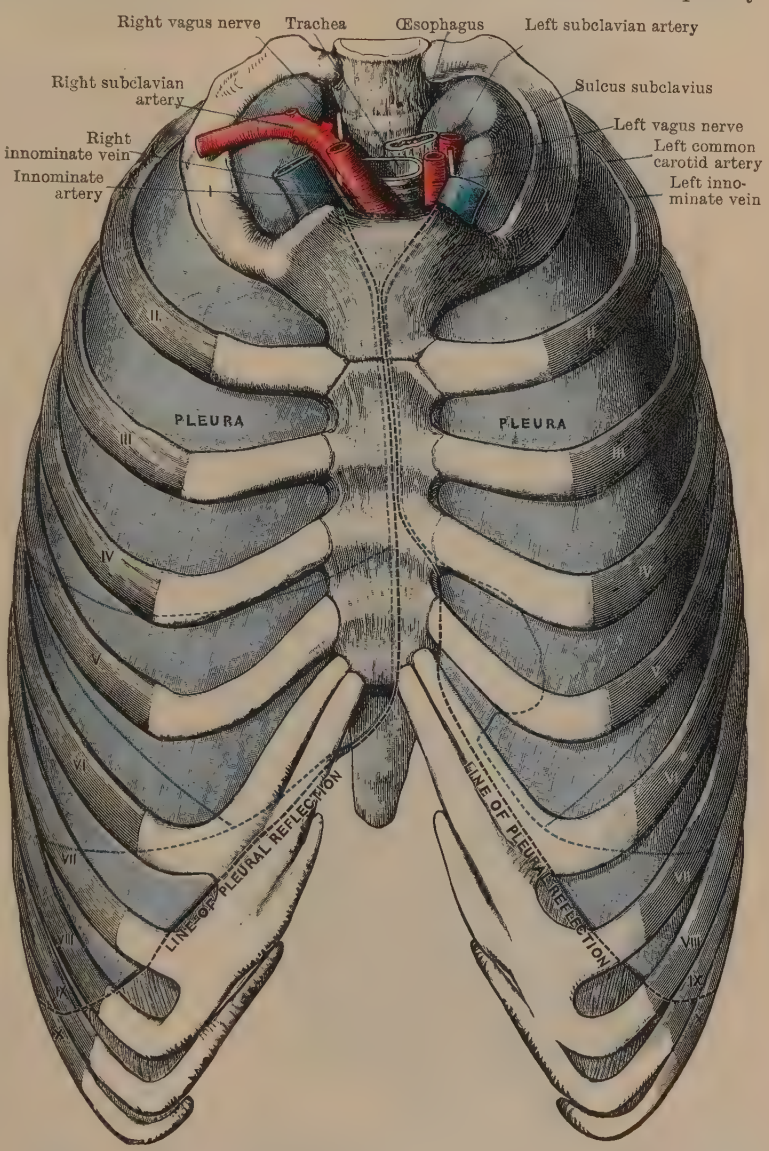

FIG. 839.—DISSECTION OF A SUBJECT HARDENED BY FORMALIN INJECTION, to show the relations of the two pleural sacs, as viewed from the front. The anterior and diaphragmatic lines of pleural reflection are exhibited by black dotted lines, whilst the outlines of the lungs and their fissures are indicated by the blue lines.

Pleura Parietalis. — Different names are applied to the **parietal pleura** as it lines the different parts of the wall of the cavity in which the lung lies. Thus there are the *costal pleura*, the *diaphragmatic pleura*, the *mediastinal pleura*, and the *cupula pleuræ*; but it must be borne in mind that these terms are merely used for convenience in description, and that the portions of the pleura so designated are all directly continuous with one another.

The **cupula pleuræ** or the cervical pleura rises into the root of the neck, through the superior aperture of the thorax, and forms a dome-shaped roof for the pleural cavity. Its highest point or summit reaches the level of the inferior border of the neck of the first rib; but owing to the great obliquity of the first costal arch, this point is placed from one to two inches above the ventral or anterior extremity of the first rib, and from a half to one and a half inches above the medial half of the clavicle. The cupula pleuræ is supported on the lateral side by the scalenus anterior and scalenus medius muscles, whilst the subclavian artery, arching laterally, lies in a groove on its

medial and ventral aspects a short distance below its summit. At a lower level the innominate and subclavian veins also lie upon its medial and ventral aspects.

The cupula pleuræ is strengthened and held in place by an aponeurotic expansion, first described by Sibson, which is spread over it, and is attached to the internal concave margin of the first rib. This fascia is derived from a small muscular slip which takes origin from the transverse process of the seventh cervical vertebra.

FIG. 840.—LATERAL VIEW OF THE RIGHT PLEURAL SAC IN A SUBJECT HARDENED BY FORMALIN INJECTION. The blue lines indicate the outline of the right lung, and also the position of its fissures.

Pleura Costalis.—The **costal pleura** is the strongest and thickest part of the parietal pleura. It lines the internal surfaces of the costal arches and of the intervening intercostal muscles. Ventrally it reaches the sternum, whilst dorsally it passes from the ribs over the sides of the bodies of the vertebræ. It is easily detached from the parts which it covers, except as it passes from the heads of the ribs on to the vertebral column. There it is somewhat tightly bound down.

Pleura Diaphragmatica.—The **diaphragmatic pleura** covers that portion of the thoracic surface of the diaphragm which lies to the lateral side of the base of the pericardium, but it does not dip down to the bottom of the narrow interval between the thoracic wall and the diaphragm. In other words, a strip of the thoracic surface of the diaphragm adjoining its costal attachment is left uncovered.

Pleura Mediastinalis.—The **mediastinal pleura** extends from the dorsal surface of the ventral thoracic wall to the vertebral column, and clothes the side of the mediastinal septum, which intervenes between the two pleural cavities. It is continuous with the costal pleura of its own side, both ventrally and dorsally, along two lines which are respectively termed the **sternal** and **vertebral lines of pleural reflection**; whilst inferiorly it becomes continuous with the diaphragmatic pleura of its own side at the base of the pericardium.

Above the root of the lung the mediastinal pleura passes directly from the sternum to the vertebral column. In that region the *left mediastinal pleura* is applied to the arch of the aorta and the phrenic and vagus nerves; to the left innominate vein, the left superior intercostal vein and the left common carotid and left subclavian arteries; to the œsophagus and the thoracic duct. The *right mediastinal pleura*, on the other hand, is applied, above the root of the lung, to

the superior part of the superior vena cava and the right innominate vein; to the innominate artery; to the vena azygos, as it hooks forwards above the bronchus; to the vagus and phrenic nerves; and to the right side of the trachea.

Opposite the root of the lung, as well as in the region below it, the mediastinal pleura clothes the corresponding aspect of the pericardium (pleura pericardiaca), and is somewhat firmly attached to it. As the phrenic nerve passes downwards upon the pericardium it likewise is covered over by the pleura. In the region corresponding to the superior part of the lateral aspect of the pericardium the mediastinal pleura is prolonged laterally, so as to form an investment for the root of the lung, and becomes continuous around the hilum of the lung with the pulmonary pleura. Below the root of the lung the two layers of pleura which invest it come into apposition with each other, and are prolonged downwards as a distinct fold, termed the **ligamentum pulmonale**. This fold stretches between the pericardium and the inferior part of the mediastinal surface of the lung, and ends inferiorly in a free border.

Dorsal to the root of the lung and the ligamentum pulmonale the mediastinal pleura on the *right side* passes over the œsophagus to the vertebral column, whilst on the *left side* it passes dorsally over the thoracic aorta, and to a small extent over the lower end of the œsophagus, in the region immediately adjoining the diaphragm and ventral to the thoracic aorta.

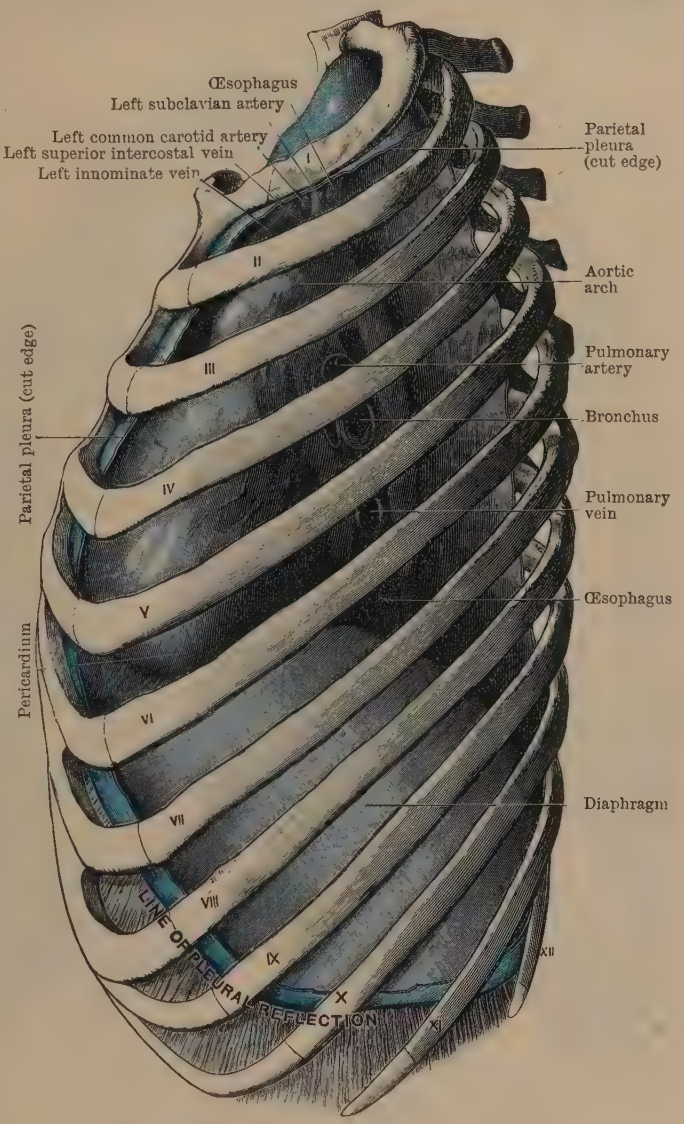

FIG. 841.—LEFT PLEURAL SAC IN A SUBJECT HARDENED BY FORMALIN INJECTION, opened into by the removal of the costal part of the parietal pleura. The lung has also been removed so as to display the mediastinal pleura.

Lines of Pleural Reflection.—These are three in number—viz., the sternal, the vertebral, and the diaphragmatic. The pleural cavities are not symmetrical. The left is longer and narrower than the right, and it thus happens that the lines of pleural reflection do not accurately correspond on the two sides of the body. Further, although the vertebral line of reflection is fairly constant, the other two reflection-lines are subject to variations in different subjects. Consequently the following description must be regarded as merely giving the average condition.

The **vertebral line of pleural reflection** is that along which the costal pleura is continued ventrally from the vertebral column to become the mediastinal pleura. On the *right side*, above the root of the lung, the pleura passes from the bodies of the vertebræ on to the right side of the trachea; whilst lower down, and dorsal to the pericardium, it passes from the vertebral bodies on to the œsophagus. On the *left side*, and above the arch of the aorta, the pleura along this line of reflection is carried from the vertebral column on to the œsophagus and thoracic duct; below that level it passes on to the thoracic aorta. In the superior part of the chest the right and left lines of reflection are placed well apart from each other, and about equidistant from the median plane. As they are traced downwards they approach more closely to each other and deviate to the left, so that whilst the reflection on the *right side* takes place from the ventral aspect of the vertebral bodies, on the *left side* it takes place from the left aspect of the vertebral column. This is due to the position of the thoracic aorta.
